Exam. From this, and some of the foregoing theorems, may be deduced the velocity and periodic time of a body revolving in a circle, at any given distance from the earth's centre, by means of its own gravity. Put $g = 16\frac{1}{2}$ feet, the space described by gravity, at the surface, in the first second of time, viz. $= AM$ in the foregoing fig. and by rule 2; then putting $r =$ the radius AC ; it is $AE = \sqrt{(AB \times AM)} = \sqrt{2gr}$ the velocity in a circle at its surface, in one second of time; and hence, putting $c = 314159 \&c.$, the circumference of the earth being $2cr = 25,000$ miles, or $132,000,000$ feet, it will be $\sqrt{2gr} : 2cr : : 1'' : c\sqrt{\frac{2r}{g}} = 5078$ seconds nearly, or $1^h 24^m 38^s$, the periodic time at the circumference: Also the velocity there, or $\sqrt{2gr}$ is $= 26000$ feet per second nearly. Then, since the force of gravity varies in the inverse duplicate ratio of the distance, by rules 8 and 9, it is $\sqrt{r} : \sqrt{r} : v$ or $26000 : 26000\sqrt{\frac{r}{R}} = v$ the velocity of a body revolving about the earth at the distance r ; and $\sqrt{r^3} : \sqrt{R^3} : t$ or $5078^s : 5078^s$ $\sqrt{\frac{r^3}{R^3}} = t$ the time of revolution in the same. So if, for instance, it be the moon revolving about the earth at the distance of 60 semidiameters; then $r = 60r$, and the above expressions become $v = 26000\sqrt{\frac{r}{60r}} = 3357$ feet per second, or $38\frac{3}{4}$ miles per minute, for the velocity of the moon in her orbit; and $t = 5078\sqrt{\frac{r^3}{60r^3}} = 2360051$ seconds, or $27\frac{3}{4}$ days nearly, for the periodic time of the moon in her orbit at that distance.

Thus also the ratio of the forces of gravitation of the moon towards the sun and earth may be estimated. For, 1 year or $365\frac{1}{4}$ days being the periodic time of the earth and moon about the sun, and $27\frac{3}{4}$ days the periodic time of the moon about the earth, also 60 being the distance of the moon from the earth, and 23920 the distance from the sun, in semidiameters of the earth, by art. 5 it is

$$\frac{60}{27\frac{3}{4}} : \frac{23920}{365\frac{1}{4}} : : f \text{ or } 1 : \frac{23902}{60} \times \frac{27\frac{3}{4}^2}{365\frac{1}{4}^2} = 2\frac{2}{3}; \text{ that is, the proportion of the moon's gravitation towards the sun, is to that towards the earth, as } 2\frac{2}{3} \text{ to } 1 \text{ nearly.}$$

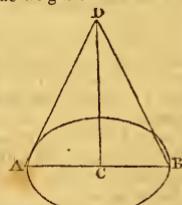

Again, we may hence compute the centrifugal force of a body at the equator, arising from the earth's rotation. For, the periodic time when the centrifugal force is equal to the force of gravity, it has been shown above, is 5078 seconds, and 23 hours 56 minutes, or 86160 seconds, is the period of the earth's rotation on its axis: therefore, by art. 5, as $86160^s : 5078^s : : 1 : \frac{r}{2\pi v}$, the centrifugal force required, which therefore is the 289th part of gravity at the earth's surface. Simpson's Flux. pa. 240, &c.

By similar means we may determine the centrifugal force of bodies in different latitudes; for as the earth turns round its axis, it is evident that those bodies on the surface of it, which lie nearer to the axis, or, which is the same thing, lie nearer to the poles, describe circles smaller than those which lie nearer to the equator, though they are all performed in the same interval of time, viz, $23^h 56^m$. Hence the periodical times being equal, the central forces are as the radii of the circles (5); and since, in different latitudes, we may use the following proportion; viz, as the radius is to the co-sine of a given latitude, so is the centrifugal force of bodies situated at the equator, to the centrifugal force of bodies at that given latitude. Now as the co-sines decrease in length the nearer they approach the poles, so the tendency of bodies to fly off from the surface of the earth is greatest at the equator, but diminishes in approaching towards the poles; and hence we perceive why the earth has been found, by means of unquestionable measurements and other observations, to be an oblate spheroid, whose polar diameter is the shortest. This circumstance furnishes a convincing evidence of the earth's daily rotation about its axis.

For another example, suppose A to be a ball of 1 ounce, which is whirled about the centre C , so as to describe the circle AEB , each revolution being made in half a second; and the length of the cord AC equal to 2 feet. Here $t = \frac{1}{2}$, $r = 2$, and it having been found above that $c\sqrt{\frac{2R}{g}} = \tau$ is the periodic time at the circumference of the earth when the centrifugal force is equal to gravity; hence then, by art. 5, as $\frac{R}{r^2} : \frac{r}{R^2} : : F \text{ or } 1 : f$, which proportion becomes $\frac{g}{2c^2} : \frac{r}{R^2} : : 1 : \frac{2c^2r}{gR^2} = \frac{16c^2}{gR^2} = \frac{16 \times 31416^2}{16 \times 1} = 9819 =$ the centrifugal force, or that by which the string is stretched, viz, nearly 10 ounces, or 10 times the weight of the ball.

Lastly, suppose the string and ball to be suspended from a point D , and describes in its motion a conical surface ADB ; then putting $DC = a$, $AC = r$, and $AD = h$; and putting $F = 1$ the force of gravity as before; then will the body A be affected by three forces, viz, gravity acting parallel to DC , a centrifugal force in the direction CA , and the tension of the string, or force by which it is stretched, in the direction DA : hence these three powers will be as the three sides of the triangle ADC respectively, and therefore as CD or $a : AD$ or $h : 1 : \frac{h}{a}$ the tension of the string as compared with the weight of the body. Also DC or $a : AC$ or $r : 1 : \frac{2c^2r}{gR^2}$ the general expression for the centrifugal force above found; hence, $gt^2 = 2ac^2$ and consequently $t = c\sqrt{\frac{2a}{g}} = 1 \cdot 108/a =$ the periodic time.

10. When the force by which a body is urged towards a point is not always the same, but is either increased or decreased as some power of the distance; several curves will then arise according to that power. If the force decreases as the squares of the distances increase, the body will describe an ellipsis, and the force is directed towards one of its foci; so that in every revolution the body once

approaches towards it, and once recedes from it: also the eccentricity of the ellipse is greater or less, according to the projectile force; and the curve may sometimes become a circle, when the eccentricity is nothing; the body may also describe the other two conic sections, the parabola and hyperbola, which do not return into themselves, by supposing the velocity greater in certain proportions. Also if the force increase in the simple ratio as the distance increases, the body will still describe an ellipse; but the force will in this case be directed to the centre of the ellipse; and the body, in each revolution, will twice approach towards it, and again twice recede from that point. For the investigations of these and other particulars, consult Simpson's Fluxions, vol. 1, sect. 12, and Gregory's Mechan. vol. 1, chap. 3, bk. 2.

The general doctrine of central forces is called most into application in investigating the orbits of the planets as urged towards the central body the sun: and, considered in that view, the following deduction of the principal laws is offered.

(1). When a body, urged by a centripetal force, moves in any curve; then, in every point of the curve, the force is in a ratio, compounded of the direct ratio of the body's distance from the centre of force, and the inverse ratio of the cube of the perpendicular on the tangent to the same point of the curve, drawn into the radius of curvature of the same point.

(2). Hence, if the body move in a circle, by a force tending to a point in the circumference, the force will be everywhere in the inverse ratio of the 5th power of the body's distance from that point.

(3). When a body moves in a conic section, the force urging it towards the focus is reciprocally proportional to the square of the distance.

(4). Hence, if a body move in an ellipsis, by a centripetal force tending to its centre, that force will be directly as the distance.

(5). Hence results an easy construction, for determining the radius of curvature in any conic section. Thus, from the given point A , draw AB through the focus F , and AR perpendicular to the curve at A , cutting the axis VC in C ; at C erect CR perpendicular to AC , and draw BR perpendicular AB ; then RA is the radius of curvature at the point A .

In the parabola, the construction becomes a little simpler. For, since $AF = FC$, and ACB a right angle, therefore F is the centre of a circle passing through A , C , B , and $AF = FB$. Hence, if AF be produced till $FB = AF$, and BR be drawn perpendicular to AB , meeting the perpendicular AR ; then R will be the centre of curvature of the parabola.

Hence, in all the conic sections, $AC : AB : : AB : AR$ the radius of curvature; which therefore is a 3d proportional to AC and AB . And when the point A coincides with the vertex V , then $AC : AB$ becomes the ratio of the two semiaxes; that is, the radius of curvature at the vertex, or extremity of the axis, is equal to a 3d proportional to the two semiaxes, and is therefore equal to the semiparameter of the axis.

Further, the radii of curvature at the extremities of the transverse and conjugate axes, are to each other reciprocally as the cubes of the axes. For, let a denote the for-

mer semiaxis, and c the latter: then the radius of curvature to the former is $\frac{c^2}{a}$, and to the latter is $\frac{a^2}{c}$; and $\frac{a^2}{c} : \frac{c^2}{a} :: c^3 : a^3$.

(6). When a body moves in a parabola, by a centripetal force tending to the focus; then the velocity of the body in the parabola, is to the velocity of a body describing a circle at the same distance, everywhere as $\sqrt{2}$ to 1. But the velocity of a body in an ellipsis, is to the velocity of a body moving in a circle at the same distance, in a less ratio than that of $\sqrt{2}$ to 1. And the velocity in an hyperbola, is to the velocity in a circle, in a greater ratio than that of $\sqrt{2}$ to 1.—If the body move in the nautical spiral, its velocity is everywhere equal to the velocity of a body describing a circle at the same distance.

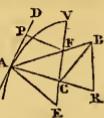

(7). Supposing a body is projected in a given direction, with a given velocity, and that it is urged by a force which is always reciprocally as the square of the distance; required to determine the curve in which the body will move.—It is plain, in the first place, that the path of the body will be one of the conic sections. Let the body be projected in the right line AP , with the given velocity c : and since the absolute quantity of the centripetal force is known, there will thence be given the velocity with which a body can describe a circle at the distance AP , by the same force: for it is equal to that acquired by a body in falling through $\frac{1}{2}AP$, while urged constantly by the same force. Let that velocity be c . Erect AC perpendicular to AP , in which take AR a 4th proportional to c^2 , c^2 , $\frac{AP^2}{FP}$,

where FP is a perpendicular on AP ; then AR will be the radius of curvature at A . Draw RB perpendicular to AP , and BC perpendicular to AR ; then drawing FC , it will give the position of the axis. Make the angle EAC equal to the angle FAC . Then, if AE be parallel to FC , the figure in which the body moves will be a parabola. But if it meet the axis FC in E ; and if the points F and E fall on the same side of the point c , the figure will be an hyperbola; but if F and E fall on contrary sides, the figure will be an ellipsis. Hence, with the foci E and F , and the axis $AF \pm AE$, the section may be described in which the body will move.

For further particulars on central forces, the reader may consult Newton's Principia, Varignon in the Memoirs of the French Academy, 1700, 1701; MacLaurin's Fluxions; Simpson's Fluxions; Gregory's Mechanics, vol. 1; Dawson's Essay on the inverse problem of central forces, in the Manchester Memoirs, or in Leybourn's Mathematical Repository, Nos. 4 and 5, n. s.; and Waring's paper on central forces, Philos. Trans. vol. 78, or my Abridgment, v. 16, p. 384.

CENTRAL RULE, is a rule or method discovered by Mr. Thomas Baker, rector of Nympton in Devonshire, which he published in his Geometrical Key, in the year 1684, for determining the centre of a circle which shall cut a given parabola in as many points as a given equation, to be constructed, has real roots; which he has applied with good success in the construction of all equations as far as the 4th power inclusive.

The Central Rule is chiefly founded on this property of the parabola; that if a line be inscribed in the curve perpendicular to any diameter, the rectangle of the segments of this line, is equal to the rectangle of the intercepted part of the diameter and the parameter of the axis.

The Central Rule has the advantage over the methods of constructing equations by Descartes and Delatertes, which are liable to the trouble of preparing the equations by taking away the second term; whereas Baker's method effects the same thing without any previous preparation whatever. See *Philos. Trans.* N^o 157.

CENTRE, or CENTER, in a general sense, signifies a point equally remote from the extremes of a line, plane, or solid; or a middle point dividing them so that some certain effects are equal on all sides of it.

CENTRE of Attraction, or Gravitation, is the point to which bodies tend by gravity; or that point to which a revolving planet or comet is impelled or attracted, by the force or impetus of gravity.

CENTRE, in Architecture. This term is used to denote a frame of timber, constructed for the purpose of supporting the stones or bricks forming an arch or vault, during the erection. Thus the centre serves as a foundation for the arch to be built upon, which at the completion of the work is struck or taken down, and then the arch will support itself by the reciprocal pressure of its parts.

CENTRE of a Bastion, is a point in the middle of the gorge, where the capital line commences, and which is usually at the angle of the inner polygon of the figure. Or it is the point where the two adjacent curtains produced intersect each other.

CENTRE of a Circle, is the point in the middle of a circle, or circular figure, from which all lines drawn to the circumference are equal.

CENTRE of a Conic Section, is the middle point of any diameter, or the point in which all the diameters intersect and bisect one another.

In the ellipse the centre is within the figure; but in the hyperbola it is without, or between the conjugate hyperbolae; and in the parabola it is at an infinite distance from the vertex.

CENTRE of Conversion, in Mechanics, a term first used by M. Parent, and may be thus conceived: Suppose a stick laid on stagnant water, and then drawn by a thread fastened to it, so that the thread always makes the same angle with the stick, either a right angle or any other; then it will be found that the stick will turn on one point of it, which will be immovable; and this point is termed the centre of conversion.

This effect arises from the resistance of the fluid to the stick partly immersed in it. And if, instead of the body thus floating on a fluid, the same be conceived to be laid on the surface of another body; then the resistance of this plane to the stick will still have the same effect, and will determine the same centre of conversion. And this resistance is precisely what is called friction, so prejudicial to the effects of machines.

M. Parent has determined this centre in some certain cases, with much laborious calculation. When the thread is fastened to the extremity of the stick, he found that the distance of the centre from this extremity would be nearly $\frac{1}{2}$ of the whole length. But when it is a surface or a solid, there will be some change in the place of this centre, according to the nature of the figure. See *Mem. of the Acad. of Sciences*, vol. 1, p. 191.

CENTRE of a Curve, of the higher kind, is the point where two diameters meet.—When all the diameters meet in the same point, it is called, by Sir Isaac Newton, the *general centre*.

CENTRE of a Dial, is the point where its gnomon or

stile, which is placed parallel to the axis of the earth, meets the plane of the dial; and from this all the hour-lines are drawn, in such dials as have centres, viz, all except that whose plane is parallel to the axis of the earth where there can be no centre; in which case all the hour-lines will be parallel to the stile, and to one another, the centre being as it were at an infinite distance.

CENTRE of Equilibrium, is the same with respect to bodies immersed in a fluid, as the centre of gravity is to bodies in free space; being a certain point, upon which if the body or bodies be suspended, they will rest in any position. To determine this centre, see *Emerson's Mechan.* prop. 92, p. 134.

CENTRE of Friction, is that point in the base of a body on which it revolves, into which if the whole surface of the base, and the mass of the body were collected, and made to revolve about the centre of the base of the given body, the angular velocity destroyed by its friction would be equal to the angular velocity destroyed in the given body by its friction in the same time.—See *Vince on the Motion of Bodies affected by friction*, in the *Philos. Trans.* 1785.

CENTRE of Gravity, is that point about which all the parts of a body do in any situation exactly balance each other. Hence, by means of this property, if the body be supported or suspended by this point, the body will rest in any position into which it is put; as also, that if a plane pass through the same point, the segments on each side will equipercentile, neither of them being able to move the other.

The centre of gravity of a body is not always within the body itself: thus the centre of gravity of a ring is not in the substance of a ring, but in the axis of its circumscribing cylinder: and the centre of gravity of a hollow staff, or of a bone, is not in the matter of which it is constituted, but somewhere in its imaginary axis. Every body however has a centre of gravity, and so has every system of bodies.

If a heavy body be sustained by two or more forces, their directions must meet either at the centre of gravity of that body, or in the vertical line which passes through it.

When a body stands upon a plane, if a vertical line passing through the centre of gravity fall within the base on which the body stands, it will not fall over; but if that vertical line passes without the base, the body will fall, unless it be prevented by a prop or cord. Where the vertical line falls upon the extremity of the base, the body may stand, but the equilibrium may be disturbed by a very trifling force; and the nearer this line passes to any edge of the base, the more easily the body is thrown over; the nearer it falls to the middle of the base, the more firmly the body stands.

The whole gravity, or the whole matter, of a body, may be conceived united in the centre of gravity; and in demonstrations it is usual to conceive all the matters as really collected in that point.

Through the centre of gravity passes a right line, called the diameter of gravity; and therefore the intersection of two such diameters determines the centre of gravity. Also the plane upon which the centre of gravity is placed, is called the plane of gravity; so that the common intersection of two such planes determines the diameter of gravity.

In homogenous bodies, which may be divided lengthways into similar and equal parts, the centre of gravity is the same with the centre of magnitude. Hence therefore the centre of gravity of a line is in the middle point of it, or that point which bisects the line. Also the centre of gravity of a parallelogram, or cylinder, or any prism

whatever, is in the middle point of the axis. And the centre of gravity of a circle or any regular figure, is the same as the centre of magnitude.

Also, if a line can be so drawn as to divide a plane into equal and similar parts, that line will be a diameter of gravity, or will pass through the centre of gravity; and it is the same as the axis of the plane. Thus the line drawn from the vertex and perpendicular to the base of an isosceles triangle, is a diameter of gravity; and thus also the axis of an ellipse, or a parabola, &c, is a diameter of gravity. The centre of gravity of a segment or arc of a circle, is in the radius or line perpendicularly bisecting its chord or base.

Likewise, if a plane divide a solid in the same manner, making the parts on both sides of it perfectly equal and similar in all respects, it will be a plane of gravity, or will pass through the centre of gravity. Thus, as the intersection of two such planes determines the diameter of gravity, the centre of gravity of a right cone, or spherical segment, or conoid, &c, will be in the axis of the same.

The centre of gravity of a ship, is always before the point, which is the middle of her absolute length: for the fore-part, being of greater capacity than the after-part, must consequently have greater weight; and therefore it carries the centre of gravity forwards in proportion to its greater weight (which in large ships is from 50 to 80 tons), and also to the interval between every centre of gravity of each particular part both forward and aft. When a ship is at sea and loaded, the centre of gravity may well be supposed not to change, unless the cargo be moved. But experience shows that the fore or after-part of the bottom of a ship plunges and labours more and more, in proportion as the wind acts with more or less force on the sails; because ships are generally not masted according to the *point relique*; so that a ship, which has the centre of the effort of her sails ill-placed, draws always more water forward or aft when the impulse of the wind upon her sails is very powerful, than when she is at ease under her burthen. From the centre of gravity of the floating line of a ship let a perpendicular be raised, and continued till it be intersected by the direction of the impulse of the water on the bows, in sailing directly before the wind; and where these two lines cut each other, that point is the *point relique*, and where the centre of effort of all the sails should be placed.

Common Centre of Gravity of two or more bodies, or the different parts of the same body, is such a point as that, if it be suspended or supported, the system of bodies will equiponderate, and rest in any position. Thus, the point of suspension in a common balance beam, or stelyard, is the centre of gravity of the same.

When any number of bodies move in right lines with uniform motions, their common centre of gravity moves also in a right line with a uniform motion; and the sum of their motions, estimated in any given direction, is precisely the same as if all the bodies in one mass were carried on with the direction and motion of their common centre of gravity. Nor is the centre of gravity of any number of bodies affected by their collision or actions on each other. For further particulars on the motion of the centre of gravity of any number of bodies, see Emerson's Mechan. Props. 48, 49, &c.

Laws and Determination of the Centre of Gravity.

1. The centre of gravity of two equal bodies or masses is equally distant from their respective centres. For these

are as two equal weights suspended at equal distances from the point of suspension; in which case they will equiponderate, and rest in any position.

2. If the centres of gravity of two bodies, A and B, be connected by the right line AB, the distances AC and BC, from the common centre of gravity c, are reciprocally as the weights or bodies A and B; that is, $AC : BC :: B : A$. See this demonstrated under the article LEVER.

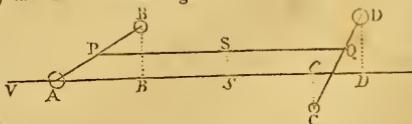

Hence, if the weights of the bodies A and B be equal, their common centre of gravity c will be in the middle of the right line AB, as in the foregoing article. Also since $A : B :: BC : AC$, therefore $A \times AC = B \times BC$; whence it appears that the powers of equiponderating bodies are to be estimated by the product of the mass multiplied by the distance from the centre of gravity; which product is usually called the momentum of the weights.

Further, from the foregoing proportion, by composition it will be $A + B : A :: AB : BC$, or $A + B : B :: AB : AC$. So that the common centre of gravity c of two bodies will be found, if the product of one weight by the whole distance between the two, be divided by the sum of the two weights. Suppose, for example, that $A = 12$ pounds, $B = 4$ lb, and $AB = 36$ inches: then $16 : 12 :: 36 : 27 = BC$, and consequently $AC = 9$, the two distances from the common centre of gravity.

3. The common Centre of Gravity of three or more given bodies or points A, B, C, D, &c, will be thus determined.—If the given bodies lie all in the same straight line AD; by the last article, find P the centre of gravity of the two A and B, and Q the centre of gravity of C and D; then, considering P as the place of a body equal to the sum of A and B, and Q as the place of another body equal to both C and D, find s the common centre of gravity of these two sums, viz, $A + B$ collected in P, and $C + D$ united in Q; so shall s be the common centre of gravity of all the four bodies, A, B, C, D. And the same for any other number of bodies, always considering the sum of any number of them as united or placed in their common centre of gravity, when found.

Otherwise, thus. Take the distances of the given bodies from some fixed point as v, calling the distance $VA = a$, $VB = b$, $VC = c$, $VD = d$, and the distance of the centre of gravity vs = r; then $sa = x - a$, $sb = x - b$, $sc = c - x$, $sd = d - x$, and by the nature of the lever $A \cdot (x - a) + B \cdot (x - b) = C(c - x) + D(d - x)$; hence $Ax + Bx + cx + dx = aa + bb + cc + dd$, and $x = \frac{aa + bb + cc + dd}{a + b + c + d} = vs$ the distance sought; which therefore is equal to the sum of all the momenta, divided by the sum of all the weights or bodies.

Or thus. When the bodies are not in the same straight line, connect them with the lines AB, CD; then, as before, find P the common centre of A and B, and Q the common centre of C and D; then, conceiving A and B united in P,

and c and d united in q , find s the common centre of p and q , which will be the centre of gravity of the whole.

Or the bodies may be all reduced to any line vab , &c., drawn in any direction whatever, by perpendiculars bb , cc , &c., let fall thereon from the centres of gravity of those bodies; and then the common centre s in this line, as before, will be at the same distance from v as the true centre s is; and consequently the perpendicular from s will pass through s the real centre.

4. From the foregoing general expression, viz,

$$x = \frac{aa + bb + cc + &c}{a + b + c + &c},$$

for the centre of gravity of any system of bodies, may be derived a general method for finding that centre in any body; for a , b , c , &c., may be considered as the elementary parts of any body, whose sum or mass is $m = a + b + c + &c$, and aa , bb , cc , &c., are the several momenta of all these parts, viz, the product of each part multiplied by its distance from the fixed point v . Hence then, in any body, find a general expression for the sum of the momenta, and divide it by the content of the body, so shall the quotient be the distance of the centre of gravity from the vertex, or from any other fixed point, from which the momenta are estimated.

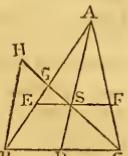

5. Thus, in a right line AB , all the particles which compose it may be considered as so many very small weights, each equal to \dot{x} , which is therefore the fluxion of the weights, or of the line denoted by x . So that the small weight \dot{x} multiplied by its distance from A , viz x , is $\dot{x}x$ the momentum of that weight \dot{x} ; that is, $\dot{x}x$ is the fluxion of all the momenta in the line AB or x ; and therefore its fluent $\frac{1}{2}x^2$ is the sum of all those momenta; which being divided by x the sum of all the weights, gives $\frac{1}{2}x$ or $\frac{1}{2}AB$ for the distance of the centre of gravity c from the point A ; that is, the centre c is in the middle of the line AB .

6. Also in the parallelogram, whose axis or length $AB = x$, and its breadth $DE = b$; drawing de parallel and indefinitely near DE , the arcola $doze = \dot{b}x$ will be the fluxion of all the weights, which multiplied by its distance x from the point A , gives $\dot{b}x\dot{x}$ for the fluxion of all the momenta, and consequently the fluent $\frac{1}{2}bx^2$ is the sum of all those momenta themselves; which being divided by bx the sum of all the weights, give $\frac{1}{2}x = \frac{1}{2}AB$ for the distance of the centre c from the extremity at A , and is therefore in the middle of the axis, as is known from other principles.

And the process and conclusion will be exactly the same for a cylinder, or any prism whatever, making b to denote the area of the end or of a transverse section of the body.

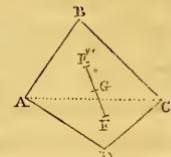

7. In a triangle ABC ; the line AD drawn from one angle to bisect the opposite side, will be a diameter of gravity, or will pass through the centre of gravity: for if that line be supported, or conceived to be laid upon the edge of something, the two halves of the triangle on both sides of that line will just balance one another, since all the parallels EF &c to the base will be bisected, as well as the base itself, and so the two halves of each line will just balance each other. Therefore, putting the base $BC = b$, and the axis or bisecting line $AD = a$,

the variable part $AS = x$; then, by similar triangles $AD : BC :: AS : EF$, that is $a : b :: x : \frac{b}{a} = EF$; which, as a weight, multiplied by \dot{x} , gives $\frac{bx\dot{x}}{a}$ for the fluxion of the weights; and this again multiplied by $\dot{x} = AS$, the distance from A , gives $\frac{bx^2\dot{x}}{a}$ for the fluxion of the momenta; the fluent of which, or $\frac{bx^3}{3a}$ divided by $\frac{bx}{a}$ the fluent for the weights, gives $\frac{1}{3}x^2$ or $\frac{1}{3}AS$ for the distance of the centre of gravity from the vertex A in the triangle AEF ; and when $x = AD$, then $\frac{2}{3}AD$ is the distance of the centre of gravity of the triangle ABC .

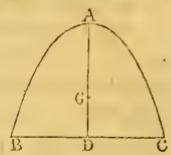

The same otherwise, without Fluxions. Since a line drawn from any angle to the middle of the opposite side passes through the centre of gravity, therefore the intersection of any two of such lines, will be that centre: thus then the centre of gravity is in the line AD ; and it is also in the line CC' bisecting AB ; it is therefore in their intersection S . Now to determine the distance of S from any angle, as A , produce CG to meet BH parallel to AS in H ; then the two triangles AGS , BGH are mutually equal and similar; for the opposite angles at H and S , and at A and B , also the side $AG = BG$; therefore the other sides BH , AS are equal. But the triangles CDS , CBH are similar, and the side $CB = 2CD$, therefore BH or its equal $AS = 2DS$, that is $AS = \frac{2}{3}AD$, the same as was found before. And in like manner $CS = \frac{2}{3}CG$.

8. In a trapezium. Divide the figure into two triangles by the diagonal AC , and find the centres of gravity E and F of these triangles; join EF , and find the common centre G of these two by this proportion, $ABC : ADC :: FG : EG$, or $ABCD : ADC :: EF : EG$.

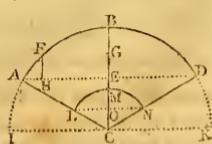

In like manner, for any other figure, whatever be the number of sides, divide it into several triangles, and find the centre of gravity of each; then connect two centres together, and find their common centre as above; do the same with this and the centre of a third, and so on, always connecting the last found common centre to another centre, till the whole are included in this process; so shall the last common centre be that which is required.

9. In the Parabola BAC . Put $AD = x$, $ED = y$, and the parameter $= p$. Then, by the nature of the figure, $px = y^2$, and $2y = 2\sqrt{px}$; hence $2\dot{x}\sqrt{px}$ is the fluxion of the mass, and $2x\dot{x}/px$ is the fluxion of the momentum; then the fluent of the latter divided by that of the former, or $\frac{2x\dot{x}}{px}$ divided by $\frac{2\dot{x}\sqrt{px}}{px}$, gives $\frac{1}{2}x = \frac{1}{2}AD$, for AO , the distance of the centre of gravity O , from the vertex A of the parabola.

10. In the Circular Arc ABD , considered as a physical line having gravity. It is manifest that the centre of gravity c of the arc, will be somewhere in the axis, or middle radius bc , c being

the centre of the circle, which is considered as the point of suspension. Suppose r indefinitely near to A , and FE parallel to BC . Put the radius BC or $AC = r$, the semiaire $AB = z$, and the semichord $AE = \dot{z}$; then is $AH = \dot{z}$, and $AF = \ddot{z}$ the fluxion of the mass; therefore $CE \times \dot{z}$ is the fluxion of the momentum. But, by similar triangles, AC or r : CE :: AF or \dot{z} : AH or \dot{z} , therefore $r\dot{z} = CE \times \dot{z}$, and so $r\dot{z}$ is also the fluxion of the momentum; the fluent of which is rz , and this divided by z the whole weight, gives $\frac{rz}{z} = \frac{AC \times AE}{AB} = \frac{AC \times AE}{AB}$ = cg the distance of the centre of gravity from the centre c of the circle; being a 4th proportional to the given arc, its chord, and the radius of the circle.

Hence, when the arc becomes the semicircle IBC , the above expression becomes $\frac{1c^2}{18}$ or $\frac{r^2}{15708r} = \frac{r}{15708} = .6366r$, viz a third proportional to a quadrant and the radius.

11. In the Circular Sector ABD . Here also the centre of gravity will be in the axis or middle radius BC . Now with any smaller radius describe the concentric arc LMN , and put the radius AC or $BC = r$, the arc $ABD = a$, its chord $AED = c$, and the variable radius CL or $CM = y$; then as $r:y::a:\frac{ay}{r}$ = the arc LMN , and $r:y::c:c\frac{y}{r}$ = the chord LOX ; also, by the last article, the distance of the centre of gravity of the arc LMN is $\frac{cm \times lon}{lmn} = \frac{cm \times aed}{abd} = \frac{cy}{a}$; hence the arc LMN or $\frac{ay}{r}$ multiplied by y gives $\frac{ay^2}{r}$ the fluxion of all the weights or mass, and this multiplied by $\frac{cy}{a}$ the distance of the common centre of gravity, gives $\frac{cy^2}{r}$ the fluxion of the momentum; the fluent of which, viz $\frac{cy^3}{3r}$ divided by $\frac{ay^2}{r}$, the fluent of the mass, gives $\frac{cy}{3a}$ for the distance of the centre of gravity of the sector $CLMN$ from the centre c ; and when $y = r$, it becomes $\frac{2cr}{3a} = cg$ for that of the sector $CABD$ proposed; being $\frac{2}{3}$ of a 4th proportional to the arc of the sector, its chord, and the radius of the circle.

Hence, when the sector becomes a semicircle, the last expression becomes $\frac{4r^2}{3a} = \frac{2c^2}{3ab}$ or $\frac{2}{3}$ of a 3d proportional to a quadrantal arc and the radius. Or it is equal to $\frac{4r}{3p} = .4244r$ from the centre c ; where $p = 3.1416$. So that the distance of the centre of gravity of the sector, is just equal to $\frac{2}{3}$ of that of its arc.

12. In the Cone ADB . Putting $a = dc$, b = area of the base AEB , and $x = dc^2$ any variable altitude; then as $a^2 : x^2 :: b : \frac{bx}{a^2}$ = area acb ; hence the fluxion of the mass is $\frac{bx^2\dot{x}}{a^2}$ whose fluent, or the solid, is $\frac{bx^3}{3a^2}$; and the fluxion of the momentum is $\frac{bx^2\dot{x}}{a^2}$, whose fluent is $\frac{bx^4}{4a^2}$; then this fluent divided by the former fluent, the whole weight or mass, gives $\frac{3}{4}\dot{x}$ or

$\frac{3}{4}x$ for the distance of the centre of gravity of the cone DAB , or $\frac{3}{4}dc$ for that of the cone DAB below the vertex D . And the same is the distance in any other pyramid. So that all pyramids of the same altitude, have the same centre of gravity.

13. General Scholium to the foregoing articles, for the place of the centre of gravity in geometrical figures.

(1). The centre of gravity of every geometrical figure, lies in its axis or diameter, being that line which is drawn from the middle of the base of one end, to the middle of the opposite end, or to the opposite angle or vertex; because this line bisects all the ordinates or sections parallel to the said base or ends. And the distance of the centre of gravity, as measured on that axis, either from the base or from the vertex, is for the several figures as below.

(2). The centre of gravity is in the middle of that axis, or length, or equally distant from both ends, or coinciding with the centre of magnitude in all regular figures, or such as have all the said parallel sections equal; such as right lines, all parallelograms and prisms, all regular plane polygons and solid polyhedrons, also the circle and sphere.

(3). In a triangle and paraboloid, it is $\frac{1}{3}$ of the axis from the base, or $\frac{2}{3}$ from the vertex.

(4). In a parabola it is $\frac{2}{3}$ from the base, or $\frac{1}{3}$ from the vertex.

(5). In a circular arc, it is from the centre of the circle, a 4th proportional to the arc, its chord, and the radius of the circle, viz, $\frac{cr}{a}$.

(6). In a circular sector, the distance from the centre is, $\frac{2cr}{aa}$ or $\frac{2}{3}$ of the said 4th proportional to the arc, chord, and radius.

(7). In a semicircle the distance from the centre is $\frac{4r^2}{3a}$, or $\frac{4}{3}$ of a 3d proportional to the arc and radius.

(8). In a circular segment, the distance from the centre is $\frac{c^3}{12 \text{ area}}$ or $\frac{1}{12}$ of the cube of the chord divided by the area of the segment, or $\frac{1}{12}$ of a 4th proportional to the said area, the square of the chord, and the same chord.

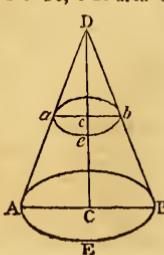

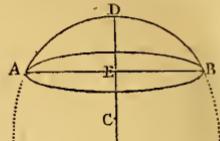

(9). In any pyramid or cone, it is $\frac{1}{4}$ from the base, or $\frac{3}{4}$ from the vertex.

(10). In the hemisphere, or hemispheroid, it is $\frac{3}{8}$ from the base, or $\frac{5}{8}$ from the vertex.

(11). In the segment of a sphere, or of a spheroid, the distance from the base is $\frac{2d-h}{6d-4h}h$; where h denotes the height of the segment, and d the whole diameter or axis.

(12). In the segment of an hyperbolic conoid, the distance from the base is $\frac{2d+h}{6d+4h}h$; where h and d are the same as above, viz, the height of the segment and the whole diameter or axis.

(13). In any figure, composed of two parts, or for any two bodies; find the centre of gravity of each of the two bodies, or two parts, and connect these two centres by a right line, in which line will lie the common centre of gravity of the compound body; and the distance of that centre from the centre of each body, or each part, will be

regulated by this proportion, viz, that each distance is reciprocally proportional to the mass or weight, or content of each body; or, as the sum of the contents of the two bodies, or of the whole compound mass, is to the whole distance of the two centres, so is each particular body or part, to the distance from the centre of the other body or part.

14. To determine the Centre of Gravity in any Body mechanically. Lay the body on the edge of any thing, as a triangular prism, or such like, moving it backwards and forwards till the parts on both sides are in equilibrio; then is that line just in, or under the centre of gravity. Balance it again in another position, to find another line passing through the centre of gravity; then the intersection of these two lines will be the centre required.

The same may be done by laying the body on an horizontal table, as near the edge as possible without its falling, and that in two positions, as lengthwise and breadthwise: then the common intersection of the two lines contiguous to the edge, will be its centre of gravity. Or it may be done by placing the body on the point of a style, &c, till it rest in equilibrio. It was by this method that Borelli found that the centre of gravity in a human body is between the nates and pubis; so that the whole gravity of the body is collected into the place of the genitals; an instance of the wisdom of the Creator, in placing the membrum virile in the part which is the most convenient for copulation.

The same otherwise: thus, Hang the body up by any point; then a plummet-line hung over the same point, will pass through the centre of gravity; because that centre will always descend to the lowest point when the body comes to rest, which it cannot do except when it falls in the plummet-line. Therefore, marking that line upon it, and suspending the body by another point, with the plummet, to find another such line, the intersection of the two will give the centre of gravity.

Or thus. Hang the body by two strings from the same tack, but fixed to different points of the body; then a plummet, hung by the same tack, will fall on the centre of gravity.

In the 4th volume of the New Acts of the Academy of Petersburg, is the demonstration of a very general theorem concerning centres of gravity, by M. Lhuillier; a particular example only of the general proposition will be as follows: Let A , B , C , be the centres of gravity of three bodies; a , b , c their respective masses, and s their common centre of gravity. Let right lines qa , qb , qc , be drawn from the common centre to that of each body, and the latter be connected by right lines ab , ac , and bc ; then

$$QA^2 \times a + QB^2 \times b + QC^2 \times c = \\ AB^2 \times \frac{ab}{a+b+c} + AC^2 \times \frac{ac}{a+b+c} + BC^2 \times \frac{bc}{a+b+c}.$$

Uses of the Centre of Gravity. This point is of the greatest use in mechanics, and many important concerns in life; because the place of that centre is to be considered as the place of the body itself, in computing mechanical effects; as in the oblique pressures of bodies, banks of earth, arches of bridges, and such like.

The same centre is even useful in finding the superficial and solid contents of bodies; for it is a general rule, that the superficies or solid generated by the rotation of a line or plane about any axis, is always equal to the product of the said line or plane drawn into the circumference or path described by the centre of gravity. For example, it

was found above at art. 11, that in a semicircle, the distance of the centre of gravity from the centre of the circle is $\frac{4r}{3p}$; and therefore the path of that centre, or the circumference described by it while the semicircle revolves about its diameter, is $\frac{8}{3}r$; also the area of the semicircle is $\frac{1}{2}pr^2$; hence the product of the two is $\frac{4}{3}pr^3$; which, it is well known, is equal to the solidity of the sphere generated by the revolution of the semicircle.

And hence also is obtained another method of finding mathematically the centre of gravity of a line or plane, from the contents of the superficies or solid generated by it. For if the generated superficies or solid be divided by the generating line or plane, the quotient will be the circumference described by the centre of gravity; and consequently this divided by $2p$ gives the radius, or distance of that centre from the axis of rotation. For example, in the semicircle, whose area is $\frac{1}{2}pr^2$, and the content of the sphere generated by it $\frac{4}{3}pr^3$; here the latter divided by the former is $\frac{8}{3}r$, and this divided by $2p$ gives $\frac{4r}{3p}$ for the distance of the centre of gravity from the axis, or from the centre of the semicircle, the same as before. The property last mentioned, relative to the relation between the centre of gravity and the figure generated by the revolution of any line or plane, is mentioned by Pappus, in the preface to his 7th book; and Father Guidini has more fully demonstrated it in his 2d and 3d books on the Centre of Gravity.

The principal writers on the centre of gravity are Archimedes, Pappus, Guidini, Wallis, Casatus, Carré, Hays, Rufus, &c. See also my Mensuration, p. 382, 4th edit.

Centre of Gyration, is that point in which if the whole mass be collected, the same angular velocity will be generated in the same time, by a given force acting at any place, as in the body or system itself. This point differs from the centre of oscillation, inasmuch as in this latter case the motion of the body is produced by the gravity of its own particles, but in the case of the centre of gyration the body is put in motion by some other force acting at one place only.

To determine the Centre of Gyration, in any body, or system of bodies composed of the parts A , B , C , &c, moving about the point s , when urged by a force f acting at any point p . See the following figure. Let n be that centre; then, by mechanics, the angular velocity generated in the system by the force f , is $\frac{f \cdot sp}{A \cdot SA^2 + B \cdot SB^2 + C \cdot SC^2 + &c}$, and, by the same, the angular velocity of the matter placed all in the point r , is $\frac{f \cdot sr}{(A + B + C + &c) \times sr^2}$; then since these two are to be equal, their equation will give sr

$$= \sqrt{\frac{A \cdot SA^2 + B \cdot SB^2 + C \cdot SC^2 + &c}{A + B + C + &c}}, \text{ for the distance of the centre of gyration sought, below the axis of motion.}$$

Now because the quantity $A \cdot SA^2 + B \cdot SB^2 + &c$ is $= so \cdot b$, where o is the centre of gravity, o the centre of oscillation, and b the whole body or sum of A , B , C , &c; therefore it follows that $sr^2 = so \cdot so$; that is, the distance of the centre of gyration, is a mean proportional between those of gravity and oscillation.

And hence also, if p denote any particle of a body, placed at the distance d from the axis of motion; then is $sr = \frac{\text{sum of all the } pd^2}{\text{body } b}$; whence the point n may be determined in bodies by means of Fluxions.

The distance of the centre of gyration from the point or axis of motion, being a mean proportional between the distances of the centres of gravity and oscillation from the same axis. Hence, when any two of these distances is known, the third may readily be determined.

The distance s_r of the centre of gyration from the axis of rotation in several bodies will be as follows:

1. In a right line, or thin cylinder, revolving about the end, $s_r = \text{length} \times \sqrt{\frac{1}{3}}$.

2. The plane of a circle, or cylinder, revolving about the axis, $s_r = \text{radius} \times \sqrt{\frac{1}{3}}$.

3. The periphery of a circle, about the diameter, $s_r = \text{radius} \times \sqrt{\frac{1}{3}}$.

4. A wheel with a very thin rim, revolving about its axle, $s_r = \text{radius}$.

5. The plane of a circle, about the diameter, $s_r = \frac{1}{2}$ radius.

6. The surface of a sphere, about the diameter, $s_r = \text{radius} \times \sqrt{\frac{2}{3}}$.

7. A globe, about the diameter, $s_r = \text{radius} \times \sqrt{\frac{2}{3}}$.

8. A cone, about the axis, $s_r = \text{radius} \times \sqrt{\frac{1}{15}}$.

CENTRE of Inertia. See CENTRE of GRAVITY.

CENTRE of Magnitude, is the point which is equally distant from all the similar external parts of a body. This is the same as the centre of gravity in homogeneous bodies that can be cut into like and equal parts according to their length, as in a cylinder or any other prism.

CENTRE of Motion, is the point about which any body, or system of bodies, moves, in a revolving motion.

CENTRE of Motion of a ship, is the point upon which a vessel oscillates or rolls, when put in motion.

CENTRE of Oscillation, is that point in the axis or line of suspension of a vibrating body, or system of bodies, in which if the whole matter or weight be collected, the vibrations will still be performed in the same time, and with the same angular velocity, as before. Hence, in a compound pendulum, its distance from the point of suspension is equal to the length of a simple pendulum whose oscillations are isochronal with those of the compound one.

Mr. Huygens, in his Horologium Oscillatorium, first showed how to find the centre of oscillation. At the beginning of his discourse on this subject, he says, that Mersenne first proposed the problem to him while he was yet very young, requiring him to resolve it in the cases of sectors of circles suspended by their angles, and by the middle of their bases, both when they oscillate sideways and flatways; as also for triangles and the segments of circles, either suspended from their vertex or the middle of their bases. But, continues he, not having immediately discovered any thing that would open a passage into this business, I was repulsed at first setting out, and stopped from a further prosecution of the subject; till being farther incited to it in adjusting the motion of the pendulums of my clock, I surmounted all difficulties, going far beyond Descartes, Fabry, and others, who had done the thing in a few of the most easy cases only, without any sufficient demonstration; and solving not only the problems proposed by Mersenne, but many others that were much more difficult, and showing a general way of determining this centre, in lines, superficies, and solids.

In the Leipsic Acts for 1691 and 1714, this doctrine is handled by the two Bernoullis; and the same is also done by Herman, in his treatise De Motu Corporum Solidorum et Fluidorum.

It may also be seen in treatises on the Inverse Method

of Fluxions, where it is introduced as one of the examples of that method. See HAYES, CARRÉ, WOLFIUS, SIMPSON, FLUXIONS, &c.

To determine the Centre of Oscillation, in any Compound Mass or Body MN, or of any System of Bodies A, B, C, &c.

Let MN be the plane of vibration, to which plane conceive all the matter to be reduced by letting fall perpendiculars to this plane from every particle in the body; a supposition which will not alter the vibration of the body, because the particles are still at the same distance from the axis of motion. Let o be the centre of oscillation, and g the centre of gravity; through the axis s draw sg, and the horizontal line sr; then from every particle A, B, C, &c, let fall perpendiculars aa and ap, bb and bp, cc and cr, &c, to these two lines; and join sa, sb, sc; also draw gm and on perpendicular to sr.

Now the forces of the weights A, B, C, to turn the body about the axis, are A. sp, B. sq, - C. sr; and, by mechanics, the forces opposing or resisting that motion are A. sa², B. sb², C. sc²; therefore the angular velocity generated by the whole system is

$$\frac{A. sp + B. sq - C. sr}{A. sa^2 + B. sb^2 + C. sc^2}$$

In like manner, the angular velocity which any body or particle p, situated in o, generates in the system, by its weight, is $\frac{p. sn}{p. so^2}$ or $\frac{sn}{so^2}$, or $\frac{sm}{sg. so}$, because of the similar triangles sgm, son. But, by the conditions of the problem, the time and angular velocity are alike in both these cases; therefore these two expressions must be equal to each other, that is,

$$\frac{sm}{sg. so} = \frac{A. sp + B. sq - C. sr}{A. sa^2 + B. sb^2 + C. sc^2}, \text{ and consequently}$$

$$so = \frac{sm}{\frac{A. sp + B. sq - C. sr}{A. sa^2 + B. sb^2 + C. sc^2}}. \text{ Again, by mechanics, the sum of the forces } A. sp + B. sq - C. sr \text{ is equal}$$

$(A + B + C) sm$ the force of the same matter collected all into its centre of gravity g; therefore

$$so = \frac{A. sa^2 + B. sb^2 + C. sc^2}{(A + B + C). sg}, \text{ which is the distance of the centre of oscillation o below the axis of suspension.}$$

Farther, because it was found under the article Centre of Gravity, that $(A + B + C). sg = A. sa + B. sb + C. sc$, therefore so = $\frac{A. sa^2 + B. sb^2 + C. sc^2}{A. sa + B. sb + C. sc}$ is the same distance of the centre of oscillation; where any of the products A. sa, B. sb, &c are to be considered negative when the points a, b, &c lie above the point s, or where the axis passes through.

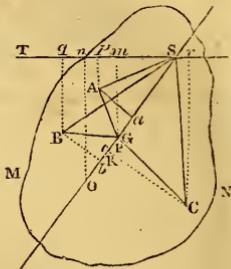

Again, because, by Eucl. II. 12 and 13,

$$sa^2 = sg^2 + ga^2 - 2sg. ga,$$

$$\text{and } sb^2 = sg^2 + gb^2 - 2sg. gb,$$

$$\text{and } sc^2 = sg^2 + gc^2 - 2sg. gc, \text{ &c};$$

and since by Mechanics, the sum of the last terms is nothing, namely $-2sg. ga + 2sg. gb + 2sg. gc &c = 0$; therefore the sum of the others, or A. sa² + B. sb² + C. sc² = $(A + B + C) sg^2 + A. ga^2 + B. gb^2 + C. gc^2 &c$, or $= b. sg^2 + A. ga^2 + B. gb^2 + C. gc^2 &c$; where b denotes the body, or sum A + B + C &c of all

the parts: this value then being substituted in the numerator of the 2d value of so above-found, it becomes

$$so = \frac{b \cdot sg^2 + A \cdot GA^2 + B \cdot GB^2 \&c}{b \cdot sg}, \text{ or}$$

$$so = sg + \frac{A \cdot GA^2 + B \cdot GB^2 \&c}{b \cdot sg};$$

From which it appears that the centre of oscillation is always below the centre of gravity, and that the difference or distance between them is $go = \frac{A \cdot GA^2 + B \cdot GB^2 \&c}{b \cdot sg}$.

It follows also from hence, that $sg \cdot go =$

$\frac{A \cdot GA^2 + B \cdot GB^2 \&c}{\text{the body } b}$; that is, the rectangle $sg \cdot go$ is always the same constant quantity; wherever the point of suspension s is placed, since the point G and the bodies A, B, &c, are constant. Or go is always reciprocally as sg , that is go is less as sg is greater; and the points G and o coincide when sg is infinite; but when s coincides with G, then go is infinite, or o is at an infinite distance.

To find the Centre of Oscillation by means of Fluxions. From the premises is derived this general method for the centre of oscillation, viz, let x be the abscissa of an oscillating body, and y its corresponding ordinate or section; then will the distance so of the centre of oscillation below the axis of suspension s, be equal to the fluent of $yx^2 \dot{x}$ divided by the fluent of $yx \dot{x}$. So that, if from the nature or equation of any given figure, the value of y be expressed in terms of x, or otherwise, and substituted in these two fluxions; then the fluents being taken, and the one divided by the other, the quotient will be the distance to the centre of oscillation in terms of the absciss x.

But when the body is suspended by a very fine thread of a given length a, then the fluent of $(a+x)^2 \cdot yx$ divided by the fluent of $(a+x) yx$ gives the distance of the same centre of oscillation below the point of suspension.

Ex. For example, in a right line, or rectangle or cylinder or any other prism, whose constant section is y, or the constant quantity u; then $yx^2 \dot{x}$ is $ax^2 \dot{x}$, whose fluent is $\frac{2}{3}ax^3$; also $yx \dot{x}$ is $ax \dot{x}$, whose fluent is $\frac{1}{2}ax^2$; and the quotient of the former $\frac{2}{3}ax^3$ divided by the latter $\frac{1}{2}ax^2$, is $\frac{4}{3}x$ for the distance of the centre of oscillation below the vertex in any such figure, namely having every where the same breadth or section, that is, at two-thirds of its length. In like manner the centre of oscillation is found for various figures, vibrating flatways, and are as they are expressed below, viz,

Nature of the Figure.

Isosceles triangle

When suspended by Vertex.

$\frac{2}{3}$ of its altitude

Common Parabola

$\frac{2}{3}$ of its altitude

Any Parabola

$\frac{2m+1}{3m+1} \times$ its altitude.

As to figures moved laterally or sideways, or edge-ways, that is about an axis perpendicular to the plane of the figure, the finding the centre of oscillation is somewhat difficult; because all the parts of the weight in the same horizontal plane, on account of their unequal distances from the point of suspension, do not move with the same velocity; as is shown by Huygens, in his Horol. Oscil. He found, in this case, the distance of the centre of oscillation below the axis, viz,

In a circle, - - - - - $\frac{2}{3}$ of the diameter:

In a rectangle, susp. by one angle, $\frac{2}{3}$ of the diagonal:

In a parabola, susp. by its vertex, $\frac{2}{3}$ axis + $\frac{1}{3}$ param.

The same susp. by mid. of base, $\frac{2}{3}$ axis + $\frac{1}{3}$ param.

The same susp. by mid. of base, $\frac{3}{4}$ arc \times radius:

In a sector of a circle - - - - - $\frac{4}{3}$ chord:

In a cone - - - - - $\frac{\frac{2}{3} \text{ axis} + \text{radius base}^2}{\text{axis}}$:

In a sphere - - - - - $g + \frac{2r^2}{3g}$, where r is the radius, and $g = a + r$ the rad. added to the length of the thread.

See also Simpson's Fluxions, art. 183 &c.

To find the Centre of Oscillation Mechanically or Experimentally. Make the body oscillate about its point of suspension; and hang up also a simple pendulum of such a length that it may vibrate or just keep time with the other body: then the length of the simple pendulum is equal to the distance of the centre of oscillation of the body below the point of suspension.

Or it will be still better found thus: Suspend the body very freely by the given point, and make it vibrate in small arcs, counting the vibrations it makes in any portion of time, as minute, by a good stop-watch; and let that number of oscillations made in a minute be called n: then shall the distance of the centre of oscillation be

$so = \frac{140850}{nn}$ inches. For, the length of the pendulum vibrating seconds, or 60 times in a minute, being $39\frac{1}{2}$ inches, and the lengths of pendulums being reciprocally as the square of the number of vibrations made in the same time, therefore $n^2 : 60^2 :: 39\frac{1}{2} : \frac{140850}{nn}$, the length of the pendulum which vibrates n times in a minute, or the distance of the centre of oscillation below the axis of motion.

CENTRE of Percussion, in a moving body, is that point where the percussion or stroke is the greatest, in which the whole percutient force of the body is supposed to be collected; or about which the impetus of the parts is balanced on every side, so that it may be stopped by an immovable obstacle at this point, and rest on it, without acting on the centre of suspension.

1. When the percutient body revolves about a fixed point, the centre of percussion is the same with the centre of oscillation; and is determined in the same manner, viz, by considering the impetus of the parts as so many weights applied to an inflexible right line void of gravity; namely, by dividing the sum of the products of the forces of the parts multiplied by their distances from the point of suspension, by the sum of the forces. And therefore what has been above shown of the centre of oscillation, will hold also of the centre of percussion, when the body revolves about a fixed point. For instance, that the centre of percussion in a cylinder is at $\frac{2}{3}$ of its length from the point of suspension, or that a stick of a cylindrical figure, supposing the centre of motion at the hand, will strike the greatest blow at a point about two-thirds of its length from the hand.— See the investigation at large in my Course of Mathematics, p. 44.

2. But when the body moves with a parallel motion, or all its parts with the same celerity, then the centre of percussion is the same as the centre of gravity; for the momenta are the products of the weights and celerities; and to multiply equiponderating bodies by the same velocity, is the same thing as to take equimultiples; but the equimultiples of equiponderating bodies do also equiponderate; therefore equivalent momenta are disposed about the centre of gravity, consequently in this case the two centres coincide, and what is shown of the one will hold in the other.

Centre of Percussion, in a fluid, is the same as out of it.

CENTRE of a Parallelogram, the point in which its diagonals intersect.

CENTRE of Position. See CENTRE of Gravity.

CENTRE of Pressure, of a fluid against a plane, is that point against which a force being applied, equal to the whole pressure, but in a contrary direction, it will keep the surface at rest. It is evident that, on a plane parallel to the horizon, or on any plane where the pressure is uniform, the centre of pressure coincides with the centre of gravity of the plane. But for other cases, it will be found by the following method.

To find the Centre of Pressure of any Plane Surface.

Let ABCD be the surface of the fluid, vw, the plane; which being produced, let cd be its intersection with the surface, p the centre of pressure, and g the centre of gravity; and conceive the whole plane to be divided into an indefinite number of extremely small parts of which one is x: draw rq, gg, xv, perpendicular to the surface, and pa, gn, xm perpendicular to cd; and join ga, gn, xm, then it is manifest that the triangles pqa, cgn, xvm are similar. Now, by the principles of hydrostatics, the pressure on x, perpendicular to vw, is as $x \times xv$; and by mechanics, its effect to turn the plane about cd, is as $x \times xv \times xm$; but $gn : gg :: xm : xv = xm \times \frac{gg}{gn}$; hence the effect of the pressure at x, to turn

the plane about cd, is as $x \times xm^2 \times \frac{gg}{gn}$; therefore the whole effect is as the sum of all the $x \times xm^2 \times \frac{gg}{gn}$. But if $a =$ the area of vw, the whole quantity of pressure on vw = $a \times eg$; therefore the effect of the pressure at p, to turn the plane about cd, is as $a \times gg \times pa$. Hence $a \times gg \times pa =$ sum of all the $x \times xm^2 \times \frac{gg}{gn}$; consequently

$\frac{\text{sum of all the } x \times xm^2 \times \frac{gg}{gn}}{a \times gn} = pa$.

Hence it appears, that p is at the same distance from cd as the centre of percussion is, cd being the axis of suspension. They do not however in general coincide or lie in the same line, that is, in the line ag; for the efficacy of the pressure at x, to turn the plane about ng, is as $x \times xv \times mn$ (or since xv varies as xm), as $x \times xm \times mn$; but the sum of all the $x \times xm \times mn$, is not generally = 0, therefore the whole pressure will not necessarily balance itself upon the line gn. The situation of the line pa must be determined by making the sum of all the $x \times xm \times mn = 0$, which in any particular case may be done by a fluxional process. It is not therefore true, in general, that the centres of pressure and percussion are the same point.

CENTRE of a Regular Polygon, or Regular Body, is the same as that of the inscribed, or circumscribed circle or sphere.

CENTRE of Rotation, is that point about which a body, otherwise at liberty, revolves or tends to revolve when it is acted upon unequally at different points, or by a force

the direction of which does not pass through its centre of gravity. M. J. Bernoulli was the first who published any thing on this subject; and he first found the point about which a body at rest would begin to revolve when struck by another body, and he called this point the *centre of spontaneous rotation*, to distinguish it from the centre of forced rotation. He observed however that D. Bernoulli had discovered the same; he has also mentioned the curve described by that point in the progressive motion of the body, and has described a method of inquiry by which the velocity of the bodies may be found after the stroke. Mr. Vince has treated this subject much at large, and with great perspicuity, in the Philos. Trans. vol. 70, for 1780, p. 546, &c.

CENTRE of a Sphere, is the same as that of its generating semicircle, or the middle point of the sphere, from whence all right lines drawn to the superficies, are equal.

CENTRE of Spontaneous Rotation, is that point which remains at rest the instant a body is struck, or about which the body begins to move. The term was first used by John Bernoulli to distinguish this centre from the centre of forced rotation, or that about which a body is compelled to revolve, such for instance as the point of suspension of a pendulum. See CENTRE of ROTATION.

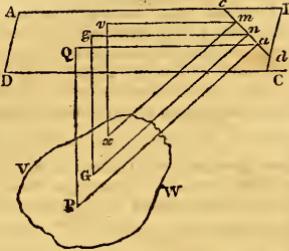

CENTRING of an Optic Glass, the grinding it so as that the thickest part be exactly in the middle.

Cassini the younger has a discourse expressly on the necessity of well centring the object glass of a large telescope, that is, of grinding it so as that the centre may fall exactly in the axis of the telescope. Mem. Acad. 1710.

Indeed, one of the greatest difficulties in grinding large optic glasses is, that in figures, so little convex, the least difference will throw the centre 2 or 3 inches out of the middle. And yet Dr. Hooke remarks, that though it were better the thickest part of a long object glass were exactly in the middle, yet it may be a very good one when it is an inch or two out of it. Philos. Trans., No. 4.

CENTRING, or CENTERING, in Building, denotes the frame of timber by which the brick or stone work of arched vaulting is supported during its erection, and from which it receives its form and curvature. For their description and properties, see the Principles of Bridges, in my new Tracts, vol. 1, p. 105.

CENTRIFUGAL Machine, a curious machine invented by a Mr. Erskine, for raising water by means of a centrifugal force, combined with the pressure of the atmosphere. This machine consists of a large tube of copper, &c, in the form of a cross, placed perpendicularly in the water, and resting at the bottom on a pivot. At the upper part of the tube is a horizontal toothed wheel, which touches the teeth of another in a vertical position; so that by the aid of a double winch the whole machine is moved round with very great velocity. Near the bottom of the perpendicular part of the tube is a valve opening upwards; and near the two extremities, but on the contrary sides of the arms, or cross part of the tube, are two other valves opening outwards. These two valves are kept shut by means of springs, till the machine is put in motion, when the centrifugal velocity of the water forces them open, and discharges itself into a cistern or reservoir placed there for that purpose. On the upper part of the arm are two holes, which are closed by pieces that screw into the metal of the tube. Before the machine can work, these holes must be opened, and water poured in through them, till the whole tube be full; by these means all the air is forced out of the machine, and,

$$\frac{\text{sum of all the } x \times xm^2 \times \frac{gg}{gn}}{a \times gn} = pa$$

the water supported in the tube by means of the valve at the bottom. The tube being thus filled with water, and the holes closed by their screw caps, it is turned round by the winch, when the water in the arms of the tube acquires a centrifugal force, opens the valves near the extremities of the arms, and flies out with a velocity nearly equal to that of the extremities of the said arms.

CENTRIFUGAL Force, is that by which a body revolving about a centre, or about another body, endeavours to recede from it. And

CENTRIPETAL Force, is that by which a moving body is perpetually urged towards a centre, and made to revolve in a curve instead of a right line.

Hence, when a body revolves in a circle, these two forces, viz, the centrifugal and centripetal, are equal and contrary to each other, since neither of them gains upon the other, the body being in a manner equally balanced by them. But when, in revolving, the body recedes farther from the centre, then the centrifugal exceeds the centripetal force; as in a body revolving from the lower to the higher apsis, in an ellipse, and respecting the focus as the centre. And when the revolving body approaches nearer to the centre, the centrifugal is less than the centripetal force; as while the body moves from the farther to the nearer extremity of the transverse axis of the ellipse.

It is one of the established laws of nature, that all motion is of itself rectilinear, and that the moving body never recedes from its first right line, till some new impulse be superadded in a different direction; after that new impulse the motion becomes compounded, but it is still rectilinear, though not in the same line or direction as before. To move in a curve it must receive a new impulse in a different direction every moment, a curve not being reducible to any number of finite right lines. If then a body, continually drawn towards a centre, be projected in a line that does not pass through that centre, it will describe a curve; in every point of which, as A , it will endeavour to recede from the curve, and proceed in the tangent AD ; and if nothing hindered, it would actually proceed in it; so as in the same time in which it describes the arch AE , it would recede the length of the line DE , perpendicular to AD , by its centrifugal force: or, being projected in the direction AD , but continually drawn out of its direction into a curve by a centripetal force, so as to fall below the line of direction by the perpendicular space DE ; then the centrifugal or centripetal force is as this line of deviation DE , supposing the arch AE indefinitely small.

The doctrine of centrifugal forces was first mentioned by Huygens, at the end of his Horologium Oscillatorium, published in 1673, and demonstrated in the volume of his Posthumous Works; as also by Guido Grandi, who gave a few easy cases in bodies revolving in the circumference of circles. But Newton, in his Principia, was the first who fully prosecuted this doctrine; at least as far as regards the conic sections. After him there have been several other writers on this subject; as Leibnitz, Varignon, in the Mem. de l'Acad., Keil, in the Philos. Trans. and in his Physics, Bernoulli, Herman, Cotes, in his Harmonia Mensurorum, Maclaurin, in his Geometrica Organica, and in his Fluxions, and Euler, in his book de Motu, where he considers the curves described by a body acted on by centripetal forces tending to several fixed points.

See also the article *Central Forces*, where this doctrine is more fully explained.

CENTROBARYCO, the same as centre of gravity.

CENTROBARY Method, is a method of determining the quantity of a surface or solid, by means of the generating line or plane, and its centre of gravity. The doctrine is chiefly comprised in this theorem: Every figure, whether superficial or solid, generated by the motion of a line or plane, is equal to the product of the generating magnitude and the path of its centre of gravity, or the line described by its centre of gravity.

See more of this subject in the art. *CENTRE of Gravity*.

CENTRUM, in Geom. Mechanics, &c. See *CENTRE*.
CENTRUM Phonicum, in Acoustics, is the place where the speaker stands in polysyllabic and articulate echoes.

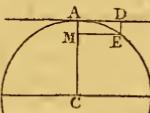

CENTRUM Phonocampicum, is the place or object that returns the voice in an echo.

CEPHEUS, a constellation of the northern hemisphere, being one of the 48 old asterisms. The Greeks fable that Cepheus was a king of Ethiopia, and the father of Andromeda, the princess who was delivered up to be destroyed by a sea monster, from which she was rescued by Perseus. The stars of this constellation, in Ptolemy's catalogue, are 13, in Tycho's 11, in Hevelius's 51, and in the Britannic catalogue 35.

CÉRBERUS, one of the new constellations, formed by Hevelius out of the unformed stars, and added to the 48 old asterisms. It contains only 4 stars, which are enumerated under Hercules in the Britannic catalogue.

CERES, or **PIAZZI**, in Astronomy, a new primary planet intermediate between the orbits of Mars and Jupiter, was discovered on the 1st of January 1801, by M. Piazzi, astronomer royal at Palermo in Sicily, who also gave it this name.

M. Piazzi in a brief account he has published of the discovery of this planet states, that having been engaged for nine years in rectifying the positions of the stars as collected in the catalogues of various astronomers, he was searching on the first of January 1801, among many others, for the 87th in the catalogue of the zodiacal stars of the Abbé de la Caille, when he observed that this star was preceded by another, which according to his usual custom he wished to observe also; especially as it did not interrupt the principal observation. Its light was somewhat faint, and its colour resembled that of Jupiter; but like many others, which, in regard to their magnitude, are usually placed in the 8th class. At that time no doubt arose respecting the nature of it; but on the evening of the 2d, having repeated his observations, and finding that they did not correspond either in time or zenith distance, he suspected that some error had been committed in his observations on the preceding day. He then began to entertain some idea that it might perhaps be a new planet. In the evening of the 3d his conjecture was confirmed, and he assured himself it was not a fixed star. However before he would speak of it, he waited till the evening of the 4th, in which he had the satisfaction of finding that it had moved according to the same laws which it had observed on the preceding days. At this time the motion was retrograde; but on the 10th of January it became direct. He continued to observe the planet till the 13th of February, when he was obliged by illness to discontinue his observations. M. Piazzi then transmitted accounts of his observations to several celebrated astronomers, in order that they might calculate the orbit of the new planet,

and trace out its progress in the heavens: but it eluded every search that was made for it, until December 7th, when it was re-discovered by the assiduous Dr. Zach of Saxe-Gotha; and soon after it was observed by Dr. Olbers at Bremen; by Mechain, at Paris; by the royal astronomer at Greenwich; by Dr. Herschel, at Slough; and by various other persons both in England and Scotland.

Elements of its Theory according to Burckhardt.

Inclination of orbit	-	-	0° 10' 37"
Place of the ascending node	-	-	2° 21' 6"
Epoch of 1801	-	-	2° 17' 19"
Place of the aphelion	-	-	10° 26' 9"
Passage of the aphelion Jan. 1, 1801	-	-	8 hours
Excentricity of orbit	-	-	0.0784
Mean distance	-	-	27677
Time of revolution	-	-	4606 years.

From the observations of Dr. Herschel it is probable that the diameter of this planet, is much less than that of the moon; it appeared under a disc of less than 2'. Yet, small as is this planet, M. Schröter suspects it has two satellites. It has been expected for nearly a century, that such a discovery as this of M. Piazzi, would be made by some diligent astronomer. Maclaurin, Lambert, Bode, Zach, Capel Loft, and others have supported the conjecture. And six astronomers assembled at Lilienthal, in September 1800, resolved to establish a society of 24 practical astronomers, dispersed throughout different parts of Europe, for the express purpose of searching out this planet between Mars and Jupiter: they elected Schröter as their president, and Dr. Zach was chosen their secretary. Accordingly, the consequence has been, that no less than four new planets have been discovered, all nearly agreeing in size, period, and situation; viz, the above one by Piazzi, one by Harding of Lilienthal, and two by Olbers of Bremen, all of which have received names of different heathen divinities: but it may be remarked on this occasion, that it would be more fit practice to call the several new planets after the names of their respective discoverers, as Herschel, Piazzi, Olbers, &c.

CETUS, the *Whale*, a southern constellation, and one of the 48 old asterisms. The Greeks pretend that it was the sea monster sent by Neptune to devour Andromeda, but was killed by Perseus.—In the neck of the whale is a remarkable star, Collo Ceti, which appears and disappears periodically, or rather becomes brighter and fainter by turns, arising it is supposed from the alternate turnings of its bright and dark sides towards us, as it revolves upon its axis, or else from the flatness of its form. The period of its changes is about 312 days. Bulliald in Phil. Trans. vol. 2, Hevelius, ibid. vol. 6, Herschel, ibid. vol. 70, Maraldi, in Mem. Acad. 1, 19.

The stars in the constellation Cetus, in Ptolemy's catalogue, are 22, in Tycho's 21, in Hevelius's 45, and in the Britannic catalogue 97.

CEULEN, or KEULEN (LUDOLPH VAN), a noted Dutch professor of mathematics, who flourished in the latter part of the 16th century. Ludolph was surnamed Van Ceulen, because he was from Cologne, which is called Ceulen or Keulen in Dutch. He was author of several pieces, both in arithmetic and geometry, in the Dutch language, some of which were translated into Latin by Willebrod Snell, as mentioned under his life. Ceulen was chiefly remarkable for his approximation to the circumference of the circle, to 36 places of figures, which he ordered to be engraved on his tombstone.

CHAIN, in Surveying, is a lineal measure, consisting of a certain number of iron links, usually 100; serving to take the dimensions of fields &c.

At every 10th link is usually fastened a small brass plate, with a figure engraven upon it, or else cut into different shapes, to show how many links it is from one end of the chain.

Chains are of various kinds and lengths;

1. A chain of 100 feet long, each link one foot, is used for measuring of large distances only, when no regard is had to acres &c, in the superficial content.

2. A chain of one pole or 16 feet and a half in length; is particularly useful in measuring and laying out gardens and orchards, or the like, by the pole or rod-measure.

3. A chain of 4 poles, or 66 feet, or 22 yards, in length, called Gunter's chain, and is peculiarly adapted to the business of land-surveying, because 10 square chains just make an English acre of land; so that the dimensions being taken in these chains, they are readily reduced to acres by dividing by 10, or barely cutting off the last figure from the square chains. But it is still better in practice to proceed thus, viz, count the dimensions, not in chains, but all in links; then the contents are in square links; and five figures being cut off for decimals, the rest are acres; that is four figures to bring the square links to square chains, and one more to bring the square chains to acres.

In this chain, the links are each 7 inches and $\frac{2}{3}$ inches, or 7.92 inches in length, which is very nearly $\frac{2}{3}$ of a foot. And hence any number of chains or links are easily reduced to feet or inches, or the contrary: the best way of doing which is this: multiply the number of links by 66, then cut off two figures for decimals, and the rest are feet: or multiply links by 22 for yards, cutting off two figures.

CHAIN Rule, called also Rule of Exchange, Rule of Reduction, and Rule of Equation, is a mode of arbitration very useful in the higher operations of exchange, as well as in the arbitration of bullion, specie, and merchandise. Foreign merchants, it seems, are very expert in their application of this rule to commercial computations; and that it is, in a great measure, to this accomplishment that their acknowledged superiority in the practice of exchange may be attributed. See ARBITRATION, also Dr. Kelly's Cambist.

CHALDER, or CHALDRON, of Coals, an English dry measure of capacity consisting of 36 bushels heaped up.

The chalderon of coal is accounted to weigh about 28 cwt. or 3136 pounds.—On ship-board, 21 chaldrons of coals are allowed to the score.

By act of parliament, a Newcastle chalderon is to weigh 52½ cwt., or 3 waggons of 17½ cwt. or 6 carts of 8½ cwt. each, making 52½ cwt. to the chalderon. The statute London chalderon is to consist of 36 bushels heaped up, each bushel to contain a Winchester bushel and one quart, and to be 19½ inches diameter externally. Now it has been found by repeated trials that 15 London chaldrons are equal to 8 Newcastle chaldrons, which, reckoning 52½ cwt. to the latter, gives 28 cwt. to the former, or 3136lb to the London chalderon.

This I find nearly confirmed by experiment. I weighed one peck of coals, which amounted to 21.3lbs. Then 4 times this gives 87lb for the weight of the bushel; and 36 times the bushel gives 3132lb for the chalderon; and to which if the weight of the odd quart be added, or 3lb nearly, it gives 3135lb for the weight of the chalderon, which is only 1 pound short of that by statute.

CHAMBER of a Mortar, or Cannon, is a cell or cavity at the bottom of the bore, to receive the charge of powder. It is not found by experience that chambers have any sensible effect on the velocity of the shot, unless in the largest ordnance, as mortars or very large cannon. Neither is it found that the form of them is very material; a small cylinder is as good as any; though mathematical speculations may show a preference of one form over another. But in practice, the chief point to be observed, is to have the chamber of a size just to contain the charge of powder, and no more, that the ball may lie close to the charge; and that its entrance may point exactly to the centre of the ball.

CHAMBERS (EPHRAIM), author of the dictionary of sciences called the Cyclopædia. He was born at Milton, in the county of Westmoreland, where he received the common education for qualifying a youth for trade and commerce. When at a proper age, he was apprenticed to Mr. Senex, the globe-maker, a business which is connected with literature, especially with geography and astronomy. It was during Mr. Chambers's residence with this skilful artist, that he acquired that taste for literature which accompanied him through life, and directed all his pursuits. At this time, he formed the design of his grand work, the Cyclopædia; some of the first articles of which were written behind the counter. To have leisure to pursue this work, he quitted Mr. Senex, and took chambers at Gray's Inn, where he chiefly resided during the rest of his life. The first edition of the Cyclopædia, which was the result of many years intense application, appeared in 1728, in 2 vols folio. The reputation that Mr. Chambers acquired by the execution of this work, procured him the honour of being elected F. R. S. Nov. 6, 1729. In less than ten years time, a second edition became necessary; which accordingly was printed, with corrections and additions, in 1738; and this was followed by a third edition the very next year.

Though the Cyclopædia was the chief business of Mr. Chambers's life, and may be regarded as almost the sole foundation of his fame, his attention was not wholly confined to this undertaking. He was concerned in a periodical publication called The Literary Magazine, which was begun in 1735. In this work he wrote a variety of articles; particularly a review of Morgan's Moral Philosopher. He was also concerned with Mr. John Martyn, professor of botany at Cambridge, in preparing for the press a translation and abridgment of the Philosophical History and Mémoirs of the Royal Academy of Sciences at Paris; which work was not published till 1742, some time after our author's decease, in 5 volumes 8vo. Mr. Chambers was also author of the translation of the Jesuit's Perspective, from the French, in 4to; which has gone through several editions. He was also joint editor, with Dr. Shaw, of a translation of Boerhaave's Institutiones Chemiae, under the title of A New Method of Chemistry; including the Theory and Practice of that Art, &c, published jointly by P. Shaw, M. B. and E. Chambers, gent. with additional notes and sculptures, Lond. 4to, 1727: and it afterwards went through several editions, with augmentations. Mr. C. was also the editor of the Abridgment of Lord Bacon's Philosophical Works, in 3 vols 4to, 1739; and of those of Mr. Boyle, 3 vols 4to, 1725. Besides which, he was the author of 3 Chemical Lectures, read in London in 1731 and 1732, and Scarborough 1733, for the improvement of arts, trades, and natural philosophy, 8vo, 2d edit. 1725.

Subsequent to which, he published Essays for the improvement of arts, manufactures, and commerce, by means of chemistry, 2d edit. improved by P. Shaw, fellow of the college of physicians, and physician in ordinary to his majesty.

Mr. Chambers's close and unremitting attention to his studies at length impaired his health, and obliged him occasionally to take a country lodging, but without much benefit; he afterwards visited the south of France, but still with little effect; he therefore returned to England, where he soon after died, at Islington, May 15, 1740, and was buried in Westminster Abbey.

After our author's death, two more editions of his Cyclopædia were published. The proprietors afterwards procured a supplement to be compiled, by Mr. Scott and Dr. Hill, which extended to two volumes more; and the whole has since been reduced into one alphabet in 4 volumes, by Dr. Rees, forming a very valuable body of the sciences. And the same is now extending in a new edition, in 4to, under the title of Encyclopaedia.

CHAMBRANLE, the border, frame, or ornament of stone or wood, surrounding the three sides of doors, windows, and chimneys. This is different in the different orders: when it is plain, and without mouldings, it is called simply and properly, band, case, or frame. In an ordinary door, it is commonly termed door-case; in a window, the window-frame.

The chambranle consists of three parts; the two sides, called ascendants; and the top, called the traverse or supercillium.

CHAMFER, or CHAMFERET, an ornament, in architecture, consisting of half a scotia; being a kind of small furrow or gutter on a column.

CHAMFERING, is used for cutting the edge or the end of any thing bevel, or aslope.

CHANCE, the *Doctrine and Laws of*, are the same as those of Expectation, or Probability, &c; which see. Chances, in play, consist of the number of ways by which events may happen. Thus, if a halfpenny, or other piece of money, be tossed up, there are two events, or chances, or sides that may turn up, namely, one chance for turning up a head, and one for the contrary; that is, it is an equal chance to throw a head or not. And in throwing a common die, which has 6 faces, there are in all 6 chances, that is one chance for throwing an ace or any other single point, and 5 chances against it; or it is 5 to 1 that such assigned point does not come up.

The term chance is applied to events, to denote that they happen without any necessary, foreknown, or intending cause; or it is used to denote the bare possibility of an event when nothing is known either to prevent or hinder it: thus, when we say a thing happens by chance, we really mean no more than that its cause is unknown to us; not, as some vainly imagine, that chance itself can be the cause of any thing.

DOCTRINE OF CHANCES, *History of*. This subject, which is no less useful than curious, does not appear to have engaged the attention of mathematicians in former times so much as its importance required. Until the beginning of the last century little is to be found in any of their writings concerning this subject. Of the few problems which they had been accustomed to investigate, they withheld the solutions both from the public and from each other; and they seem to have considered the doctrine of chances rather as an exercise for their ingenuity,

than as capable of being applied to any useful purpose. Before Mr. Huygens published his book *De Ratiociniis in Ludo Aleae*, no person had treated the subject methodically; and, with the exception of Messrs. Pascal and Fermat, who had solved a few problems of no great importance or difficulty, he appears to have been the first who attempted either to give rules for the solutions of any question, or to lay down the principles from which those solutions might be deduced. To this work succeeded a small anonymous tract, *On the Laws of Chance*, which was published in London in 1692, and a French publication of not much larger size, entitled *L'Analyse des Jeux de Hazard*, written by M. Monmort, and published in the year 1708. In this latter work, the author having chiefly insisted on the same mode of reasoning with Huygens, in the solution of his problems, Mr. Demoivre (who considered such reasoning as neither genuine nor natural) was induced in his celebrated work on the *Doctrine of Chances* (which was first published in 1717), to adopt a plainer and less exceptionable mode, in which he has proceeded from the most simple to the most complicated cases; so that by the variety of his problems, as well as by the improvements and additions which he made in two subsequent editions, he had rendered his work one of the best and most copious that has ever been written on the subject. In the year 1740, Mr. Thomas Simpson published a small treatise on *The Nature and Laws of Chance*, which, like his other publications, is not only clear and concise, but contains some problems, whose solutions had either never been attempted, or at least never before communicated to the public. Prior however to the two last-mentioned publications, a posthumous work of Mr. James Bernoulli was published in the year 1713, entitled *De Arte Conjectandi*, containing an explanation of Huygens's tract, and the solution of a great variety of other problems, deduced from the general principles of combination. The second part of this valuable work has lately been translated into English by Mr. Baron Maseres, with notes and commentaries. In the year 1765, and at other times, M. Dalembert, in his *Opuscules &c.*, wrote different essays on the doctrine of chances; and not long ago M. Condorcet published a small treatise on the same subject. In addition to these, which are the principal publications on the subject, may be noticed a small tract, *De Mensura Sortis*, given by Demoivre in his *Miscellanea Analytica*, and some other papers written by him, by Messrs. Bernoulli, Euler, and others, in the *Acts of Leipsic*, the *Journal des Scavans*, the *Philosophical Transactions*, &c., among which may be particularly mentioned an *Essay on the Method of calculating the exact Probability of all Conclusions founded on Induction*, and a *Supplement to that Essay*; the one preserved from the papers of the late Rev. Mr. Bayes, and communicated with an appendix, by Dr. Price, to the Royal Society in the year 1762; the other chiefly written by Dr. Price, and communicated in the following year. These tracts contain the investigation of a problem, the converse of which had formerly exercised the ingenuity of Bernoulli, Demoivre, and Simpson. Indeed both the problem and its converse may justly be considered not only as the most difficult, but as the most important that can be proposed on the subject; having (as Dr. Price well observes) "no less an object in view than to show what reason we have for believing that there are in the constitution of things, fixed laws, according to which events happen; and that therefore, the frame of

the world must be the effect of the wisdom and power of an intelligent cause; and thus to confirm the argument taken from final causes for the existence of the Deity."

For the doctrine itself consult Demoivre, T. Simpson, and a work on the same subject lately published by the celebrated Laplace. See also *CREDIBILITY, GAMING, EXPECTATION, and PROBABILITY*.

CHANDELIERS, in Fortification, a kind of wooden parapet, consisting of upright timbers supporting others laid across the tops of them, 6 feet high, and fortified with fascines, &c. They are used to cover the workmen in approaches, galleries, and mines. And they differ from blinds only in this, that the former serve to cover the men before, and the latter over head.

CHANGES, the permutations or variations of any number of things, with regard to their position, order, &c.; as how many changes may be rung on any number of bells, or how many different ways any number of persons may be placed, or how many several variations may be made of any number of letters, or any other things proposed to be varied.

To find out such numbers of changes, multiply continually together all the terms in a series of arithmetical progression, whose first term and common difference are each unity or 1, and the last term the number of things proposed to be varied, thus $1 \times 2 \times 3 \times 4 \times 5 \&c.$, till the last number be the proposed number of things. For let there be two things as a and b . Then since they may be placed either thus ab or ba , it is obvious that the number of changes is 1×2 or 2. If three things, as a, b, c be supposed; they will admit of 6 variations as in the margin; for each of the three may be combined three different ways with each combination of the other two; thus a may be first combined with bc and then with cb , and hence the number of changes arises, viz., $1 \times 2 \times 3 = 6$.

$\begin{array}{cccc} a & b & c \\ b & a & c \\ b & c & a \\ a & c & b \\ c & a & b \\ c & b & a \end{array}$

And if there be 4 things, each of them may be combined 4 ways with each combination of the other three, that is 4 times 6 ways, or $1 \times 2 \times 3 \times 4 = 24$ ways.

In like manner, the combinations of 5 things are $1 \times 2 \times 3 \times 4 \times 5 = 120$
of 6 things are $1 \times 2 \times 3 \times 4 \times 5 \times 6 = 720$
 $\&c.$

So that if it be proposed to assign how many different ways a company of 6 persons may be placed, at table for instance, the answer will be 720 ways. Also the number of changes that can be rung on 7 bells, is $1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 = 5040$,

CHAPITERS, the crowns or upper parts of a pillar or column.*

CHAPPE (JEAN D'AUTEROCHE), a French astronomer, was born at Mauriac, in Auvergne, March 2, 1728. A taste for drawing and mathematics appeared in him at a very early period; and he owed to Dom. Germain a knowledge of the first elements of mathematics and astronomy. M. Cassini, after assuring himself of the genius of this young man, undertook the cultivation of it. He employed him on the map of France, and the translation of Halley's tables, to which he made considerable additions. The king charged him in 1753 with drawing the plan of the county of Bitche, in Lorraine, all the elements of which he determined geographically. He occupied him-

self greatly with the two comets of 1760; and the fruit of his labour was his Elementary treatise on the theory of those comets, enriched with observations on the zodiacal light, and on the aurora borealis. Soon after he went to Tôbolsk, in Siberia, to observe the transit of Venus over the sun; a journey which greatly impaired his health. After two years absence he returned to France in 1762, where he occupied himself for some time in arranging the great number of observations he had then made. Mr. Chappe also went to observe the next transit of Venus, viz, that of 1769, at California, on the west side of North America, where he died of an epidemic disease, the 1st of August 1769. He had been named adjunct astronomer to the Academy the 17th of January 1759.

The published works of M. Chappe, are,

1. The Astronomical Tables of Dr. Halley; with observations and additions: in 8vo, 1754.

2. Voyage to California to observe the transit of Venus over the sun, June 3, 1769; in 4to, 1772.

over the sun, June 3, 1769. in 40, 1772.

3. He had a considerable number of papers inserted in the Memoirs of the Academy, for the years 1760, 1761, 1764, 1765, 1766, 1767, and 1768; chiefly relating to astronomical matters.

CHAPTRREL, the same with Impost.

CHARACTERISTIC, of a *Logarithm*, the same as Index, or Exponent. This term was first used by Briggs in the 4th section of his *Arithmetica Logarithmica*, where he treats particularly of it; meaning by it, the integral or first part of a logarithm towards the left hand, which expresses 1 less than the integer places or figures in the number answering to that logarithm, or how far the first figure of this number is removed from the place of units; namely, that 0 is the characteristic of all numbers from 1 to 10; and 1 the characteristic of all those from 10 to 100; and 2 the characteristic of all those from 100 to 1000; and so on.

CHARACTERS, are certain marks used by astronomers, mathematicians, &c, to denote certain things, whether for the sake of brevity, or perspicuity, in their operations.

1. ASTRONOMICAL CHARACTERS.

The twelve Signs or Constellations of the Zodiac.

- | | |

2. MATHEMATICAL &c. CHARACTERS.

Numerical Characters used by different Nations.

The most common numerical characters, are those
VOL. I.

called Arabic or Indian, viz, 1, 2, 3, 4, 5, 6, 7, 8, 9, with 0 for cipher or nothing.

The Roman numeral characters are seven, viz, I one, V five, X ten, L fifty, C a hundred, D or CD five hundred, M or CM a thousand. Other combinations are as in the following synopsis of the Roman Notation.

1 = I
 2 = II: As often as any character is repeated,
 3 = III so many times its value is repeated.
 4 = IIII, or IV: A less character before a greater
 5 = V diminishes its value.
 6 = VI: A less character after a greater increases
 7 = VII its value.
 8 = VIII
 9 = IX
 10 = X
 50 = L
 100 = C
 500 = D or 10: For every 3 added, this becomes
 10 times as many.
 1000 = M or C10: For every C and 3 added, set one at each
 2000 = MM end, it becomes 10 times as much.
 5000 = CC or V: A line over any number increases
 6000 = VI it 1000 fold.
 10000 = X or CC100
 50000 = CC50
 60000 = LX or CCC100
 100000 = C or CCC100
 1000000 = M or CCCCC1000
 2000000 = MM, &c.

Greek Numerals.

The Greeks had three ways of expressing numbers. First, For every single letter, according to its place in the alphabet, was denoted a number from α 1 to w 24; in which manner the books of Homer's Ilias are distinguished. Secondly, Another way was by dividing the alphabet into (1st) 8 units, α , β , γ , &c.; (2nd) 8 tens, ι , κ , λ , &c.; (3d) 8 hundreds, ϵ 100, σ 200, &c.; and thousands, they expressed by a point or accent under a letter, as α 1000, β 2000, &c. Thirdly, By six capital letters, thus, Ι (α for $\mu\varepsilon\alpha$) 1, Π ($\pi\varepsilon\nu\tau\epsilon$) 3, Δ ($\delta\varepsilon\nu\alpha$) 10, Η ($\he乎\varepsilon\kappa\alpha\tau\omega$) 100, Χ ($\chi\varepsilon\rho\alpha\zeta$) 1000, Μ ($\mu\varepsilon\varepsilon\alpha$) 10000: and when the letter Η inclosed any of these, except I, it shewed that the inclosed letter was 5 times its own value, as $\overline{\Delta}$ 50, \overline{H} 500, $\overline{\chi}$ 5000, \overline{M} 50000.

Hebrew Numerals.

Characters used in Arithmetic and Algebra.

The first letters of the alphabet, a , b , c , &c., denote given quantities; and the last letters, z , y , x , &c., represent such as are unknown or sought. Stifelius first used the capitals A , B , C , &c., for the unknown or required quantities. After that, Vieta employed the capital vowels A ,

E, I, o, u, y, for the unknown or required quantities, and the consonants **b, c, d, &c.**, for known or given numbers. Harriot changed Vieta's capitals into the small letters, *viz.* **a, e, i, o, u**, for unknown, and **b, c, d, &c.**, for known quantities. And Descartes changed Harriot's vowels for the latter letters **z, y, x, &c.**, and the consonants for the leading letters, **a, b, c, d, &c.**

Newton denotes the several orders of fluxions of variable quantities by as many points over the latter letters; as, of **x, y, z;** as $\dot{x}, \dot{y}, \dot{z}$ are the 1st fluxions,
 $\ddot{x}, \ddot{y}, \ddot{z}$ are the 2d fluxions,
 $\dddot{x}, \dddot{y}, \dddot{z}$ are the 3d fluxions.

And Leibnitz denotes the differentials of the same quantities by prefixing **d** to each of them, thus **dx, dy, dz.**

Powers of quantities are denoted by placing the index or exponent after them, towards the upper part; thus **a²** is the 2d power, **a³** the third power, and **aⁿ** the *n* power of **a.** Diophantus marked the powers by their initials, thus **δ , χ , $\delta\delta$, $\delta\chi$, $\chi\chi$, &c.**, for dynamis, cubus, dynamodynamis, &c., or the 2d, 3d, 4th, &c, powers; and the same method has been practised by several of the early writers, since the introduction of algebra into Europe: but the first of them, as Pacioli, Cardan, &c., used no mark for powers, but the words themselves. Stifel, and others about his time, used the initials or abbreviations **2, 3, 4, 5, 33, &c.**, of res or cosa, zenzus, cubus, zenzenzus, &c., barbarous corruptions of the Italian cosa, census, cubo, censensus, &c. But he used also numeral exponents, both positive and negative, to the general characters or roots **a, b, c, &c.**. Bombelli made use of a half circle thus \smile as a general character for the unknown or quantity required to be found in any question, and the several powers of it he denoted by figures set above it; thus $\smile^1, \smile^2, \smile^3$, are the 1st, 2d, 3d powers of \smile ; which powers he called dignities. Stevinus used a whole circle for the same unknown quantity, with the numeral index within it, and that both integral and fractional; thus **0, 1, 2, 3** are the 0, 1, 2, 3 powers of the general quantity **O**; also **\oplus, \ominus, \otimes** , he uses as the square root, cube root, 4th root of the same; and **\oslash** , the cube root of the square, and **$\oslash\oslash$** , the square root of the cube, and so on.

And these fractional exponents were adopted and farther practised by his commentator Albert Girard. So that Stevinus ought to be esteemed the first person who rendered general the notation of all powers and roots in the same way, the former by integral, and the latter by fractional exponents. Harriot denoted his powers by a repetition of the letters; thus **a, aa, aaa, &c.** And Descartes, instead of this, set the numeral index at the upper part of the letters, as at present, thus **a, a², a³, &c.**; though, I am informed, by such as have seen Harriot's posthumous papers, that he also there makes use of exponents.

The character **$\sqrt{}$** is the sign of radicality, or of a root, being derived from the initial **r** or **r**, which was used at first by Pacioli, Cardan, &c. This character **$\sqrt{}$** , I find first used by Stifel, in 1544, and by Robert Recorde in 1557. The bare character **$\sqrt{}$** denotes the square root only; but at first they prefixed the initial of the name after it, to denote the several roots: as **\sqrt{q}** the quadrate or square root, **\sqrt{c}** the cube root, &c. But the numeral indices of the root were prefixed by Albert Girard, exactly the same as they are used at present, *viz.* **$\sqrt{2}, \sqrt{3}, \sqrt{4}$** , the 2d, 3d, or 4th root.

The character **+** represents addition, and a positive

quantity. At first the word itself was used, plus, piu, or the initial **p.** by Pacioli, Cardan, Tartalea, &c. And the character **+** for addition occurs in Stifelius.

- is the character of subtraction, and denotes also a negative quantity; which also first occurs in the same author Stifelius. Before that, the word minus, meno, or the initial **m.** was used. Other characters have also been sometimes used by other authors, for addition and subtraction; but they are now obsolete.

x is the character of multiplication, and was introduced by Oughtred.

÷ representing division, was introduced by Dr. Pell. Division is also denoted like a fraction, thus $\frac{a}{b}$ or $\frac{b}{a} = 2.$

= denotes equality, and was used by Robert Recorde. Descartes employs **\bowtie** for the same purpose.

The character **:** for proportionality, or equality of ratios, was introduced by Oughtred; as was also the mark **\therefore** continued proportion.

> for greater, and **<** for less, were used by Harriot. And **\sqsupset** and **\sqsubset** were used by Oughtred for the same purposes.

Dr. Pell used **\odot** for involution, and **ω** for evolution.

\sim denotes a general difference between any two quantities, and was used by Dr. Wallis.

The Parenthesis **()**, as a vinculum, was invented by Albert Girard, and used in such expressions as these, $\sqrt{72 + \sqrt{5120}}$, and **B(Bq + cq)**, both for universal roots, and multiplication, &c.

The straight-lined vinculum, **$\overline{}$** , was used by Vieta for the same purpose; thus **A - B** in **B + C.**

Characters in Geometry and Trigonometry.

□ A Square	△ An Angle
△ A Triangle	∟ A Right angle
□ A Rectangle	⊥ Perpendicular
○ or ◎ A Circle	 Parallel

CHARGE, in Electricity, in a strict sense, imports the accumulation of the electric matter on one surface of an electric, as the Leyden phial, a pane of glass, &c., while an equal quantity passes off from the opposite surface. Or, more generally, electrics are said to be charged, when the equilibrium of the electric matter on the opposite surface is destroyed, by communicating one kind of electricity on one side, and the contrary kind to the opposite side: nor can the equilibrium be restored till a communication be made by means of conducting substances between the two opposite surfaces: and when this is done, the electric is said to be discharged. The charge properly refers to one side, in contradistinction from the other; since the whole quantity in the electric is the same before and after the process of charging; and the operation cannot succeed, unless what is gained on one side is lost by the other, by means of conductors applied to it, and communicating either with the earth, or with a sufficient number of non-electrics. To facilitate the communication of electricity to an electric plate, &c., the opposite surfaces are coated with some conducting substance, usually with tin-foil, within some distance of the edge; in consequence of which the electricity communicated to one part of the coating is readily diffused through all parts of the surface of the electric in contact with it; and a discharge is easily made by forming a communication with any conductor from one coating to the other. If the opposite coatings approach

too near each other, the electric matter forces a passage from one surface to the other before the charge is complete. And some kinds of glass have the property of conducting the electricity over the surface, so that they are altogether unfit for the operation of charging and discharging. If indeed the charge be too high, and the glass plate or phial too thin, the attraction between the two opposite electricities forces a passage through the glass, making a spontaneous discharge, and the glass becomes unfit for farther use. See CONDUCTORS, ELECTRICS, LEYDEN PHIAL, &c.

CHARGE, in Gunnery, the load of a piece of ordnance, or the quantity of powder and ball, or shot, with which it is prepared for execution.

The charge of powder, for proving guns, is equal to the weight of the ball; but for service, it is $\frac{1}{2}$ or $\frac{3}{5}$ the weight of the ball, or still less; and indeed in most cases of service, the quantity of powder used is too great for the intended execution. In the British navy, the allowance for 32-pounders is but $\frac{3}{5}$ of the weight of the ball. For it is probable that, if the powder in all ship guns was reduced to $\frac{1}{2}$ the weight of the ball, or even less, it would be a considerable advantage, not only by saving ammunition, but by keeping the guns cooler and quieter, and at the same time more effectually injuring the vessels of the enemy. With the present allowance of powder, the guns are heated, and their tackle and furniture strained; and all this only to render the ball less efficacious; for a ball which can but just pass through a piece of timber, and in the passage loses almost all its motion, is found to rend and fracture it much more, than when it passes through with considerable velocity. See Robins's Tracts, vol. 1, pa. 290, 291; and my own Tracts, vols. 2 and 3.

Again, the same author observes, that the charge is not to be determined by the greatest velocity that may be produced; but that it should be such a quantity of powder as will produce the least velocity necessary for the purpose in view; and if the windage be moderate, no field-piece should ever be loaded with more than $\frac{5}{6}$, or at the utmost $\frac{2}{3}$ of the weight of its ball in powder; nor should the charge of any battering piece exceed $\frac{1}{2}$ of the weight of its bullet. Ib. pa. 266.

Different charges of powder, with the same weight of ball, produce different velocities in the ball, which are in the subduplicate ratio of the weights of powder; and when the weight of powder is the same, and the ball varied, the velocity produced is in the reciprocal subduplicate ratio of the weight of the ball: which is agreeable both to theory and practice. See my paper on Gunpowder in the Philos. Trans. 1778, pa. 50; and my Tracts, vols. 2 and 3.

But this is on a supposition that the gun is of an indefinite length; whereas, on account of the limited length of guns, there is some variation from this law in practice, as well as in theory; in consequence of which it appears that the velocity of the ball increases with the charge only to a certain point, which is peculiar to each gun, where the velocity is the greatest; and that by farther increasing the charge, the velocity gradually diminishes, till the bore is quite full of powder. By an easy fluxionary process it is found that, calling the length of the bore of the gun b , the length of the charge producing the greatest velocity, ought to be $\frac{b}{2718281828}$, or about $\frac{1}{6}$ of the length of the bore; where 2718281828 is the number whose hyp. log. is 1. But, for several reasons, in practice the length of the charge

producing the greatest velocity, falls short of that above mentioned, and the more so as the gun is longer. From many experiments I have found the length of the charge producing the greatest velocity, in guns of various lengths of bore, from 15 to 40 calibers, as follows:

Length of Bore. in Calibers.	Length of Charge for greatest Veloc.
15	- - - $\frac{3}{5}$
20	- - - $\frac{3}{5}$
30	- - - $\frac{3}{5}$
40	- - - $\frac{3}{5}$

CHARLES'S WAIN, a name by which some of the astronomical writers, in our own language, have called Ursula Major, or the great bear; though some writers say the lesser bear. Indeed both of the two bears have been called waggons or wains, and by the Latins, who have followed the Arabians, two biers, Feretrum majus et minus.

CHART, or SEA-CHART, a hydrographical or sea map, for the use of navigators; being a projection of some part of the sea in plan, showing the sea coasts, rocks, sands, bearings, &c. Fournier ascribes the invention of sea-charts to Henry son of John king of Portugal. These charts are of various kinds, the Plain chart, Mercator's or Wright's chart, the Globular chart, &c.

In the construction of charts, great care should be taken that the several parts of them preserve their position to one another, in the same order as on the earth; and it is probable that the finding out of proper methods to do this, gave rise to the various modes of projection.

There are many ways of constructing maps and charts; but they depend chiefly on two principles. First, by considering the earth as a large extended flat surface; and the charts made on this supposition are usually called Plain Charts. Secondly, by considering the earth as a sphere; and the charts constructed on this principle are sometimes called Globular Charts, or Mercator's Charts, or Reduced Charts, or Projected Charts.

Plain Charts have the meridians, as well as the parallels of latitude, drawn parallel to each other, and the degrees of longitude and latitude every where equal to those at the equator. And therefore such charts must be deficient in several respects. For, 1st, Since in reality all the meridians meet in the poles, it is absurd to represent them, especially in large charts, by parallel right lines. 2dly, As plain charts show the degrees of the several parallels as equal to those of the equator, therefore the distance of places lying east and west, must be represented much larger than they really are. And 3dly, In a plain chart, while the same rhumb is kept, the vessel appears to sail on a great circle, which is not the case. Yet plain charts made for a small extent, as a few degrees in length and breadth, may be tolerably exact, especially for any part within the torrid zone; and even a plain chart made for the whole of this zone will differ but little from the truth.

Mercator's Chart, like the plain charts, has the meridians represented by parallel right lines, and the degrees of the parallels or longitude, every where equal to those at the equator; so that they are increased more and more, above their natural size, as they approach towards the pole; but then the degrees of the meridians, or of latitude, are increased in the same proportion at the same part; so that the same proportion is preserved between them as on the globe itself. This chart has its name from that of the author, Girard Mercator, who first proposed it for use in the year 1569, and made the first charts of this kind; though

they were not altogether on true or exact principles, nor does it appear that he perfectly understood them. Neither indeed was the thought originally his own, viz., of lengthening the degrees of the meridian in some proportion, for this was hinted by Ptolemy near two thousand years ago. It was not perfected however till Mr. Wright first demonstrated the same about the year 1590, and showed a ready way of constructing this chart, by enlarging the meridian line by the continual addition of the secants. See his *Correction of Errors in Navigation*, published in 1599.

Globular Chart, is a projection so called from the conformaty it bears to the globe itself; and was proposed by Messrs. Senex, Wilson, and Harris. This is a meridional projection, in which the parallels are equidistant circles, having the pole for their common centre, and the meridians curvilinear and inclined, so as all to meet in the pole, or common centre of the parallels. By which means the several parts of the earth have their proper proportion of magnitude, distance, and situation, nearly the same as on the globe itself; which renders it a good method for geographical maps.

Selenographic Charts, are particular descriptions of the appearances, spots, and maculae of the moon.

Topographic Charts, are draughts of some small parts only of the earth, or of some particular place, without regard to its relative situation, as London, York, &c.

For the Construction of Charts, see **GEOGRAPHY, MAPS, PROJECTION, &c.**

CHASE, of a Gun, is its bore or cylinder.

CHAULNES (THE DUKE DE), a peer of France, remarkable as an astronomer and mathematician, was born at Paris, Dec. 30, 1714.—At an early period he discovered a singular taste and genius for the sciences; and in the tumults of armies and camps, he cultivated mathematics, astronomy, mechanics, &c. He was named honorary academician of the 27th of February 1743, and few members were more punctual in attending the meetings of that body; where he often brought different constructions and corrections of instruments of astronomy, of dioptrics, and achromatic telescopes. These researches were followed with a new parallactic machine, more solid and convenient than those that were in use; together with many reflections on the manner of applying the micrometer to those telescopes, and of measuring exactly the value of the parts of that instrument. The Duke of Chaulnes proposed many other works of the same kind, when death surprised him the 23d Sept. 1769.

He had several papers published in the volumes of *Memoirs of the Academy of Sciences*, as follow:

1. Observations on some Experiments in the 4th part of the 2d book of Newton's Optics: an. 1755.—2. Observations on the Platform for dividing mathematical instruments: 1765.—3. Determination of the distance of Arcturus from the sun's limb, at the summer solstice: 1765.—4. On some means of perfecting astronomical instruments: 1765.—5. On some experiments relative to dioptrics: 1767.—6. The art of dividing mathematical instruments: 1768—7. Observations on the Transit of Venus, June 3, 1769.—8. New method of dividing mathematical and astronomical instruments.

CHAUSE TRAPPES, or *Caltrops*, or *Crowsfeet*, are iron instruments of spikes about 4 inches long, made like a star, in such a manner that whichever way they fall, one point stands always upwards, like a nail. They are usually thrown and scattered into moats and breaches, to

gall the horses' feet, and stop the hasty approaches of the enemy.

CHAZELLES (JOHN-MATTHEW), a French mathematician and engineer, was born at Lyons in 1657, and educated there in the college of Jesuits, from whence he removed to Paris in 1675. He first became acquainted with Du Hamel, secretary to the Academy of Sciences, and through him with Cassini, who employed him with himself at the Observatory, where Chazelles greatly improved himself, and also assisted Cassini in the measurement of the southern part of the meridian of France. Having, in 1684, instructed the Duke of Montemar in the mathematical sciences, this nobleman procured him the appointment of hydrography-professor to the galleys of Marseilles. In discharging the duties of this department, he made numerous geometrical and astronomical observations, from which he drew a new map of the coast of Provence.—He also performed many other services in that department, and as an engineer, along with the armies and naval expeditions. To make observations in geography and astronomy, he undertook also a voyage to the Levant, and among other things he measured the pyramids of Egypt, and found the four sides of the largest of them exactly to face the four cardinal points of the compass. He made a report of his voyage, on his return, to the Academy of Sciences, upon which he was named a member of their body in 1695, and had many papers inserted in the volumes of their *Memoirs*, from 1693 to 1708. Chazelles died at Marseilles the 16th of January 1710.

CHEMIN des Ronds, in Fortification, the way of the rounds, or a space between the rampart and the low parapet under it, for the rounds to go about it.

CHEMISE, a wall that lines a bastion, or ditch, or the like, for its greater support and strength.

CHEVAL de Frise, pl. *Chevaux de Frise*, or Friseland Horse, so called because it was first used in that country. It consists of a joist or piece of timber, about a foot in diameter, and 10 or 12 long, pierced and transversed with a great number of wooden spikes of 5 or 6 feet in length, and armed or pointed with iron. It is also called *turpique*, or *tourniquet*, and is chiefly used to stop a breach, defend a passage, or make a retrenchment to stop the cavalry.

CHEVRETTE, in Artillery, an engine to raise guns or mortars into their carriage. It is formed of two pieces of wood of about 4 feet long, standing upright upon a third, which is square. The uprights are about a foot asunder, and pierced with holes exactly opposite to one another, to receive a bolt of iron, which is put in either higher or lower at pleasure, to serve as a support to a handspike by which the gun is raised up.

CHEYNE (GEORGE), a British physician and mathematician, was born in Scotland, 1671, and educated at Edinburgh under Dr. Pitcairn. He passed his youth in close study and great abstinence; but on coming to London, at 30 years of age, he suddenly changed his whole manner of living; which had such an effect on his constitution, that his body grew to an immense size, weighing it is said 448 pounds. From this load of oppression however he was afterwards in a great measure relieved, by means of a milk and vegetable diet, which reduced his weight to about one-third of what it had been, and restored him to a good state of health; by which his life was prolonged to the 72d year of his age.

Dr. Cheyne was author of various medical and other tracts, and of a treatise on the Inverse method of Flux-

ions, under the title of Fluxionum Methodus Inversa; sive quantitatuum fluentium leges generaliores: in 4to, 1703. Upon this book Demoivre wrote some animadversions in an 8vo vol. 1704; which were replied to by Cheyne in 1705. Besides this work, he published Philosophical Principles of Religion, natural and revealed. Also the English Mala-dy, or a Treatise on Nervous Diseases.

CHILIAD, an assemblage of several things ranged by thousands. It was particularly applied to tables of logarithms, because they were at first divided into thousands. Thus, in the year 1624, Mr. Briggs published a table of logarithms for 20 chiliads of absolute numbers; afterward, he published 10 chiliads more; and lastly, one more; making in all 31 chiliads.

CHILIAEDRON, a solid figure having a thousand faces.

CHILIAGON, a regular plane figure of a thousand sides and angles.

CHÖRD, a right line connecting the two extremes of an arch; so called from its resemblance to the chord or string of a bow; as AB , which is common to the two parts or arches ADE , AEB that make up the whole circle. The chords have several properties:

1. The chord is bisected by a perpendicular CF drawn to it from the centre.—2. Chords of equal arcs, in the same or equal circles, are equal to each other.—3. Unequal chords have to one another a less ratio than that of their arcs.—4. The chord of an arc, is a mean proportional between the diameter and the versed sine of that arc.

Scale or Line of Chords. See Plane Scale.

CHORD, or CORD, in Music, denotes the string or line by whose vibrations the sensation of sound is excited; and by whose divisions the several degrees of tune are determined. Chords of gold wire in harpsichords, yield a sound almost twice as strong as those of brass; while chords of steel impart a feebler sound than those of brass.

To divide a Chord AB in the most simple manner, so as to exhibit all the original concords.

Divide the given line into two equal parts at C ; then subdivide the part CD into two equal parts at D , and again the part CD into two equal parts at E . Here AC to AB is an octave; AC to AD a fifth; AD to AB a fourth; AC to AE a greater third, and AE to AD a less third; AE to EB a greater sixth, and AE to AB a less sixth. Malcolm's Treatise of Music, ch. 6. sec. 3. See MONOCHORD.

To find the number of Vibrations made by a Musical Chord or String in a given time; having given its weight, length, and tension. Let l be the length of the chord in feet, 1 its weight, or rather a small weight fixed to the middle and equal to that of the whole chord, and w the tension, or weight by which the chord is stretched. Then shall the time of one vibration be expressed by

$\frac{l}{\sqrt{\frac{w}{3240}}}$, and consequently $\frac{7}{4}\sqrt{\frac{3240}{l}}$ will be the number of vibrations per second.

For example, suppose $w = 28800$, or the tension equal to 28800 times the weight of the chord, and the length of it 3 feet; then the last theorem gives 354 nearly for the number of vibrations made in each second of time.—But if w were 14400, there would be made but 250 vibrations

per second; and if w were only 288, there would be no more than $35\frac{1}{3}$ vibrations per second. See my Tracts, vol. 3, prob. 21 & 22, pa. 246.

On the supposition that chords or strings are perfectly elastic, the following proportions have been deduced mathematically. 1. If the length of the chord and the tending force be given, the inflicting force will be nearly as the space through which the chord is bent. 2. If the length of the string and the space through which it is bent be given, the inflicting force is as the tension. 3. If the tending force, and the space through which the chord is bent be given, the inflicting force is inversely as the length of the chord. 4. If the diameter of the chord, and the tension be given, the times of vibration are as the length of the chord: on which principle the monochord is founded. 5. If the tension and length of the chord be given, the time of vibration is as the diameter of the chord. 6. If the diameter, and length of the chord be given, the time of vibration is inversely as the square root of the tension.

CHORD, in Music, is also used for the union of two or more sounds uttered at the same time, and forming together a complete harmony.

Chords are divided into perfect and imperfect. In the perfect chord we have the third, fifth, and octave of the fundamental sound: they are also subdivided into major and minor, according as the thirds which enter into their composition are flat or sharp. Imperfect chords are those in which the sixth, instead of the fifth, prevails; and in general all those whose lowest are not their fundamental sounds.

Chords are again divided into consonances and dissonances. The consonances are the perfect chord, and its derivatives. Every other chord is a dissonance. A table of both, according to the system of M. Rameau, may be seen in Rousseau's Musical Dictionary, vol. 1, pa. 27.

CHROMATIC, a species of music which proceeds by semitones and minor thirds. The word is derived from the Greek *χρωμα*, which signifies colour, and perhaps the shade or intermediate shades of colour, which mingle and connect colours, like as the small intervals in this scale easily slide or run into each other.

Boethius and Zarlin ascribe the invention of the chromatic genus to Timotheus, a Milesian, in the time of Alexander the Great. The Spartans banished it their city on account of its softness. The character of this genus, according to Aristides Quintilianus, was sweetness and pathos.

CHROMATICS, is that part of optics which explains the several properties of the colours of light, and of natural bodies.

Before the time of Newton, the notions concerning colour were very vague and extravagant. The Pythagoreans called colour the superficies of bodies: Plato said that it was a flame issuing from them: According to Zeno, it is the first configuration of matter: And Aristotle said it was that which made bodies actually transparent. Descartes accounted colour a modification of light, and he imagined that the difference of colour proceeds from the prevalence of the direct or rotatory motion of the particles of light. Grimaldi, Dechales, and many others, conjectured that the differences of colour depended on the quick or slow vibrations of a certain elastic medium pervading the universe. Rohault conceived, that the different colours were made by the rays of light entering the eye at different angles with respect to the optic axis. And Dr. Hooke ima-

gined that colour is caused by the sensation of the oblique or uneven pulse of light; which being capable of but two varieties, he concluded there could be no more than two primary colours.

Sir I. Newton, in the year 1666, began to investigate this subject; when finding that the coloured image of the sun, formed by a glass prism, was of an oblong, and not of a circular form, as, according to the laws of equal refraction, it ought to be, he conjectured, that light is not homogeneous; but that it consists of rays of different colours, and endued with divers degrees of refrangibility. And, from a further prosecution of his experiments, he concluded that the different colours of bodies arise from their reflecting this or that kind of rays most copiously. This method of accounting for the different colours of bodies soon became generally adopted, and still continues to be the most prevailing opinion. It is hence agreed that the light of the sun, which to us appears white and perfectly homogeneal, is composed of no less than seven different colours, viz. red, orange, yellow, green, blue, purple, and violet or indigo: that a body which appears of a red colour, has the property of reflecting the red rays more profusely than the rest; and so of the other colours, the orange, yellow, green, &c: also that a body which appears black, instead of reflecting, absorbs all or the most part of the rays that fall upon it; while, on the contrary, a body which appears white, reflects the greatest part of all the rays indiscriminately, without separating them one from another.

The foundation of a rational theory of colours being thus laid, the next inquiry was, by what peculiar mechanism, in the structure of each particular body, it was rendered capable of reflecting one kind of rays more than another; and this is attributed, by Sir I. Newton, to the density of these bodies. Dr. Hooke had remarked, that thin transparent substances, particularly soap-water blown into bubbles, exhibited various colours, according to their thinness; and yet, when they have a considerable degree of thickness, they appear colourless. And Sir Isaac himself had also observed, on compressing two prisms hard together, in order to make their sides (which happened to be rather convex) to touch one another, that in the place of contact they were both perfectly transparent, as if they had been but one continued piece of glass: but round the point of contact, where the glasses were a little separated from each other, rings of different colours appeared. And when he afterwards, further to elucidate this matter, employed two convex glasses of telescopes, pressing their convex sides upon each other, he observed several series of circles or rings of such colours, different, and of various intensities, according to their distance from the common central pellucid point of contact.

As the colours were thus found to vary according to the different distances between the glass plates, Sir Isaac conceived that they proceeded from the different thickness of the plate of air intercepted between the glasses; this plate of air being, by the mere circumstance of thinness or thickness, disposed to reflect or transmit the rays of this or that particular colour. Hence he concluded, that the colours of all natural bodies depend on their density, or the magnitude of their component particles: and hence also he constructed a table, in which the thickness of a plate necessary to reflect any particular colour, was expressed in millionths parts of an inch.

From a great variety of such experiments, and observa-

tions upon them, our author deduced his theory of colours. And from which it appears that every substance in nature is transparent, provided it be made sufficiently thin; as gold, the densest substance we know of, when reduced into thin leaves, transmits a blueish-green light through it. If we suppose any body therefore, as gold for instance, to be divided into a vast number of plates, so thin as to be almost perfectly transparent; it is evident that all, or the greatest part of the rays, will pass through the upper plates, and when they lose their force will be reflected from the under ones. They will then have the same number of plates to pass through which they had before penetrated; and thus, according to the number of those plates through which they are obliged to pass, the object appears of this or that colour, just as the rings of colours appeared different in this experiment of the two plates, according to their distance from one another, or the thickness of the plate of air between them.

This theory of colours has been illustrated and confirmed by various experiments, made by other philosophers. Mr. E. H. Delaval produced similar effects by the infusion of flowers of different colours, and also by the intimate mixture of the various metals with glass, when they are reduced to very fine parts; the denser metals imparting to the glass the less refrangible colours, and the lighter ones those colours that are more easily refrangible. Dr. Priestley and Mr. Canton also, by laying very thin leaves or slips of the metals upon glass, ivory, wood, or metal, and passing an electrical stroke through them, found that the same effect was produced, viz. that the substrated was tinged with different colours, according to the distance from the point of explosion.

However, the Abbé Mazeas and M. du Tour contend ed, that the colours between the glasses are not to be ascribed to the thin stratum of air, since they equally produced them by rubbing and pressing together two flat glasses, which cohered so strongly that it required the greatest force to move or slide them over each other. See Priestley's *History of Vision*.

Of Newton's 8th Exper. in the 2d Book of Optics.

The event of this experiment, which has been contradicted by repetitions of the same by other philosophers, having been the occasion of much controversy; and relating to a material part of the doctrine of chromatics, it will not be improper here to give an account of what has passed concerning it. Newton found, that when light, by contrary refractions through different mediums, is so corrected, that it emerges in lines parallel to the incident rays, it continues ever after to be white: But that if the emergent rays be inclined to the incident ones, the whiteness of the emerging light will, by degrees, in passing on from the place of emergence, become tinged at its edges with colours. And these laws he inferred from experiments made by refracting light with prisms of glass, placed within a prismatic vessel of water.

By theorems deduced from this experiment he infers, that the refraction of the rays of every sort, out of any medium into air, are known by having the refraction of the rays of any one sort: and also, that the refraction out of one medium into another is found, whenever we have the refractions out of them both, into any third medium.

Now the same experiment, having been since performed by other persons, and turning out contrary to what is stated above, has occasioned rather free reflections to be thrown on Newton concerning it; but which however have

been very satisfactorily obviated by Mr. Peter Dollond, in a pamphlet on this subject; as we shall show below.

In the first place then, M. Klingenstierna, a Swedish philosopher, having in the year 1755 considered the controversy between Euler and Mr. John Dollond, relative to the refraction of light, formed a theorem of his own, from geometrical reasoning, by which he was induced to believe that the result of Newton's experiment could not be as he has represented; except when the angles of the refracting mediums are small. See the paper on this matter by Klingenstierna in the pamphlet above cited by Mr. Peter Dollond.

This paper of Klingenstierna being communicated to Mr. John Dollond by Mr. Mallet, to whom it was sent for that purpose, made Dollond entertain doubts concerning Newton's report of the result of his experiment, and determined him to have recourse to experiments of his own, which he accordingly made in the year 1757, as follows.

Having cemented two glass planes together by their edges, so as to form a prismatic vessel, when closed at the ends or bases; and the edge being turned downward, he placed it in a glass prism with one of its edges upward, filling up the vacancy with clear water; so that the refraction of the prism was contrived to be contrary to that of the water, in order that a ray of light, transmitted through both these refracting mediums, might be affected by the difference only between the two refractions. As he found the water to refract more or less than the glass prism, he diminished or augmented the angle between the glass plates, till the two contrary refractions became equal, which he discovered by viewing an object through this double prism. For when it appeared neither raised nor depressed, he concluded that the refractions were equal, and that the emergent rays were parallel to the incident ones.

Now, according to the prevailing opinion, he observes, that the object ought to have appeared through this double prism in its natural colour; for if the difference of refrangibility had been in all respects equal, in the two equal refractions, they would have rectified each other. But this experiment fully proved the fallacy of the received opinion, by showing that the divergency of the light by the glass prism, was almost double of that by the water; for the image of the object, though not at all refracted, was yet as much infected with prismatic colours, as if it had been seen through a glass wedge only, having its angle near 30 degrees.

This experiment is the very same with that of Newton's above-mentioned, notwithstanding the result was so strikingly different. Mr. Dollond plainly saw however, that if the refracting angle of the water-vessel could have admitted of a sufficient increase, the divergency of the coloured rays would have been greatly diminished, or entirely rectified; and that there would have been a very great refraction without colour, as he had already produced a great discoloring without refraction: but the inconvenience of so large an angle as that of the prismatic vessel must have been, to bring the light to an equal divergency with that of the glass prism, whose angle was about 60 degrees, rendered it necessary to try some experiments of the same kind with smaller angles.

Accordingly he procured a wedge of plate-glass, whose angle was only 9 degrees; and, using it under the same circumstances, he increased the angle of the water-wedge, in which it was placed, till the divergency of the light by

the water was equal to that by the glass; that is, till the image of the object, though considerably refracted by the excess of the refraction of the water, appeared nevertheless quite free from any colours proceeding from the different refrangibility of the light.

Many conjectures were made as to the cause of so great a difference in the results of the same experiment; but none that gave any great satisfaction; till it was afterwards shown to be probably owing to the nature of the glass then used by Newton. This conjecture is made by Mr. Peter Dollond, son of John, the inventor of the achromatic telescope, in a pamphlet by him published in defence of his father's invention, against the misrepresentations of some persons who have unjustly attempted to give the invention to other philosophers, who themselves never imagined that they had any just claim to it. After a full and satisfactory vindication of his father, Mr. P. Dollond then adds,

"I now come to a more agreeable part of this paper, which is, to endeavour to reconcile the different results of the 8th experiment of the 2d part of the 1st book of Newton's Optics, as related by himself, and as it was found by Dollond, when he tried the same experiment, in the year 1757. Newton observes, that light, as often as by contrary refractions it is so corrected, that it emergeth in lines parallel to the incident, continues ever after to be white. Now Dollond says, when he tried the same experiment, and made the mean refraction of the water equal to that of the glass prism, so that the light emerged in lines parallel to the incident, he found the divergency of the light by the glass prism to be nearly double to what it was by the water prism. The light appeared to be so evidently coloured, that it was directly said by some persons who were present, that if Newton had actually made the experiment, he must have perceived it to have been so. Yet who could for a moment doubt the veracity of Newton? or feel indifferent in vindicating if possible the assertion of such a character? Many conjectures were therefore made by different persons. Mr. Murdoch in particular gave a paper to the Royal Society in defence of Newton; but it was such as very little tended to clear up the matter. Philos. Trans. vol. 53, p. 192.—Some have supposed that Newton made use of water strongly impregnated with *saccharum saturni*, because he mentions sometimes using such water, to increase the refraction, when he used water prisms instead of glass prisms. Newton's Opt. p. 62.—And others have thought that he tried the experiment with so strong a persuasion in his own mind, that the divergency of the colours was always in the same proportion to the mean refraction, in all sorts of refracting mediums, that he did not attend so much to that experiment as he ought to have done, or as he usually did. None of these conjectures having appeared at all satisfactory, I have therefore endeavoured to discover the true cause of the difference, and thereby show, how the experiment may be made to agree with Newton's description of it, and to get rid of those doubts, which have hitherto remained to be cleared up."

"It is well known, that in Newton's time the English were not the most famous for making optical instruments: telescopes, opera-glasses, &c, were imported from Italy in great numbers, and particularly from Venice; where they manufactured a kind of glass which was much more proper for optical purposes than any made in England at

that time. The glass made at Venice was nearly of the same refractive quality as our own crown-glass, but of a much better colour, being sufficiently clear and transparent for the purpose of prisms. It is probable that Newton's prisms were made with this kind of glass; and it appears to be the more so, because he mentions the specific gravity of common glass to be to water as 2·58 to 1, Newton's Opt. p. 247, which nearly answers to the specific gravity we find the Venetian glass generally to have. Having a very thick plate of this kind of glass, which was presented to me about 25 years ago by the late Professor Allemand, of Leyden, and which he then informed me had been made many years; I cut a piece from this plate of glass to form a prism, which I conceived would be similar to those made use of by Newton himself. I have tried the Newtonian experiment with this prism, and find it answers so nearly to what Newton relates, that the difference which remains may very easily be supposed to arise from any little difference which may and does often happen in the same kind of glass made at the same place at different times. Now the glass prism made use of by Dollond to try the same experiment, was made of English flint-glass, the specific gravity of which I have never known to be less than 3·22. This difference in the densities of the prisms, used by Newton and Dollond, was sufficient to cause all the difference which appeared to the two experimenters in trying the same experiment.

"From this it appears, that Newton was accurate in this experiment as in all others, and that his not having discovered that which was discovered by Dollond so many years afterwards, was owing entirely to accident; for if his prism had been made of glass of a greater or less density, he would certainly have then made the discovery, and refracting telescopes would not have remained so long in their original imperfect state." See ACHROMATIC, and TELESCOPE.

Mr. Delaval's experiment on the colours of opaque bodies.—Besides the experiments of this gentleman, before-mentioned, on the colours of transparent bodies, he has also published an account of some made upon the permanent colours of opaque substances, the discovery of which must be of the utmost consequence in the arts of colour-making and dyeing.

The changes of colour in permanently coloured bodies, our author observes, are produced by the same laws that take place in transparent colourless substances; and the experiments by which they are investigated consist chiefly of various methods of uniting the colouring particles into larger masses, or dividing them into smaller ones. Sir Isaac Newton made his experiments chiefly on transparent substances; and in the few places where he treats of others, he acknowledges his want of experiments. He makes the following remark however on those bodies which reflect one kind of light and transmit another, viz, that if these glasses or liquors were so thick and massy that no light could get through them, he questioned whether they would not, like other opaque bodies, appear of one and the same colour in all positions of the eye; though he could not yet affirm it from experience. Indeed it was the opinion of this great philosopher, that all coloured matter reflects the rays of light, some reflecting the more refrangible rays most copiously, and others those that are less so; and that this is at once the true and only reason of these colours. He was likewise of opinion that opaque bodies reflect the

light from their anterior surface, by some power of the body evenly diffused over and external thereto. With respect to transparent coloured bodies, he thus expresses himself: "A transparent body which looks of any colour by transmitted light, may also appear of the same colour by reflected light; the light of that colour being reflected by the farther surface of that body, or by the air beyond it: and then the reflected colour will be diminished, and perhaps cease, by making the body very thick, and pitching it on the back-side, to diminish the reflection of its farther surface, so that the light reflected from the tingeing particles may predominate. In such cases the colour of the reflected light will be apt to vary from that of the light transmitted."

To investigate the truth of these opinions, Mr. Delaval entered upon a course of experiments with transparent coloured liquors and glasses, as well as with opaque and semitransparent bodies. And from these experiments he discovered several remarkable properties of the colouring matter; particularly, that in transparent coloured substances it does not reflect any light; and when, by intercepting the light which was transmitted, it is hindered from passing through such substances, they do not vary from their former colour to any other, but become entirely black.

This incapacity of the colouring particles of transparent bodies to reflect light, being deduced from very numerous experiments, may therefore be taken as a general law. It will appear the more extensive, if it be considered that, for the most part, the tingeing particles of liquors, or other transparent substances, are extracted from opaque bodies; that these bodies owe their colours to those particles, in the same manner as the transparent substances; and that by the loss of them they are also deprived of their colours.

Notwithstanding these and many other experiments, the theory of colours is not yet determined with certainty; and it must be acknowledged that very strong objections might be brought against every hypothesis on this subject that has been invented. The discoveries of Newton however are sufficient to justify the following Aphorisms.

Aphorism 1. All the colours in nature arise from the rays of light.

2. There are seven primary colours, namely red, orange, yellow, green, blue, indigo, and violet.

3. Every ray of light may be separated into these seven primary colours.

4. The rays of light, if passing through the same medium, have different degrees of refrangibility.

5. The difference in the colours of light arises from its different refrangibility: that which is the least refrangible producing red; and that which is the most refrangible, violet.

6. By compounding any two of the primary, as red and yellow, or yellow and blue, the intermediate colour, orange or green, may be produced.

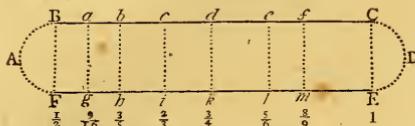

7. The colours of bodies arise from their dispositions to reflect one sort of rays, and to absorb the others: those that reflect the least refrangible rays appearing red; and those that reflect the most refrangible, violet.

8. Such bodies as reflect two or more sorts of rays, appear of various colours.

9. The whiteness of bodies arises from their disposition to reflect all the rays of light promiscuously.

10. The blackness of bodies proceeds from their incapacity to reflect any of the rays of light.—And from their thus absorbing all the rays of light that are thrown upon them, it arises, that black bodies when exposed to the sun, become hot sooner than all others.

Of the Diatonic Scale of Colours.—Newton, in the course of his investigations of the properties of light, discovered that the lengths of the spaces occupied in the spectrum by the seven primary colours, exactly correspond to the lengths of chords that sound the seven notes in the diatonic scale of music: which is made evident by the following experiment.

On a paper, in a dark chamber, let a ray of light be largely refracted into the spectrum ABCDEF, marking upon it the precise boundaries of the several colours, as *a*, *b*, *c*, &c; and across the spectrum draw the perpendicular lines *ag*, *bh*, &c. Then it will be found that the spaces, by which the several colours are bounded, viz., *bagf* containing the red, *abhg* containing the orange, *bcih* containing the yellow, &c, will be in exact proportion to the divisions of a musical chord for the notes of an octave; that is, as the intervals of these numbers $\frac{1}{2}$, $\frac{9}{16}$, $\frac{3}{8}$, $\frac{2}{3}$, $\frac{4}{9}$, $\frac{5}{6}$, $\frac{8}{9}$, $\frac{1}{1}$.

CHRONOLOGICAL, belonging to chronology.

CHRONOLOGICAL Characters, are characters by which times are distinguished. Of these, some are natural, or astronomical; others are artificial or historical. The natural characters are such as depend on the motions of the stars or luminaries; as eclipses, solstices, equinoxes, the different aspects of planets, &c. And the artificial characters are those that have been invented and established by men; as the solar cycle, the lunar cycle, &c. Historical Chronological Characters are those supported by the testimonies of historians, when they fix the dates of certain events to certain periods.

CHRONOLOGY, the art of measuring and distinguishing time; with the doctrine of dates, epochs, eras, &c. The measurement of time in the most early periods, was by means of the seasons, or the revolutions of the sun and moon. The succession of Juno's priestesses at Argos served Hellanicus for the regulation of his narrative; while Ephorus reckoned his matters by generations. Even in the histories of Herodotus and Thucydides, there are no regular dates for the events recorded; nor were there any endeavours to establish a fixed era until the time of Ptolemy Philadelphus, who attempted it by comparing and correcting the dates of the olympiads, the kings of Sparta, and the succession of the priestesses of Juno at Argos. Eratosthenes and Apollodorus digested the events related by them, according to the succession of the olympiads and of the Spartan kings.

The chronology of the Latins is still more uncertain. The records of the Romans were destroyed by the Gauls; and Fabius Pictor, the most ancient of their historians, was obliged to borrow the chief part of his information from the Greeks. In other European nations the chronology is still more imperfect, and of a later date: and even in modern times a considerable degree of confusion and inaccuracy has arisen, from the want of attention in the

historians to ascertain the dates and epochs with precision.

Hence it is evident, how necessary a proper system of chronology must be for the right understanding of history, and also how difficult it must be to establish such a system. For this purpose, however, several learned men have spent much time, particularly Julius Africanus, Eusebius of Cesarea, George Syncelle, John of Antioch, Dennis, Petavius, Clavius, Calvisius, Scaliger, Vieta, Newton, Usher, Simson, Marsham, Helvius, Vossius, Strauchius, Blair, Playfair, and Hales.

A system of this kind is founded, 1st, On Astronomical observations, especially of the eclipses of the sun and moon, combined with calculations of the years and eras of different nations. 2d, The testimonies of credible authors. 3d, Such epochs in history as are so well attested and determined, that they have never been controverted. 4th, Ancient medals, coins, monuments, and inscriptions.

The most obvious division of time, is derived from the apparent or real revolutions of the luminaries, the sun and moon. Thus, the apparent revolution of the sun, or the real rotation of the earth on her axis causing the sun to appear to rise and set, constitutes the vicissitudes of day and night, which must be evident to the most barbarous and ignorant nations. The moon, by her revolution about the earth, and her changes, as naturally and obviously forms months; while the great annual course of the sun through the several constellations of the zodiac, points out the larger division of the year.

The Day is divided into hours, minutes, &c; while the month is divided into weeks, and the year into months, having particular names, and a certain number of days.—See a particular account of each of these under the respective words.

Besides the natural divisions of time arising immediately from the revolutions of the heavenly bodies, there are others which are formed from some of the less obvious consequences of these revolutions, and are called Cycles, or circles. The most remarkable of these are, 1, The Solar Cycle, or cycle of the sun, a period or revolution of 28 years, in which time the days of the months return to the same days of the week, the sun's place to the same signs and degrees of the ecliptic on the same months and days, and the leap-years begin the same course over again with respect to the days of the week on which the days of the months fall. 2, The Lunar Cycle, or cycle of the moon, commonly called the Golden Number, is a revolution of 19 years; in which time the conjunctions, oppositions, and other aspects of the moon, are on the same days of the months as they were 19 years before, and within an hour and a half of the time of the day.

The *Indiction*, or Roman Indiction, is a period of 15 years, used only by the Romans for indicating the times of certain payments made by the subjects to the republic.

The *Cycle of Easter*, called also the *Dionysian Period*, is a revolution of 532 years, and is produced by multiplying the solar cycle 28, by the lunar cycle 19.

The *Julian Period*, is a revolution of 7980 years, and is produced from the continual multiplication of the three numbers 28, 19, 15, of the three former cycles, viz., the solar, lunar, and induction.

As there are certain fixed points in the heavens, from which astronomers begin their computations, so there are certain points of time, from which historians begin to reckon; and these points or roots of time are called Eras

or Epochs. The most remarkable of these are, those of the Creation, the Greek Olympiads, the building of Rome, the era of Nabonassar, the death of Alexander, the birth of Christ, the Arabian Hegira, or flight of Mahomet, and the Persian Jesdegird. All of which, with some others of less note, have their beginnings fixed by chronologers to the years of the Julian period, to the age of the world, and to the years before and after the birth of Christ.

The testimony of authors is the second principal part of historical chronology. Though no man has a right to be considered as infallible, it would however be making a very unfair judgment of mankind, to treat them all as dupes or impostors; and it would be an injury offered to public integrity, to doubt the veracity of authors universally esteemed, and facts that are truly worthy of belief. When the historian is allowed to be completely able to judge of an event, and to have no intent of deceiving by his relation, his testimony cannot be refused.

The *Epochs* form the 3d principal part of chronology; being those fixed points in history that have never been contested, and of which there cannot reasonably be any doubt. Notwithstanding that chronologers fix upon the events which are to serve as epochs, in a manner quite arbitrary; yet this is of little consequence, provided the dates of these epochs agree, and that there is no contradiction in the facts themselves.

Medals, Monuments, and Inscriptions, form the last of the four principal parts of chronology; and this study is but of very modern date, scarcely more than 200 years having elapsed since close application has been made to the study of these. To the celebrated Spanheim we owe the greatest obligations, for the progress that is made in this method; and it is by the aid of medals that M. Vail-lant has composed his judicious history of the kings of Syria, from the time of Alexander the Great to that of Pompey. Nor have they been of less service in elucidating all ancient history, especially that of the Romans; and even sometimes that of the middle ages.

Besides the foregoing general account, there are some few systems of chronology which may deserve some more particular notice, as follows.

Sacred Chronology. There have been various systems relating to sacred chronology; which is not to be wondered at, as the three chief copies of the Bible give a very different account of the first ages of the world. For while the Hebrew text reckons about 4000 years from the creation to the birth of Christ, and to the flood 1656 years; the Samaritan makes the former much longer, though it reckons from the creation to the flood only 1307 years; and the Septuagint removes the creation of the world to 6000 years before Christ, and 2250 years before the flood. Many attempts have been made to reconcile these differences; though none of them are quite satisfactory. Walton and Vossius give the preference to the account of the Septuagint; while others have defended the Hebrew text. See an abstract of the different opinions of learned men on this subject, in Strauchi's *Brev. Chron.* translated by Sault, p. 166 and 176.

The Chinese Chronology. No nation has boasted more of its antiquity than the Chinese; but though they be allowed to trace their origin as far back as the deluge, they have few if any authentic records of their history for so long a period as 500 years before the Christian era. This indeed may be owing to the general destruction of ancient remains by the tyrant Tsin-chi-hoang, in the year 213, or

some say 246, before Christ. From a chronology of the Chinese history (for which we are obliged to an illustrious Tartar who was viceroy of Canton in the year 1724, and of which a Latin translation was published at Rome in 1730), we learn that the most remote epoch of the Chinese chronology does not surpass the first year of Guel-lie-wang, or 424 years before our vulgar era. And this opinion is confirmed by the practice of two of the most approved historians of China, who admit nothing into their histories previous to this period.

The Chinese, in their computation, make use of a cycle of 60 years, called kia-tse, from the name given to the first year of it, which serves as the basis of their whole chronology. Every year of this cycle is marked with two letters which distinguish it from the others; and all the times of the emperors, for upwards of 2000 years, have names in history common to them with the corresponding years of the cycle. Philos. Trans. Abridg. vol. 9, pa. 343.

According to M. Freret, in his Essays, the Chinese date the epocha of Yao, one of their first emperors, about the year 2145, or 2057, before Christ; and they reckon that their first astronomical observations, and the composition of their calendar, preceded Yao 150 years: whence it is inferred that the era of their astronomical observations coincides with that of the Chaldeans. But later authors date the rise and progress of the sciences in China from the grand dynasty of Tcheou, about 1200 years before the Christian era, and show that all historical relations of events prior to the reign of Yao are fabulous. Mem. de l'Histoire des Sciences, &c. Chinois. vol. 1, Paris 1776.

The Hindu Chronology. The Hindus employ, in their chronology, certain large periods, called Yoogs or Yergs. These are 4 in number, the last of which, called cali yug, or kaled yug, is only now attended to, and began 3101 before the Christian era. It comprehends within it the following, viz,

The era of Bikramajit, which began 3045 years before Christ, Salabán, 78 years after Christ, Bengal, not strictly Hindu, cycle of 60 years: the present began 1807 of Christ.

Their solar-sideral year contains 365^d 6^h 12^m 30^s, and their tropical year 365^d 5^h 50^m 35^s. They divide the zodiac into 28 lunar, and into 12 solar constellations or signs; and their astronomical year commences when the sun arrives at the first point of Aries. The length of their months is determined by the time employed by the sun in passing through each sign, and they are accordingly longer in the apogee, and shorter in the perige; that which corresponds with the higher apsis being 31^d 14^h 39^m, and that with the lower 29^d 8^h 21^m. For civil purposes, they count the days by the age of the moon that happens to fall within each month, and often from the simple phase of the moon.

Their fasts and festivals, like those of the Jews and Christians, being regulated by the lunar revolutions, they therefore employ a lunar year. This they make to consist of 12 months, of 30 lunar days, or each semi-lunation of 15 days, which are somewhat shorter than the natural day. The commencement of the solar day is counted from sunrise, and the interval till the next sun-rise, is divided into 60 equal parts, each equal to 24 of our minutes. The subdivisions also follow the sexagesimal scale.

The days of the week are denominated from the planets, as with the Europeans, and their arrangement is the same also, proceeding from the sun and moon, to Mars, Mercury, Jupiter, Venus, and Saturn. Friday, or Venus's

day, appears as the first of the week in their calculations, and probably because the cali yug began on that day; but in common, the week is considered by the Hindus as beginning with Sunday. From the view of their astronomy and chronology, they appear to be quite astrological; and they further appear to be the parents or originals of those of the Europeans and other nations.

For more particular information, see the *Philos. Trans. Abridg.* vol. 16, p. 742, and vol. 17, p. 250.

Babylonian, Egyptian, and Chaldean Annals. These, M. Gibert has attempted to reduce to our chronology, in a letter published at Amsterdam in 1743. He begins with showing, by the authorities of Macrobius, Eudoxus, Varro, Diodorus Siculus, Pliny, Plutarch, St. Augustin, &c., that by a year, the ancients meant the revolution of any planet in the heavens; so that it might consist sometimes of only one day. Thus, according to him, the solar day was the astronomical year of the Chaldeans; and so the boasted period of 473,000 years, assigned to their observations, is reduced to 1297 years 9 months; the number of years which, according to Eusebius, elapsed from the first discoveries of Atlas in astronomy, in the 384th year of Abraham, to the march of Alexander into Asia in the year 1682 of the same era. And the 17,000 years added by Berossus to the observations of the Chaldeans, reduced in the same manner, will give 46 years and 6 or 7 months; being the exact interval between Alexander's march, and the first year of the 123d Olympiad, or the time to which Berossus carried his history.

Epigenius ascribes 720,000 years to the observations preserved at Babylon; but these, according to M. Gibert's system, amount only to 1971 years 3 months; which differ from Callisthenes's period of 1903 years, allotted to the same observations, only by 68 years, the period elapsed from the taking of Babylon by Alexander, which terminated the latter account, and to the time of Ptolemy Philadelphus, to which Epigenius extended his account.

The Newtonian Principles of Chronology.—Sir Isaac Newton has shown, that the chronology of ancient kingdoms is involved in the greatest uncertainty: that the Europeans in particular had no chronology before the Persian empire, which commenced 530 years before the birth of Christ, when Cyrus conquered Darius the Mede: that the antiquities of the Greeks are full of fables, because their writings were in verse only, till the conquest of Asia by Cyrus the Persian; about which time prose was introduced by Pherecides Syrius and Cadmus Milesius. After this time several of the Greek historians introduced the computation by generations. The chronology of the Latins was still more uncertain: their old records having been burnt by the Gauls 120 years after the expulsion of their kings, or 64 years before the death of Alexander the Great, answering to 388 before the birth of Christ. The chronologers of Gaul, Spain, Germany, Scythia, Sweden, Britain, and Ireland, are of a still later date. For Scythia, beyond the Danube, had no letters till Ulphilas, their bishop, formed them, about the year 276. Germany had none till it received them from the western empire of the Latins, about the year 400. The Huns had none in the days of Procopius, about the year 526. And Sweden and Norway received them still later.

Newton, after a general account of the obscurity and defects of the ancient chronology, observes that, though many of the ancients computed by successions and gene-

rations, yet the Egyptians, Greeks, and Latins, reckoned the reigns of kings equal to generations of men, and three of them to a hundred, and sometimes to 120 years; and this was the foundation of their technical chronology. He then proceeds from the ordinary course of nature, and a detail of historical facts, to show the difference between reigns and generations; and that, though a generation from father to son may at an average be reckoned about 33 years, or three of them equal to 100 years, yet, when they are taken by the eldest sons, three of them cannot be estimated at more than about 75 or 80 years; and the reigns of kings are still shorter; so that 18 or 20 years may be allowed a just medium. Sir Isaac then fixes on four remarkable periods, viz, the return of the Heraclidae into the Peloponnesus, the taking of Troy, the Argonautic expedition, and the return of Sesostris into Egypt, after his wars in Thrace; and he settles the epoch of each by the true value of a generation. To instance only his estimate of that of the Argonautic expedition: Having fixed the return of the Heraclidae to about the 159th year after the death of Solomon, and the destruction of Troy to about the 76th year after the same period, he observes, that Hercules the Argonaut was the father of Hyllus, the father of Clerdus, the father of Aristomachus, and the father of Aristodemus, who conducted the Heraclidae into Peloponnesus; so that reckoning by the chief of the family, their return was four generations later than the Argonautic expedition, which therefore happened about 43 years after the death of Solomon. This is further confirmed by another argument: Æsculapius and Hercules were Argonauts: Hippocrates was the 18th inclusively from the former by the father's side, and the 19th from the latter by the mother's side: now, allowing 28 or 30 years to each of them, the 17 intervals by the father, and the 18 intervals by the mother, will on a medium give 507 years; and these, reckoning back from the commencement of the Peloponnesian war, or the 431st year before Christ, when Hippocrates began to flourish, will place the Argonautic expedition in the 43d year after the death of Solomon, or 937 years before Christ.

The other kind of reasoning, by which Newton endeavours to establish this epoch, is purely astronomical. The sphere was formed by Chiron and Musæus, for the use of the Argonautic expedition, as is plainly shown by several of the asterisms referring to that event: and at the time of the expedition the cardinal points of the equinoxes and solstices were placed in the middle of the constellations Aries, Cancer, Chele, and Capricorn. This point is established by Newton from the consideration of the ancient Greek calendar, which consisted of 12 lunar months, and each month of 30 days, which required an intercalary month. Of course this luni-solar year with the intercalary month, began sometimes a week or two before or after the equinox or solstice; and hence the first astronomers were led to the before-mentioned disposition of the equinoxes and solstices: and that this was really the case, is confirmed by the testimonies of Eudoxus, Aratus, and Hipparchus. Upon these principles Sir Isaac proceeds to argue in the following manner. In the end of the year 1689 the star called the Prima Arietis, was in $\varphi\ 230^{\circ} 51'$, with north latitude $70^{\circ} 8' 55''$; and the star called the Ultima caudæ Arietis was in $\delta\ 190^{\circ} 3' 42''$, with north latitude $20^{\circ} 34' 5''$; consequently the equinoctial colure at this time cut the ecliptic in $\delta\ 60^{\circ} 44'$; and by this he reckons that the equinox had then gone back $360^{\circ} 44'$ since

the time of the Argonautic expedition. But it recedes 50' in a year, or 1° in 72 years, and consequently 360° 44' in 2645 years; and this, counted backwards from the beginning of 1690, will place this expedition about 25 years after the death of Solomon. But as there is no necessity for allowing that the middle of the constellations, according to the general account of the ancients, should be precisely the middle between the *prima Arietis* and *ultima Cauda*, our author proceeds to "examine what were those stars through which Eudoxus made the colures to pass in the primitive sphere, and in this way to fix the position of the cardinal points." Now from the mean of five places he finds, that the great circle, which in the primitive sphere, described by Eudoxus, or which at the time of the Argonautic expedition was the equinoctial colure, did in the end of 1689 cut the ecliptic in 8° 60' 29" 15'. In the same manner our author determines that the mean place of the solstitial colure is 8° 60' 28" 46", and as it is at right angles with the other, he concludes that it is rightly drawn. And hence he infers that the cardinal points, in the interval between that expedition and the year 1689, have receded from those colures 1° 60' 29"; which, allowing 72 years to a degree, amounts to 2627 years; and these counted backwards, as above, will place the Argonautic expedition 43 years after the death of Solomon. Our author has, by other methods also of a similar nature, established this epoch, and reduced the age of the world 500 years.

This elaborate system has not escaped censure; Mess. Freret and Souciet having both attacked it, and on much the same ground: but the former has confounded reigns and generations, which are carefully distinguished in this system. The astronomical objections of both have been answered by Sir Isaac Newton himself, and by Dr. Halley. *Philos. Trans. abr. vol. 7, pa. 172, 191*; *Newton's Chronol. ch. 1*.

CHRONOMETER, is any instrument or machine used in measuring time; such as dials, clocks, watches, &c.

The term is however more particularly used for a kind of clock, so contrived as to measure a small portion of time, even to the 16th, or the 40th part of a second; one of this latter kind I have seen, made by an ingenious artist; but it could not be stopped to the 10th part of the proposed degree of accuracy. There is a description of one also in Desagulier's *Experimental Philosophy*, invented by the late ingenious Mr. George Graham; which might be of great use for measuring small portions of time in astronomical observations, the time of the fall of bodies, the velocity of running waters, &c. But long intervals of time cannot be measured by it with sufficient exactness, unless its pendulum be made to vibrate in a cycloid; for otherwise it is liable to err considerably, as is the case of all clocks with short pendulums that swing in large arches of the circle.

Various other contrivances, besides clocks, have been used for measuring time for some particular purposes. See a musical chronometer described in Malcolm's *Treatise of Music*, pa. 407. The excellent watches that have lately been made, for the purpose of finding the longitude, by the ingenious artists, Harrison, Arnold, Mudge, Emery, Hardy, &c, are sometimes called chronometers, also time-keepers.

CHRONOSCOPE, a word sometimes used for a pendulum, or machine, to measure time.

CHIRYSTALLINE. See *CRYSTALLINE*.

CIMA, or **SIMA**, in Architecture, a member, or moulding, called also *ogee*, and *cimatum*.

CINCTURE, in Architecture, is a ring or list around the shaft of a column, at its top and bottom.

CINTRE, in Building, the same as *Centre*; which see.
CIPHER, or *Cypher*, one of the numeral characters, or figures, thus formed 0. The word comes from the Hebrew *saphar*, to number.

The cipher of itself signifies nothing, or implies a privation of value; but when combined with other numeral characters, it alters their value in a tenfold proportion, for every cipher so annexed; viz, when set after a figure in common integral arithmetic, it increases its value in that proportion, though it has no effect when placed before or to the left-hand side of such figures; but on the contrary, in decimal arithmetic, it decreases their value in that proportion when set before the figures, yet makes no alteration in their value when placed after them.

Thus, 5 is five,
but 50 is fifty,
and 500 is five hundred;
whereas .05, or .005, &c, is still but 5 or five. ~

Also '5 is five tenths,
but '05 is five hundredths,
'005 is five thousandths;
whereas '50, or '500, &c, is still but '5 or five tenths.

The invention and use of the cipher, as in the common arithmetic and notation of numbers, is one of the happiest devices that can be imagined; and is ascribed to the Indians, by the Arabians, by whom it was made known to Europe at the revival of literature.

CIRCLE, a plane figure, bounded by a curve line which returns into itself, called its circumference, and which is everywhere equally distant from a certain point within, called its centre. The circumference or periphery itself is sometimes called the circle, but improperly, as that name denotes the space contained within the circumference.—A circle is described with a pair of compasses, fixing one foot in the centre, and turning the other round to trace out the circumference.

The circumference of every circle is supposed to be divided into 360 equal parts, called degrees, and marked °; each degree into 60 minutes or primes, marked'; each minute into 60 seconds, marked"; and so on. So 24° 12' 15" 20", is 24 degrees 12 minutes 15 seconds and 20 thirds.

Circles have many curious properties, some of the most important of which are the following.

1. The circle is the most capacious of all plain figures, or contains the greatest area within the same perimeter, or has the least perimeter about the same area; being the limit and last of all regular polygons, having the number of its sides infinite.

2. The area of a circle is always less than the area of any regular polygon circumscribed about it, and its circumference always less than the perimeter of the polygon. But on the other hand, its area is always greater than that of its inscribed polygon, and its circumference greater than the perimeter of the said inscribed polygon. However, the area and perimeter of the circle approach always nearer and nearer to those of the two polygons, as the number of the sides of these is greater; the circle being always limited between the two polygons.

3. The area of a circle is equal to that of a triangle whose base is equal to the circumference, and perpendi-

ular equal to the radius. And therefore the area of the circle is found by multiplying half the circumference by half the diameter, or the whole circumference by the whole diameter, and taking the 4th part of the product; as demonstrated by Archimedes.

4. Circles, like other similar plane figures, are to one another, as the squares of their diameters. And the area of the circle is to the square of the diameter, as 11 to 14 nearly, as proved by Archimedes; or as .7854 to 1 more nearly; or still more nearly as

$$\begin{aligned} & 7853981633,9744830961,5660845819,8757210492, \\ & 9234984377,6455243736,1480769541,0157155224, \\ & 9657008706,3355292669,9553702162,8318076661, \\ & 7734611 + to 1; \end{aligned}$$

as it has been found by modern mathematicians.

In Wallis's Arithmetic of Infinites are contained the first infinite series for expressing the ratio of a circle to the square of its diameter: viz,

$$\begin{aligned} & 1st, \text{ The circle is to the square of its diameter,} \\ & \text{as } 1 \text{ to } \frac{3 \times 3 \times 5 \times 5 \times 7 \times 7 \&c.}{2 \times 4 \times 4 \times 6 \times 6 \times 8 \&c.}, \text{ discovered by Wallis} \\ & \text{or } 1 \text{ to } \frac{9}{8} \times \frac{25}{24} \times \frac{49}{48} \&c., \text{ himself;} \\ & \text{or as } 1 \text{ to } 1 + \frac{1}{9}, \text{ by Ld. Brouncker;} \\ & \quad 2 + \frac{25}{9}, \\ & \quad 2 + \frac{49}{25}, \\ & \quad 2 + \frac{9}{49}. \end{aligned}$$

or as $1 - \frac{1}{2 \times 3} - \frac{1}{2 \times 4 \times 5} - \frac{1 \times 3}{2 \times 4 \times 6 \times 7} \&c.$ to 1, by Sir I. Newton; or as $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} \&c.$ to 1, by Gregory and Leibnitz; and a great many other forms of series have been invented also by other authors to express the same ratio between the circle and circumscribed square.

5. The circumferences of circles are one to another, as their diameters, or radii. Hence, as the areas of circles are proportional to the rectangles of their radii and circumferences; the quadrature of the circle will therefore be effected by the rectification of its circumference; that is, if the true length of the circumference could be found, the true area could be determined also. But while several mathematicians have endeavoured to investigate the true area and circumference, others have even doubted of the possibility of the same. Of this latter opinion is Dr. Isaac Barrow: towards the end of his 15th mathematical lecture he says, he is of opinion, that the radius and circumference of a circle, are lines of such a nature, as to be not only incommensurable in length and square, but even in length, square, cube, biquadrate, and all other powers to infinity: for, continues he, the side of the inscribed square is incommensurable to the radius, and the square of the side of the inscribed octagon is incommensurable to the square of the radius; and consequently the square of the octagonal perimeter is also incommensurable to the square of the radius; and thus the ambitions of all regular polygons, inscribed in a circle, may have their superior powers incommensurate with the co-ordinate powers of the radius; whence the last polygon, that is, the circle itself, appears to have its periphery incommensurable with the radius; which, if true, will put a final stop to the quadrature of the circle, since the ratio of the circumference to the radius is altogether inexplicable from the nature of the thing, and consequently the problem requiring the explication of such a ratio, is impossible to be solved, or rather it requires

that for its solution which is impossible to be apprehended. He concludes by observing that this great mystery cannot be explained in a few words: but if time and opportunity had permitted, he would have endeavoured to produce many things for the elucidation and confirmation of this conjecture. Newton also, in book 1 of his Principia, has attempted to demonstrate the impossibility of the general quadrature of oval figures, by the description of a spiral, and likewise the impossibility of determining, by a finite equation, the intersections of that oval and spiral, which must be the case, if the oval be quadable. And several other authors have attempted to demonstrate the impossibility of the general quadrature of the circle by any means whatever. On the other hand, many mathematicians not only believe in the possibility of the quadrature of the circle, but some have even professed to have discovered the same, and have published to the world their pretended discoveries: of which no one has rendered himself more conspicuous than our countryman Mr. Hobbes, though a great scholar, and of excellent understanding in other matters. See QUADRATURE.

The approximate quadrature of the circle however, or the determination of the ratio between the diameter and the circumference, is what the mathematicians of all ages have successfully attempted, and with different degrees of accuracy, according to the improved state of science. Archimedes, in his book de Dimensione Circuli, first gave a near value of that ratio in small numbers, being that of 7 to 22, which are still used as very convenient numbers for this purpose in common measurements. Other and nearer ratios have since been successively assigned, but in larger numbers,

$$\begin{aligned} & \text{as } 106 \text{ to } 333, \\ & \text{or } 113 \text{ to } 355, \\ & \text{or } 1702 \text{ to } 5347, \\ & \text{or } 1815 \text{ to } 5702, \&c., \end{aligned}$$

which are each more accurate than the foregoing: and several of these same ratios, as well as others, have lately been found in the mathematical books of the Hindus, accounts of which may be seen in my Tracts, vol. 2, pa. 158, &c. Vieta, in his Universalium Inspectionum ad Canonum Mathematicum, published 1579, by means of the inscribed and circumscribed polygons of 393216 sides, has carried the ratio to ten places of figures, showing that if the diameter of a circle be 1000 &c, the circumference will be greater than 314,159,265,35, but less than 314,159,265,37.

And Van Culen, in his book De Circulo et Adscriptis, has, by the same means, carried that ratio to 36 places of figures; which were also recomputed and confirmed by Willebrord Snell. After these, that indefatigable computer Mr. Abraham Sharp extended the ratio to 72 places of figures, in a paper, published about the year 1706, by means of the series of Dr. Halley, from the tangent of an arc of 30 degrees. And the ingenious Mr. Machin also carried the same to a hundred places, by other series, depending on the differences of arcs whose tangents have certain relations to one another. See this method explained in my Mensuration, pa. 89, 4th edit.; or my new Tracts, vol. 1, pa. 266. And, finally, M. De Lagny, in the Mémoires de l'Acad. 1719, by means of the tangent of the arc of 30 degrees, has extended the same ratio to the astonishing length of 128 places of figures; finding, that, if the diameter be 1000 &c, the circumference will be

31415,92653,58979,32384,62643,38327,95028,
84197,16939,93751,05820,97494,45923,07816,
40628,62089,98628,03482,53421,17067,98214,
80865,13272,30664,70938,446 + or 447 -

From such methods as the foregoing, a variety of series have been discovered for the length of the circumference of a circle, such as the following, viz. If the diameter be 1, the circumference c will be variously expressed thus,

$$c = 4 \times \left(1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \frac{1}{13} - \frac{1}{15} + \dots\right) \text{ &c},$$

$$c = \sqrt{8} \times \left(1 + \frac{1}{3} - \frac{1}{5} + \frac{1}{7} - \frac{1}{9} + \frac{1}{11} - \frac{1}{13} + \frac{1}{15} + \dots\right) \text{ &c},$$

$$c = \sqrt{12} \times \left(1 - \frac{1}{3.3} + \frac{1}{5.3^2} - \frac{1}{7.3^3} + \frac{1}{9.3^4} + \dots\right) \text{ &c},$$

$$c = 8 \times \left(\frac{1}{1.1.3} + \frac{1}{1.3.5} - \frac{1}{3.5.7} + \frac{1}{5.7.9} - \frac{1}{7.9.11} + \dots\right) \text{ &c},$$

$$c = 8 \times \left(\frac{2}{3} - \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \frac{1}{13} + \dots\right) \text{ &c},$$

$$c = 4\sqrt{2} \times \left(\frac{2}{3} - \frac{1}{5.2} + \frac{1}{7.4.2^2} - \frac{1}{9.6.2^2} + \frac{1}{11.8.1.2^3} + \dots\right) \text{ &c},$$

$$c = 4 \times \left(1 - \frac{1}{2.3} - \frac{1}{2.4.5} + \frac{1}{2.4.6.7} - \frac{1}{2.4.6.8.9} + \dots\right) \text{ &c}.$$

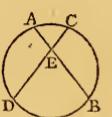

And many other series might here be added. See my Mensuration in several places; also my paper on such series in the Philos. Trans. 1776, or my new Tracts, vol. 1, pa. 268; Euler's Introductio in Analysis Infinitorum; and many other authors.

6. Some of the more remarkable properties of the circle are as follow:

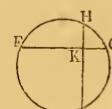

If two lines AC, CD cut the circle, and intersect within it, the angle of intersection E is measured by half the sum of the intercepted arcs AC, DB .

But if the lines intersect without the circle, the angle E is measured by half the difference of the intercepted arcs AC, DB .

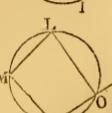

7. The angle at the centre of a circle is double the angle at the circumference, standing on the same arc; and all angles in the same segment are equal. Also the angle at the centre is measured by the arc it stands upon, and the angle at the circumference by half the same arc.

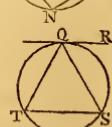

8. If the chords FG, HI intersect each other at right angles, the sums of the opposite arcs are equal; viz., $FH + GI = FI + GH$.

9. If one side NO of a trapezium inscribed in a circle be produced out, the external angle LOP , will be equal to the internal opposite angle M .

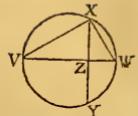

10. Any angle, as ROS , formed by a tangent QR and chord QS , is measured by half the arc of the chord QS , and is equal to any angle T in the alternate segment QTS .

11. If vw be a diameter, and xzy a chord perpendicular to it; then is xz or zy a mean proportional between

the segments vz, zw . So that if d denote the diameter vw , x the absciss vz , and y the ordinate zx ; then is $y^2 = (d-x) \times x$ or $= dx - x^2$; which is called the equation of the circle.

The chord vx is a mean proportional between the diameter vw and the versed sine vz ; and the chord wx is a mean proportional between the diameter and the versed sine wz ; also each versed sine is proportional to the square of the corresponding chord; viz., $vz : wz :: vx^2 : wx^2$.

12. If the diameter pq be divided into two parts at any point r ; and if rs be drawn perpendicular to pq , also rt applied equal to the radius, and tr produced to the circumference at v : Then, between the two segments pr, rq ,

rt is the arithmetical mean,

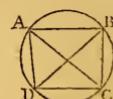

rs is the geometrical mean,

rv is the harmonical mean.

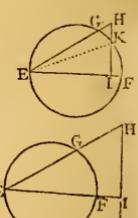

13. When two lines cut the circle, whether they intersect within the circle, or without it, as in the two figures to article 6, the segments between the common intersection and the two points where each line cuts the curve, are reciprocally proportional, and their rectangles are equal; viz., $EA \times EC : ED \times EB$,

$$\text{or } EA \times EB = EC \times ED.$$

14. In a trapezium inscribed in a circle, the rectangle of the two diagonals is equal to the sum of the two rectangles contained by each pair of opposite sides; viz., $AC \times BD = AB \times DC + AD \times BC$.

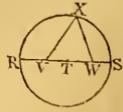

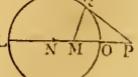

15. If any chords EF, EG , drawn from the same point e in the circumference, be cut by any other line HI , the rectangles will be all equal which are contained by each chord and the part intercepted by this line, viz., $EF \times EI = EG \times EH = EK^2$.

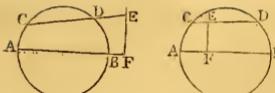

16. In a circle whose centre is N and radius no , if two points m, r , in the radius produced, be so taken that the three, Nm, no, Np , be in continued proportion; then if from the points m and r lines be drawn to any, or every point in the circumference, as q ; these lines will be always in the given ratio of mo to ro ; or $mq : pq :: mo : po$.

17. If vw be two points in the diameter, equidistant from the centre T ; and if two lines be drawn from these to any point x in the circumference; the sum of their squares will be equal to the sum of the squares of the segments of the diameter made by either point; viz., $vx^2 + wx^2 = rv^2 + vs^2$, or $= rw^2 + ws^2$, or $= 2rt^2 + 2vt^2$.

18. If a line fe perpendicular to the diameter ab , meet any other chord cd in the point e ; then is $af \times fb = ce \times ed + ef^2$.

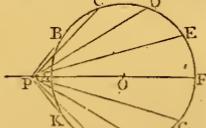

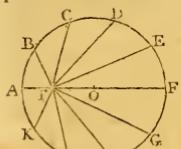

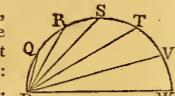

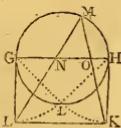

19. If upon the diameter GH of a circle there be formed a rectangle $GHKI$, whose breadth GI or HK is equal to GL or HL , the chord of a quadrant, or side of the inscribed square; then if from I and K lines be drawn to any point M in the circle GHI , they will cut the diameter GH in such a manner that $GO^2 + HM^2 = GH^2$.

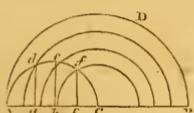

20. If the arcs PQ , QR , RS , &c, be equal, and there be drawn the chords PQ , PR , PS , PT , &c, then it will be $PQ : PR : : PQ : PQ + PS : : PS : PR + PT : : PT : PS + PV$, &c.

21. The centre of a circle being O , and P a point in the radius, or in the radius produced; if the circumference be divided into as many equal parts AB , BC , CD , &c, as there are units in $2n$, and lines be drawn from P to all the points of division; then shall the continual product of all

the alternate lines, viz., $PA \times PC \times PE \times \&c$ be $= r^n - x^n$ when P is within the circle, or $= x^n - r^n$ when P is without the circle; and the product of the rest of the lines, viz $PB \times PD \times PF \times \&c = r^n + x^n$; where $r = AO$ the radius, and $x = OP$ the distance of P from the centre.

22. To divide a circle into any number of equal parts, by means of concentric circles.—
ADB being half the given circle, divide its radius AC into the like number of parts; at the points of division erect the perpendicular ad , be , cf , meeting the semicircle $defc$ in the points d , e , f , &c. Lastly, from the centre c , describe circles through the points d , e , f , &c, and these will divide the space in the manner required, either all equal, or in any ratios as the radius AC is first divided into. See my Tracts, vol. 3, p. 378, &c.

23. A circle may thus be divided into any number of parts that shall be equal to one another both in area and perimeter. Divide the diameter QR into the same number of equal parts at the points s , t , v , &c; then, on one side of the diameter describe semicircles on the diameters qs , qr , rv , and on the other side of it describe semicircles on rv , rt , rs ; so shall the parts 1, 7, 3, 5, 3, 7, 1, be all equal, both in area and perimeter. See my Tracts, vol. 1, p. 254.

24. To describe a Circle either about or within a given

Regular Polygon. Bisect two of its angles, or two of its sides, with perpendiculars, and the intersection of the bisecting lines will, in either case, be the centre of the circles.

Parallel, or Concentric Circles, are such as are equally distant from each other in every point of their peripheries; or that have the same centre. As, on the other hand, those are called the *excentric* circles, that have not the same point for their centres.

The *Quadrature of the Circle*, is the manner of describing, or assigning, a square, whose surface shall be perfectly equal to that of a circle. This problem has exercised the geometers of all ages, but it is now generally abandoned as a problem impossible to be effected, by most persons that have any just claim to that rank. Descartes insists on the impossibility of it, for this reason, that a right line and a circle being of different natures, there can be no strict proportion between them; which is not satisfactory. Dr. Barrow shows the strongest probability of the same thing; and not only that the diameter and circumference themselves, but that all powers of them to infinity, are incommensurate.

The Emperor Charles v offered a reward of 100,000 crowns to any person who should resolve this celebrated problem: and the States of Holland also proposed a reward for the same thing. See QUADRATURE.

Circles of the Higher Orders, are curves in which

$$wy^m : yz^m :: yz : yx,$$

$$\text{or } wy^m : yz^m :: yz^n : yx^n.$$

When m and n are each equal to 1, then $wy : yz : yz : yx$, which is the property of the common circle.

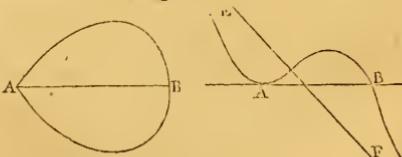

Put $wy = x$, $yz = y$, $wx = a$; then is $yx = a - x$, and the above proportions become

$$x^m : y^n :: y : (a - x) \text{ or } y^{m+1} = x^m \cdot (a - x) \text{ and}$$

$$x^m : y^m :: y^n : (a - x)^n \text{ or } y^{m+n} = x^m \cdot (a - x)^n,$$

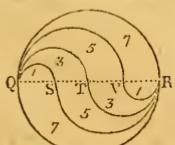

the equations to curves of this kind.

Curves defined by this equation will be ovals when m is an odd number. Thus suppose $m = 1$, then the equation becomes $y^2 = x \cdot (a - x)$, or $ax - x^2$, the equation to the common circle. And if $m = 3$, the equation is $y^4 = x^3 \cdot (a - x)$ or $ax^3 - x^4$, which denotes a curve of the form AB , the first fig. below.

But when m denotes an even number, the curve will have two infinite legs. So if $m = 2$, the equation becomes $y^2 = x^2 \cdot (a - x)$, or $ax^2 - x^3$, for a circle of the 2d order, and which defines one of Newton's defective hyperbolae, being his 37th species of curves, whose asymptote is the right line EF , making an angle of 40 degrees with the abscissa AB , as in the 2d fig.

Circle of Curvature, or circle of equi-curvature, is that circle which has the same curvature with a given curve at a certain point; or that circle whose radius is equal to the radius of curvature of the given curve at that point.

A circular arc is the only curve line that is equally curved in every point. In all other curve lines, such as the arc of an ellipse, or a parabola, or an hyperbola, or a cycloid, the curvature is different in different points, and the degree of curvature in any point is estimated by the curvature of a circle which is said to have the same curvature as the proposed curve line in that point; by which is understood the circle which, having the tangent of the proposed curve in the said point for its tangent, approaches so nearly to the proposed curve that no other circle whatever can be drawn between it and that curve.

This circle is also said to *oscculate* the curve in the said point, and is therefore often called the *osculating circle*, as well as the *circle of equal curvature* with the curve in that point. And the radius of this circle is called the *radius of curvature* of the proposed curve in the said point; also its centre is called the *centre of curvature*.

Now there are some curve lines so very highly curved in particular points, that every circle, of how small a radius soever, having the tangent to the curve in one of those points for its tangent, will pass without the curve, or between the curve and its tangent. This, for example, is the case with the curve of a cycloid in the two points contiguous to its base, as also with the cissoid at its vertex. And in such points the curvature of these curves is said to be *infinite*, because it is greater than the curvature of any circle, how small soever. Also the radius of the circle of curvature in such points is nothing; the length of that radius being always inversely or reciprocally as the degree of curvature at any point.

The theory of these circles of equal curvature with curves in particular points was first cultivated by Apollonius in his *Conic Sections*: and it has since been carried much farther by several great mathematicians of modern times; particularly by Mr. Huygens in his doctrine of Evolute Curves and Curves of Evolution, and by the great Sir Isaac Newton. See CURVATURE.

CIRCLES of the Sphere, are such as cut the mundane sphere, and have their circumference in its surface.

These circles are either fixed or moveable.

The latter are those whose peripheries are in the moveable or revolving surface; and which therefore move or turn with it; as the meridians, &c. The former, having their periphery in the immovable surface, do not revolve; as the ecliptic, equator, and its parallels.

The circles of the sphere are either great or lesser circles.

A Great Circle of the Sphere, is that which divides it into two equal parts or hemispheres, having the same centre and diameter with it. As the horizon, meridian, equator, ecliptic, the colures, and the azimuths.

A Lesser Circle of the Sphere, divides the sphere into two unequal parts, having neither the same centre nor diameter with the sphere; its diameter being only some chord of the sphere less than its axis. Such are the parallels of latitude, &c.

CIRCLES of Altitude, or Almucantars, are lesser circles parallel to the horizon, having their common pole in the zenith, and still diminishing as they approach it. They are so called from their use, which is to show the altitude of a star above the horizon.

CIRCLES of Declination, are great circles intersecting each other in the poles of the world.

CIRCLE of DISSIPATION, in Optics. See DISSIPATION.

Durnal CIRCLES, are parallels to the equinoctial, supposed to be described by the several stars, and other points

of the heavens, in their apparent diurnal rotation about the earth.

CIRCLE Equant, in the Ptolemaic Astronomy, is a circle described on the centre of the equant. Its chief use is, to find the variation of the first inequality.

CIRCLES of Excursion, are lesser circles parallel to the ecliptic, and at such a distance from it, that the excursions of the planets towards the poles of the ecliptic, may be included within them; being usually fixed at about 10 degrees.

It may here be observed, that all the circles of the sphere, described above, are transferred from the heavens to the earth: and thence come to have a place in geography as well as in astronomy: all the points of each circle being conceived as let fall perpendicularly on the surface of the terrestrial globe, and thus tracing out circles perfectly similar to them. So, the terrestrial equator is a circle conceived precisely under the equinoctial line, which is in the heavens; and so of the rest.

Horary CIRCLES, in Dialling, are the lines which show the hours on dials. These are straight lines on the dials, but called circles as being the projections of the meridians.

Horary CIRCLE, or Hour Circle, on the globe, is a small brazen circle fixed to the north pole, divided into 24 hours, and furnished with an index to point them out, thereby showing the difference of meridians in time, and serving for the solution of many problems, on the artificial globes.

CIRCLE of Illumination, is that imaginary circle on the surface of the earth, which separates the illuminated side or hemisphere of the earth from the dark side: and all lines passing from the sun to the earth, being physically parallel, are therefore perpendicular to the plane of this circle.

CIRCLES of Latitude, or Secondaries of the Ecliptic, are great circles perpendicular to the plane of the ecliptic, intersecting each other in its poles, and passing through every star and planet, &c.—These are so called, because they serve to measure the latitude of the stars, which is an arch of one of these circles, intersected between the star and the ecliptic.

CIRCLES of Longitude, are lesser circles parallel to the ecliptic, diminishing more and more as they recede from it, or as they approach the pole of that circle.

They are so called, because the longitudes of the stars are reckoned upon them.

CIRCLES of Perpetual Apparition, one of the lesser circles parallel to the equator, described by the most northern point of the horizon, as the sphere revolves round by its diurnal motion.—All the stars included within this circle, are continually above the horizon, and consequently never set.

CIRCLE of Perpetual Occultation, is another lesser circle at a like distance from the equator, but on the other side of it, being described by the most southern point of the horizon, and contains all those stars which never appear in our hemisphere, or which never rise.

All other stars, being contained between these two circles, do alternately rise and set, at certain moments of the diurnal rotation.

Polar CIRCLES, are immovable circles, parallel to the equator, and at such a distance from the pole as is equal to the greatest declination of the ecliptic, which is now nearly $23^{\circ} 28'$. That next the northern pole is called the arctic, and that next the southern one the antarctic.

CIRCLES of Position, are circles passing through the common intersections of the horizon and meridian, and

through any degree of the ecliptic, or the centre of any star, or other point in the heavens; and are used for finding the situation or position of any star. These are usually 6 in number, cutting the equinoctial into 12 equal parts.

CIRCUIT, Electrical, denotes the course of the electric fluid from the charged surface of an electric body, to the opposite surface, into which the discharge is made. Some electricians at first apprehended, that the same particles of the electric fluid that were thrown on one side of the charged glass, actually made the whole circuit of the intervening conductors, and arrived at the opposite side: whereas Dr. Franklin's theory only requires, that the redundancy of electric matter on the charged surface should pass into those bodies which form that part of the circuit which is contiguous to it, driving forward that portion of the fluid which they naturally possess; and that the deficiency of the exhausted surface should be supplied by the neighbouring conductors, which form the last part of the circuit. On this supposition, a vibrating motion is successively communicated through the whole length of the circuit.

Many attempts were made, both in France and England, at an early period in the practice of electricity, to ascertain the distance to which the electric shock might be carried, and the velocity of its motion. The French philosophers, at different times, caused it to pass through circuits of 900 and even 2000 toises, or about 2 English miles and a half; and they discharged the Leyden phial through a basin of water, whose surface was equal to one acre. M. Monier found that the fluid, in passing through an iron wire of .950 toises in length, did not spend a quarter of a second; and that its motion was instantaneous through a wire of 1319 feet. In 1747, Dr. Watson, and other English philosophers, after many experiments of a similar kind, conveyed the electric matter through a circuit of 4 miles; and, from two several trials, they concluded that its passage is instantaneous. By all which doubtless is meant, that its motion is too rapid to be measured. Priestley's Hist. of Elect. vol. 1, p. 128, 8vo edit.

CIRCULAR, appertaining to a circle; as a circular form, circular motion, &c.

CIRCULAR Instruments of Reflection, or Multiplying Circles, are such circles as, in small size, by means of reflection, procure at pleasure all the advantages of the size of large instruments, as well as diminishing the errors of division.—Circular instruments are in fact considerable improvements on Hadley's octant, and the marine sextant, devised for the same purposes. We shall here describe the progress of these instruments under the contrivances of Tobias Mayer, Chevalier Borda, and Captain Mendoza.

Mr. Mayer proposed to complete the limb of the sextant to a whole circle, with the horizon glass moveable round the centre, and with an additional index, which may be called the horizon index, to distinguish it from the centre index, to which the centre glass is attached. This instrument is represented in plate 7, fig. 8; and the manner of using it is as follows: After the index a is set at o (the beginning of the divisions) the two glasses are rendered parallel, as in using Hadley's quadrant, by moving the horizon index b , till the horizon of the sea (or the sun or any other object), or its direct image, and the doubly reflected image of the same, seen through the telescope, coincide. After fixing the horizon index in that position, the centre index a is to be moved, in order to measure the

distance of the two objects s and l (suppose the sun and moon), by bringing into contact the double reflected image of the sun with the direct image of the moon, seen through the telescope. The centre image will then be at m , and the arch om might give, as in the sextant, the angular distance required; but the construction of the circle renders it easy, in this position, to effect again the parallelism of the glasses, and to make another observation of the contact, in the like manner as from o ; which operation will bring the centre index to n . The index will then give ox , or double the distance; which divided by 2, reduces the errors of the instrument to one half. And it is obvious, that by successive repetitions of the same process, triple, quadruple, &c., the distance may be obtained, and the said error further reduced, in the inverse ratio of the multiplication of the distance, to any degree of approximation desired.

The method of rendering the glasses parallel, by means of the horizon of the sea, is not accurate, on account of the indistinctness of the images; and when the sun is used for that purpose, the observation becomes fatiguing to the eye. The repetition of that observation remained therefore a considerable inconvenience attached to this circle. The author himself seems to have been aware of it, as he proposed to provide the instrument with a diagonal ruler, fixed on one of the indexes, so that the other index should touch it when the glasses were parallel: but an adjustment of this nature must be subject to great errors, and never was adopted in practice. The chevalier Borda, wishing to remove that imperfection, contrived to render the parallelism of the glasses unnecessary, by substituting the observation of the angular distance of the two objects, for that of the coincidences of the images of the same object. This constitutes the second great improvement of the reflecting circle.

In Borda's circle, the telescope is fixed at some distance from the centre, and the horizon glass is carried near the border of the instrument, as in plate 7, fig. 9. By this arrangement, the rays of light can arrive at the centre glass, both from the heavenly bodies situated to the right of the horizon index, as s' , and from those situated to the left, as s . Thus, if the glasses are parallel to one another, when the centre index is at o , it is obvious that there are two ways of making the observations. While the direct image of the moon l is seen through the telescope, the angular distance to the sun, if at s , may be measured by moving the centre index to m , in order to produce the contact; or, if the sun be at s' , the same operation may be performed, by using the contrary motion to m' . The first kind of observation, M. Borda calls observation to the left; and the second observation to the right. Suppose now, that (the horizon index being fixed in the same position) the distance from l to s is observed to the left, by bringing into contact the double reflected image of s with the image of l , seen without reflection; let us then turn the instrument round, keeping it in the same plane, so as to have the direct image of s through the telescope, and thus make an observation of the same distance to the right; the position of the centre index being in the first observation at m , and in the second at m' , it is clear, that if o be the point where the parallelism of the glasses takes place, om will be equal to om' , and that the arch nm' , determined by the two positions, will give double the distance.—It will be more convenient to have the centre index at o , when the first observation is made,

in order to take the double distance at one reading, after the second observation. For this purpose, the first part of the process may be inverted, by previously fixing the centre index at the beginning of the divisions, and moving the horizon index n towards o , instead of moving the centre index A to m , or towards n .

The last kind of observation, in which the incident ray, which produces the first image on the centre glass, may be conceived to run double the angular distance, passing in its way over the line of collimation, has by M. Borda been called the crossed observation.—The same process may be repeated, by fixing alternately one of the indexes, and moving the other, and continuing successive sets of observations; each set of two crossed observations, one to the right and another to the left. The angle given by the instrument, will be equal to double the angular distance multiplied by the number of sets observed.

Whether a circle is used simply, as Mayer proposed it, or in Borda's method, its peculiar advantages chiefly depend on the multiplication of the distance sought. Capt. Mendoza has therefore turned his attention to the improvement of this principle, and has accordingly contrived the following construction: In the crossed observations made with Borda's circle, the indexes move alternately through an arch which, in the divisions, is equal to double the distance: for example, the centre index comes, in the first crossed observation, from m to m' ; in the third crossed observation, from m' to m'' , &c.; and the horizon index, in the 2d crossed observation, to h' ; in the 4th crossed observation to h'' , &c.; and by each of the two indexes may be found the same multiple of the distance sought. Let us now place the nonius in a circle moving round the centre, over, or adjacent to, the usual limb which contains the divisions: then it will easily be conceived that, by attaching that circle, which M. Mendoza calls the flying nonius, alternately to each of the indexes, it will serve as nonius for both; and that, after any number of observations, it will give the compound motion of the two indexes. Thus, after the first observation, the flying nonius will, at each crossed observation, advance double the distance over the divisions, while each separate nonius, fixed on the indexes, requires a set of two observations to produce the same effect in Borda's circle. The peculiar property of the instrument being that of giving double the distance, it was thought proper to divide the circle into 360 degrees, and not into 720 according to the nature of the sextant. Thus, after a crossed observation, the reading of the nonius will, without reduction, exhibit the measure of the simple distance. Mendoza has also extended the nonius round the circumference, so that, by the coincidence of two divisions, the number of degrees will appear on the limb, and that of the minutes and seconds on the flying nonius. See Philos. Trans. 1801.

For more on the nature of circular instruments of reflection, see Montula, *Histoire des Mathématiques*, tom. 3, p. 527: for the computation of the probable extent of the errors to which they are liable, see Swanberg, *Exposition des opérations faites en Laponie &c.*, p. 29; and for a catalogue of papers &c., connected with such instruments, consult Dr. T. Young's *Natural Philos.* vol. 2, p. 350.—For Sir Howard Douglas's Reflecting Circle or Semicircle, see the article **REFLECTING** in this Dictionary.

CIRCULAR Lines, a name given by some authors to such straight lines as are divided by means of the divisions

made in the arch of a circle. Such as the Sines, Tangents, Secants, &c.

CIRCULAR Numbers, are such as have their powers ending in the roots themselves. As the number 5, whose square is 25, and its cube 125, &c.

Napier's **CIRCULAR Parts**, are five parts of a right-angled or a quadrantal spherical triangle; they are the two legs, the complement of the hypotenuse, and the complements of the two oblique angles.

Concerning these circular parts, Napier gave a general rule in his *Logarithmorum Canonis Descriptio*, which is this: “The rectangle under the radius and the sine of the middle part, is equal to the rectangle under the tangents of the adjacent parts, and to the rectangle under the cosines of the opposite parts. The right angle or quadrantal side being neglected, the two sides and the complements of the other three natural parts are called the circular parts; as they follow each other as it were in a circular order. Of these, any one being fixed upon as the middle part, those next it are the adjacent, and those farthest from it the opposite parts.” Lord Buchan's *Life of Napier*, pa. 98.

This excellent, though very concise rule, including all the particular rules for the solution of right-angled spherical triangles, may be readily applied to those that are oblique, by letting fall a perpendicular, excepting the two cases in which there are given either the three sides, or the three angles.—And for these a similar expedient has been devised by Lord Buchan and Dr. Minto. M. Pingre, in the *Mémoires de Mathématique et de Physique* for the year 1756, reduces the solution of all the cases of spherical triangles to four analogies. These four analogies are in fact, under another form, Napier's rule of the circular parts, and his second or fundamental theorem, with its application to the supplemental triangle. Though it would be no difficult matter to get by heart the four analogies of M. Pingre, yet there are few persons blessed with a memory capable of retaining them for any considerable time. For this reason, the rule for the circular parts ought to be kept under its present form. If the reader attends to the circumstance of the second letters of the words *tangens* and *cosines* being the same with the first of the words *adjacent* and *opposite*, he will find it almost impossible to forget it. And the rule for the solution of the two cases of spherical triangles, for which the former alone is insufficient, may be thus expressed: Of the circular parts of an oblique spherical triangle, the rectangle under the tangents of half the sum and half the difference of the segments at the middle part (formed by a perpendicular drawn from an angle to the opposite side), is equal to the rectangle under the tangents of half the sum and half the difference of the opposite parts. By the circular parts of an oblique spherical triangle, are meant its three sides and the supplements of its three angles. Any of these six being assumed as a middle part, the opposite parts are those two of the same denomination with it; that is, if the middle part is one of the sides, the opposite parts are the other two, and if the middle part is the supplement of one of the angles, the opposite parts are the supplements of the other two.—Since every plane triangle may be considered as described on the surface of a sphere of an infinite radius, these two rules may be applied to plane triangles, provided the middle part be restricted to a side.

“Thus it appears that two simple rules suffice for the solution of all the possible cases of plane and spherical

triangles. These rules, from their neatness and the manner in which they are expressed, cannot fail of engraving themselves deeply on the memory of every one who is a little versed in trigonometry. It is a circumstance worthy of notice, that a person of a very weak memory may carry the whole art of trigonometry in his head." Napier's Life, pa. 102.

CIRCULAR Sailing, is that performed in the arch of a great circle.—It is chiefly on account of the shortest distance that this method of sailing has been proposed; and for the most part it is advantageous for a ship to reach her port by the shortest course.

As the solutions of the cases in Mercator's sailing are performed by plane triangles; so the cases in great-circle sailing are resolved by the solution of spherical triangles. But, after all, the several cases in this kind of sailing serve rather for exercises in the solution of spherical triangles, than for any real use towards the navigating of a ship.

CIRCULAR Spots, are made on pieces of metal by large electrical explosions. See Philos. Trans. vol. 58, pa. 68; or my Abridgment, vol. 12, p. 510; also Priestley's Hist. of Electricity, vol. 2, sect. 9, edit. 8vo.

These beautiful spots, produced by the moderate charge of a large battery, discharged between two smooth surfaces of metals, or semi-metals, lying at a small distance from each other, consist of one central spot, and several concentric circles, which are more or less distinct, and more or fewer in number, as the metal on which they are marked is more easy or difficult of fusion, and as a greater or less force is employed. They are composed of dots or cavities, which indicate a real fusion. If the explosion of a battery, issuing from a pointed body, be repeatedly taken on the plain surface of a piece of metal near the point, or be received from the surface on a point, the metal will be marked with a spot, consisting of all the prismatic colours disposed in circles, and formed by scales of the metal separated by the force of the explosion.

CIRCULAR Velocity, a term in Astronomy, signifying that velocity of a planet, or revolving body, which is measured by the arch of a circle.

CIRCULATING Decimals, called also recurring or repeating decimals, are those in which a figure or several figures are continually repeated. They are distinguished into single and multiple, and these again into *pure* and *mixed*.

A *pure single* circulate, is that in which one figure only is repeated; as .²22 &c., and is marked thus .²2.

A *pure multiple* circulate, is that in which several figures are continually repeated; as .²32323 &c., marked .²3; and .⁵24524 &c., marked .⁵24.

A *mixed single* circulate, is that which consists of a terminal part, and a single repeating figure; as 4.²22 &c., or 4.². And

A *mixed multiple* circulate, is that which contains a terminal part with several repeating figures; as 45.⁵24.

That part of the circulate which repeats, is called the repetend: and the whole repetend, supposed infinitely continued, is equal to a vulgar fraction, whose numerator is the repeating number, or figures, and its denominator the same number of nines: so .² is = $\frac{2}{9}$; and .²3 is = $\frac{23}{99}$; and .⁵24 is = $\frac{524}{999}$.

It seems it was Dr. Wallis who first distinctly considered, or treated of infinite circulating decimals, as he

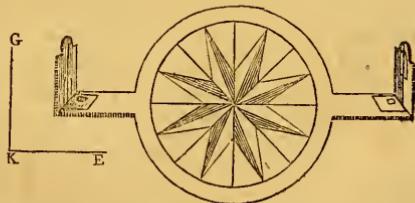

himself informs us in his *Treatise of Infinites*. Since his time many other authors have treated on this part of arithmetic; the principal of these, however, to whom the art is mostly indebted, are Messrs. Brown, Cunn, Martin, Emerson, Malcolm, Donn, and Henry Clarke, in whose writings the nature and practice of this branch of arithmetic may be fully seen, especially in the last-mentioned ingenious author.

CIRCUMFERENCE, in a general sense, denotes the line or lines bounding any figure. But it is commonly used in a more limited sense, to denote the curve line which bounds a circle, and which is otherwise called the periphery; the boundary of a right-lined figure being expressed by the term perimeter.

The circumference of a circle is every where equidistant from the centre. And the circumferences of different circles are to one another as their radii or diameters, or the ratio of the diameter to the circumference is the same in every circle, which is nearly as 7 to 22, as it was found by Archimedes, or, more nearly, as 1 to 3.1416. Under the article *Circle*, may be seen various other approximations to that ratio, one of which is carried to 128 places of figures, viz, by M. De Lagny.

The circumference of every circle is supposed to be divided into 360 equal parts, called degrees.—Any part of a circumference is called an arc or arch; and a right line drawn from one end of an arc to the other, is called its chord.—The angle at the circumference is equal to half the angle at the centre, standing on the same arc; and therefore it is measured by the half of that arc.

CIRCUMFERENTOR, a particular instrument used by surveyors for taking angles. It consists of a brass circle and index all of one piece; the diameter of the circle is commonly about 7 inches; the index about 14 inches long, and an inch and a half broad. On the circle is a card or compass, divided into 360 degrees; the meridian line of which answers to the middle of the breadth of the index. On the limb, or circumference of the circle, is soldered a brass ring; which, with another fitted with a glass, forms a kind of box for the needle, which is suspended on a pivot in the centre of the circle. There are also two sights to screw on, and slide up and down the index, as also a spangle and socket screwed on the underside of the circle, to receive the head of the three-legged staff.

To take, or observe, the Quantity of an Angle by the Circumferentor. The angle proposed being EKG; place the instrument at K, with the flower-de-luce of the card towards you; then direct the sights to E, and observe what degrees are cut by the south end of the needle, which let be 295; then, turning the instrument about on its stand, direct the sights to G, noting again what degrees are cut by the south end of the needle, which suppose are 213. This done, subtract the less number from the greater, viz,

213 from 295, and the remainder, or 82 degrees, is the quantity of the angle EKG sought.

CIRCUMGYRATION, is the revolving motion of any body about a centre; as of the planets about the sun, &c.

CIRCUM-POLAR Stars, are those stars which, by reason of their vicinity to the pole, move round it, without setting.

CIRCUMSCRIBED Figure, is a figure which is drawn about another, so that all its sides or planes touch the latter or inscribed figure.

The area and perimeter of every polygon that can be circumscribed about a circle, are greater than those of the circle; and the area and perimeter of every inscribed polygon, are less than those of the circle; but they approach always nearer to equality as the number of sides is greater. And on these principles Archimedes, and some other authors since his time, attempted the quadrature of the circle; which is nothing else, in effect, but the measuring the area or capacity of a circle.

CIRCUMSCRIBED Hyperbola, is one of Newton's hyperbolae of the 2d order, that cuts its asymptotes, and contains the parts cut off within its own space.

CIRCUMVALLATION, or Line of Circumvallation, in the Art of War, is a trench, bordered with a parapet, thrown up around the besieger's camp, as a security against any army that may attempt to relieve the place, as well as to prevent desertion.

CIRCUMVOLUTION, in Architecture, the torus of the spiral line of the Ionic order.

CISSOID, is a curve line of the second order, invented by Diocles for the purpose of finding two continued mean proportionals between two other given lines. The generation or description of this curve is as follows:

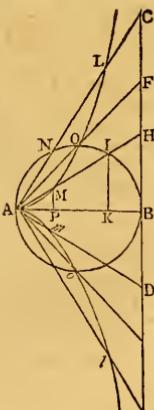

On the extremity B of the diameter AB of the circle AOB , erect the indefinite perpendicular CBD , to which from the other extremity A draw several lines, cutting the circle in $r, o, n, \&c.$; and on these lines set off the corresponding equal distances, viz. $HN = AI$, $FO = AO$, and $CL = AN$, &c.; then the curve line drawn through all the points $M, O, L, \&c.$, is the cissoid of Diocles, who was an ancient Greek geometer.

This curve is, by Newton, reckoned among the defective hyperbolae, being the 42d species in his Enumeratio Linearum Tertii Ordinis. And in his Appendix de Equationum Constructione Linearis, at the end of his Arithmetica Universalis, he gives another elegant method of describing this curve by the continual motion of a square ruler. Other methods have also been devised by different authors for the same thing.

The Properties of the Cissoid are the following:

1. The curve has two infinite legs $AMOL$, $ANOL$ meeting in a cusp A , and tending towards the indefinite line CBD , which is their common asymptote.

2. The curve passes through o and o , points in the circle equally distant from A and B ; or it bisects each semi-circle.

3. Letting fall perpendiculars MP , IK from any corresponding points I, M ; then is $AP = BK$, and $AM = HI$, because $AI = MH$.

4. $AP : PB :: MP^2 : AP^2$. So that, if the diameter AB be $= a$, the absciss $AP = x$, and the ordinate $PM = y$; then is $x : a - x : y^2 : x^2$, or $x^3 = (a - x) \cdot y^2$, which is the equation of the curve.

5. Sir Isaac Newton, in his last letter to M. Leibnitz, has shown how to find a right line equal to one of the legs of this curve, by means of the hyperbola; but he there suppressed the investigation, which however may be seen in his Fluxions.

6. The whole infinitely long cissoidal space, contained between the infinite asymptote CBD , and the curves $LOAL$ &c., of the cissoid, is equal to triple the generating circle $AOBA$.—See more of this curve in Dr. Wallis's Works, vol. 1, pa. 545.

CIVIL Day. See Day.

CIVIL Month. See Month.

CIVIL Year, is the legal year, or annual account of time which every government appoints to be used within its own dominions. It is so called in contradistinction from the natural year, which is measured exactly by the revolution of the heavenly bodies.

CLAIRAUT (ALEXIS-CLAUDE), a celebrated French mathematician and academician, was born at Paris the 13th of May 1713, and died the 17th of May 1765, at 52 years of age. His father, a teacher of mathematics at Paris, was his sole instructor; and such was the progress of our author under him, that at the early age of 4 years, he could read and write. The letters of the alphabet he taught him in the figures of Euclid's Elements. At 9 years of age he studied Guisnée's Application of Algebra to Geometry; at 10 De l'Hôpital's Conic Sections; and between 12 and 13 he read a memoir to the Academy of Sciences concerning 4 new geometrical curves of his own invention. About the same time he laid the first foundation of his work upon curves that have a double curvature, which he finished in 1729, at 16 years of age. He was named Adjoint-Mechanician to the Academy in 1731, at the age of 18, Associate in 1733, and Pensioner in 1738. During his connexion with the Academy, he had a great number of learned and ingenious communications inserted in their Memoirs, besides several other works which he published separately; the list of which is as follows:

1. On Curves of a Double Curvature; in 1730, 4to.
2. Elements of Geometry; 1741, 8vo.
3. Theory of the Figure of the Earth; 1743, 8vo.
4. Elements of Algebra; 1746, 8vo.
5. Tables of the Moon; 1754, 8vo.

His papers inserted in the Memoirs of the Academy are too numerous to be particularized here; but they may be found from the year 1727, for almost every year till 1762; being upon a variety of subjects, astronomical, mathematical, optical, &c.

CLARKE (DR. SAMUEL), a celebrated English divine, philosopher, and metaphysician, was born at Norwich the 11th of Oct. 1675. He was the son of Edward Clarke, esq., alderman of that city, and for several years one of its representatives in parliament. He received instruction in classical learning at the free-school of that town; and in 1691 removed thence to Caius-college, Cambridge, where his shining abilities soon began to display themselves.—Though the philosophy of Descartes was at that time the

established system of the university, yet Clarke's sagacity soon discovered its imperfections, and led him to the belief of one more solid and rational, viz., the new system of Newton; this he soon mastered; and in order to his first degree of arts, performed a public exercise in the schools upon a question taken from it. He greatly contributed to the establishment of the Newtonian philosophy by an excellent translation of Routhault's Physics, with notes, which he finished before he was 22 years of age, a book which had been for some time the system used in the university, and founded on Cartesian principles. This was first published in the year 1697, and it soon after went through several other editions, all with improvements.

Mr. Whiston relates that, in that year, 1697, while he was chaplain to Dr. Moore, bishop of Norwich, he met with young Clarke, then wholly unknown to him, at a coffee-house in that city, where they entered into a conversation about the Cartesian philosophy, particularly Routhault's Physics, which Clarke's tutor, as he tells us, had put him upon translating. "The result of this conversation was," says Whiston, "that I was greatly surprised that so young a man as Clarke then was, should know so much of those sublime discoveries, which were then almost a secret to all but a few particular mathematicians. Nor did I remember (continues he) above one or two at the most, whom I had then met with, that appeared to know so much of that philosophy as Mr. Clarke."

He afterwards turned his thoughts to divinity; and having taken holy orders, in 1698, he succeeded Mr. Whiston as chaplain to Dr. Moore, bishop of Norwich, who was ever after his constant friend and patron. Soon after he published some theological treatises; and Bishop Moore gave him the rectory of Drayton, near Norwich, with a lectureship in that city. In 1704, he was appointed to preach Boyle's lecture; and the subject he chose was, *The Being and Attributes of God*. He succeeded so well in this, and gave so much satisfaction, that he was appointed to preach the same lecture the next year, when he chose for his subject, *The Evidences of Natural and Revealed Religion*. These sermons were first printed in two volumes, in 1705 and 1706, and contained some remarks on such objections that had been made by Hobbes and Spinoza, and other opposers of natural and revealed religion. In the 6th edition was added, *A Discourse concerning the Connexion of the Prophecies of the Old Testament, and the application of them to Christ*.

About this time, Mr. Whiston informs us, he discovered that Mr. Clarke (having read much of the primitive writers) began to suspect that the Athanasian doctrine of the Trinity was not the doctrine of those early ages; and it was particularly remarked of him, that he never read the Athanasian Creed at his parish church.

In the midst of his theological labours, Mr. Clarke found time to show his regard to mathematical and philosophical researches, with his exact knowledge and skill in them. And his natural affection and capacity for these studies were not a little improved by the friendship of Newton; at whose request he translated his Optics into Latin in 1706. With this version Sir Isaac was so highly pleased, that he presented him with the sum of 500*l* or 100*l* to each of his 5 children.

The same year, also, Bishop Moore procured for him the rectory of St. Bennett's, Paul's Wharf, in London; and soon after carried him to court, and recommended him to

the favour of Queen Anne. She appointed him one of her chaplains in ordinary; and also presented him to the rectory of St. James's, Westminster, when it became vacant in 1709. On this occasion he took the degree of D. D. when the public exercise which he performed for it at Cambridge was highly admired.

In 1715 and 1716, Dr. Clarke had a dispute with the celebrated Leibnitz, concerning the principles of natural philosophy and religion; and a collection of the papers which passed between them was published in 1717. This work was addressed to Queen Caroline, then princess of Wales, who was pleased to have the controversy pass through her hands. It related chiefly to the subjects of liberty and necessity.

About the year 1718 he was presented by the lord Lechmere to the mastership of Wigston's hospital in Leicestershire. In 1724 and 1725 he published 18 sermons, preached on several occasions. In 1727, on the death of Newton, he had the offer of succeeding him as Master of the Mint, a place worth from 12 to 15 hundred a year; but to this secular preferment he could not reconcile himself, and therefore absolutely refused it. In 1728 was published, *A Letter from Dr. Clarke to Mr. Benjamin Hoadley*, occasioned by the Controversy relating to the Proportion of Velocity and Force of Bodies in Motion, which was printed in the Philosophical Transactions, No. 401. Dr. Clarke died the 17th of May, 1729, in the 54th year of his age.

Queen Caroline took great pleasure in the doctor's conversation and friendship; seldom a week passed in which she did not receive some proof of the greatness of his genius and the force of his understanding.

As to the character of Dr. Clarke, he is represented as possessing one of the most amiable and affectionate dispositions, remarkably free and easy in his conversation, cheerful and even playful in his manner. Bishop Hare says of him, "He was a man who had all the good qualities that could meet together to recommend him. He was possessed of all the parts of learning that are valuable in a clergyman, in a degree that few possess any single one. He had joined to a good skill in the three learned languages a great compass of the best philosophy and mathematics, as appears by his Latin works; and his English ones are such a proof of his own piety and of his knowledge in divinity, and have done so much service to religion, as would make any other man, that was not under a suspicion of heresy, secure of the friendship of all good churchmen, especially the clergy.—Much more may be seen, related in his praise, by Bishop Hoadley, Dr. Sykes, and Mr. Whiston, in their Memoirs of his life.

CLAVIUS (CHRISTOPHER), a German Jesuit, was born at Bamberg in Germany, in 1537. He became a very studious mathematician and elaborate writer; his works, when collected, and closely printed, making 5 large folio volumes, being a complete body or course of mathematics. They are mostly elementary, with commentaries on Euclid and others, possessing very little of invention of his own. His talents and writings have been variously spoken of, and it must be acknowledged that they are heavy and elaborate. He was invited to Rome, to assist, with other learned men, in the reformation of the calendar, by Pope Gregory, of which he afterwards undertook a defence against Scaliger, Vietta, and others, who attacked it. He died at Rome the 6th of February, 1612, at 75 years of age, after

more than 50 years close application to the mathematical sciences.

CLEF, or CLIFF, in Music, a mark at the beginning of the lines of a song, which shows the tone or key in which the piece is to begin. Or, it is a letter marked on any line, which explains and points out the name of all the rest.

Anciently, every line had a letter marked for a clef; but now a letter on one line suffices; since by this all the rest are known, reckoning up and down, in the order of the letters.

It is called the clef, or key, because that thereby are known the names of all the other lines and spaces; and consequently the quantity of every degree or interval. But because every note in the octave is called a key, though, in another sense, this letter marked is called peculiarly the *signed clef*; since, being written on any line, it not only signs and marks that one, but it also explains all the rest. By clef, therefore, for distinction sake, is meant that letter, signed on a line, which explains the rest; and by key, the principal note of a song, in which the melody closes.

There are three of these signed clefs, *c, f, g*. The clef of the highest part in a song, called *treble*, or *alt*, is *g*, set on the second line, reckoning upwards. The clef of the bass, or the lowest part, is *f*, on the 4th line upwards. For all the other mean parts, the clef is *c*, sometimes on one, and at others on another line. Indeed, some that are really mean parts, are sometimes set with the *g* clef. It must however be observed, that the ordinary signatures of clefs bear little resemblance to those letters. Mr. Malcolm is of opinion that it would be well if the letters themselves were used. Kepler takes great pains to show, that the common signatures are only corruptions of the letters they represent.

The clefs are always taken fifths to one another. So the clef *f* being lowest, *c* is a fifth above it, and *g* a fifth above *c*.

When the place of the clef is changed, which is not frequent in the mean clef, it is with a design to make the system comprehend as many notes of the song as possible, and so to have the fewer notes above or below it. So that, if there be many lines above the clef, and few below it, this purpose is answered by placing the clef in the first or second line; but if there be many notes below the clef, it is placed lower in the system. In effect, according to the relation of the other notes to the clef note, the particular system is taken differently in the scale, the clef line marking one in all the variety.

But still, in whatever line of the particular system any clef is found, it must be understood to belong to the same of the general system, and likewise to be the same individual note or sound in the scale. By this constant relation of clefs, we learn how to compare the several particular systems of the several parts, and to know how they communicate in the scale, that is, which lines are unison and which are not; for it is not to be supposed that each part has certain bounds, within which another may never enter—some notes of the treble, for example, must be lower than some of the mean parts, or even of the bass. Therefore, to join together into one system all the parts of a composition written separately, the note of each particular part must be placed at the same distances above and below the proper clef, as they stand in the separate system: and because all the notes that are consonant, or heard together, must stand directly over each other, that the notes belong-

ing to each part may be distinctly ascertained, they may be made with such differences as shall not confound or alter their significations with respect to time, but only show their relation to this or that part. Thus we shall discover in what manner the parts change and pass through one another; and which, in every note, is highest, lowest, or unison.

It must here be observed, that for the performance of any single piece, the clef only serves for explaining the intervals in the lines and spaces: so that it need not be regarded what part of any greater system it is; but the first note may be taken as high or low as we please. For as the proper use of the scale is not to limit the absolute degree of tone, so the proper use of the *signed clef* is not to bound the pitch at which the first note of any part is to be taken, but to determine the tune of the rest, with respect to the first; and considering all the parts together, to determine the relation of their several notes by the relations of their clefs in the scale: thus, their pitch of tune being determined in a certain note of one part, the other notes of that part are determined by the constant relations of the letters of the scale, and the notes of other parts by the relations of their clefs.

In effect, for performing any single part, the clef note may be taken in an octave, that is, at any note of the same name; provided we do not go too high or too low for finding the rest of the notes of a song. But in a concert of several parts, all the clefs must be taken, not only in the relations, but also in the places of the system abovementioned, that every part may be comprehended in it.

The natural and artificial note expressed by the same letter, as *c* and *c* \sharp , are both set on the same line or space. When there is no character of flat or sharp, at the beginning with the clef, all the notes are natural; and if in any particular place the artificial note be required, it is denoted by the sign of a flat or sharp, set on the line a space before that note.

If a sharp or flat be placed at the beginning in any line or space with the clef, all the notes on that line or space are artificial ones; that is, are to be taken a semitone higher or lower than they would be without such sign. And the same affects all their octaves above and below, though they are not marked so. In the course of the song, if the natural note be sometimes required, it is signified by the character \natural .

CLEPSYDRA, a kind of water-clock, or an hour-glass serving to measure time by the fall of a certain quantity, commonly out of one vessel into another.—There have been also clepsydras made with quicksilver; and the term is also used for hour-glasses of sand.

By this instrument the Egyptians measured their time and the course of the sun. Also Tycho Brahé, in modern times, made use of it to measure the motion of the stars, &c.; and Dudley used the same contrivance in making all his maritime observations.

The use of clepsydras is very ancient. They were probably invented in Egypt under the Ptolemies; though some authors ascribe the invention of them to the Greeks, and others to the Romans. Pliny informs us, that Scipio Nasica, about 150 years before Christ, gave the first hint for the construction of them: and Pancirollus has particularly described them. According to his account, the clepsydra was a vessel made of glass, with a small hole in the bottom, edged with gold: in the upper part of this vessel

a line was drawn, and marked with the 12 hours: the vessel was filled with water, and a cork with a pin fixed in it floated on the surface, pointing to the first hour; and as the water sunk in the vessel by issuing out of the small hole, the pin indicated the other hours as it descended. The same kind of instruments were also used by the Hindus, for measuring time; and from the invention might come into all the countries westward from them. See my Tracts, vol. 2, p. 178.

Clepsydrae were chiefly used in the winter; as sun-dials served for the summer. They had however two great defects; the one, that the water ran out more or less easily, as the air was more or less dense; the other, that the water flowed more rapidly at the beginning, than towards the conclusion when its quantity and pressure were much decreased. Amontons has invented a clepsydra which, it is said, is free from both these inconveniences; and the same effect is produced by one described by Mr. Hamilton, in the Philos. Trans. vol. 44, pa. 171, or my Abridg. vol. 9, pa. 236. Varignon also, in the Memoires de l'Acad. 1699, delivers a general geometrical method of making clepsydrae, or water-clocks, with any kind of vessels, and with any given orifices for the water to run through.

Vitrivius, in lib. 9 of his Architecture, treats of these instruments; and Pliny in chap. 60, lib. 7, says that Scipio Nasica was the first who measured time at Rome by clepsydra, or water-clocks. Gesner, in his Pandects, pa. 91, gives several contrivances for these instruments. Solomon de Caus also treats on this subject in his Reasons of Moving Forces, &c. So also does Ozanam, in his Mathematical Recreations, in which is contained a Treatise on Elementary Clocks, translated from the Italian of Dominique Martinelli. There is likewise a treatise on Hour-Glasses by Arcangelo Maria Radi, called Nova Scienza de Horologi Polvere. See also the Technica Curiosa of Gasper Schottus; and Amontons Remarques et Experiences Physiques sur la Construction d'une nouvelle Clepsydre, exempt des défauts des autres.

CLERC (JOHN LE), a celebrated writer and universal scholar, was born at Geneva in 1657. After passing through the usual course of study at Geneva, he went to France in 1678; but returning the year after, he took holy orders. In 1682 Le Clerc visited England, to learn the language: but the smoky air of London not agreeing with his constitution, he soon returned to Holland, where he settled; and was appointed professor of philosophy, polite literature, and the Hebrew tongue, in the school at Amsterdam. Here he long continued to read lectures; for which purpose he drew up and published his Logic, Ontology, Pneumatology, and Natural Philosophy. He published also Ars Critica; a Commentary on the Old Testament; a Compendium of Universal History; an Ecclesiastical History of the first two centuries; a French translation of the New Testament, and other works. In 1686, he began, jointly with M. de la Crose, his Bibliotheque Universelle et Historique, in imitation of other literary journals; which was continued to the year 1693, making 26 volumes. In 1703 he commenced his Bibliotheque Choisie, and continued it to 1714, when he began another work on the same plan, called Bibliotheque Ancienne et Moderne, which he continued to the year 1728; all of them justly esteemed excellent stores of useful knowledge. He published also, in 1713, a small treatise on Practical Geometry, in 2 vols. small 8vo, called Pratique

de la Geometrie, sur le papier et sur le terrain. In 1728 he was seized with a palsy and fever; and after spending the last six years of his life with little or no understanding, he died in 1736, at 79 years of age.

CLIFF, in Music, the same as Clef, which see.

CLIMACTERIC, a critical year in a person's life.

According to some, this is every 7th year: but others allow it only to those years produced by multiplying 7 by the odd numbers 3, 5, 7, 9. These years, observe they, bring with them some remarkable change with respect to health, life, or fortune: the grand climacteric is the 63d year; but some add also the 81st to it: the other remarkable climacteries are the 7th, 21st, 35th, 49th, and 56th.

CLIMATE, or *Clime*, in Geography, a part of the surface of the earth bounded by two lesser circles parallel to the equator; and of such a breadth, as that the longest day in the parallel nearer the pole exceeds the longest day in that next the equator, by some certain space, as half an hour, or an hour, or a month.

The beginning of a climate, is a parallel circle in which the day is the shortest; and the end of the climate, is that in which the day is the longest. The climates therefore are reckoned from the equator to the pole; and are so many zones or bands, terminated by lines parallel to the equator: though, in strictness, there are several climates, or different degrees of light or temperature, in the breadth of one zone. Each climate only differs from its contiguous ones, in that the longest day in summer is longer or shorter, by half an hour, for instance, in the one place than in the other.

As the climates commence at the equator, at the beginning of the first climate, that is at the equator, the day is just 12 hours long; but at the end of it, or at the beginning of the 2d climate, the longest day is 12 hours and a half long; and at the end of the 2d, or beginning of the 3d climate, the longest day is 13 hours long; and so of the rest, as far as the polar circles, where the hour climates terminate, and month climates commence. And as an hour climate is a space comprised between two parallels of the equator, in the first of which the longest day exceeds that in the latter by an hour; so the month climate is a space contained between two circles parallel to the polar circles, and having its longest day longer or shorter than that of its contiguous one, by a month, or 30 days. But some authors, as Riccioli, make the longest day of the contiguous climates to differ by half hours, to about the latitude of 45 degrees; then to differ by an hour, or sometimes 2 hours, to the polar circle; and after that by a month each. See tables of climates in Varenius, chap. 25, prop. 13.

The ancients, who confined the climates to what they thought the habitable parts of the earth, reckoned only seven, the middles of which they made to pass through some remarkable places; as the 1st through Meroe, the 2d through Sienna, the 3d through Alexandria, the 4th through Rhodes, the 5th through Rome, the 6th through Pontus, and the 7th through the mouth of the Borysthenes. But the moderns, who have sailed further towards the poles, make 30 climates on each side.

Vulgarly the term climate is bestowed on any country or region differing from another either in respect of the seasons, the quality of the soil, or even the manners of the inhabitants; without any regard to the length of the longest day. Abulfeda, an Arabic author, distinguishes

the first kind of climates by the term Real Climates, and the latter by that of Apparent Climates.

CLOCK, a machine now constructed in such a manner, and so regulated by the uniform motion of a pendulum, as to measure time, and all its subdivisions, with great exactness. Before the invention of the pendulum, a balance, not unlike the fly of a kitchen-jack, was used instead of it.—They were at first called nocturnal dials, to distinguish them from sun-dials, which showed the hour by the shadow of the sun.

The invention of clocks with wheels is ascribed to Pacificus, archdeacon of Verona, in the 9th century, on the credit of an epitaph quoted by Ughelli, and borrowed by him from Panvinius. Others attribute the invention to Boethius, about the year 510.

Mr. Derham however reduces clock-work to a much older date; ranking Archimedes's sphere, made 200 years before Christ, as mentioned by Claudian, and that of Poseidonius, mentioned by Cicero, among machines of this kind: not that either their form or use were the same with those of modern mechanics; but that they had their motion from some hidden weights, or springs, with wheels or pulleys, or some such clock-work principle.

In the Disputationes Monasticæ of Benedictus Haëften, published in the year 1644, we are informed, that clocks were invented by Silvester IV, a monk of his order, about the year 998, as Dithmarus and Bozii have also shown; for before that time, they had nothing but sun-dials and clepsydrae for pointing out the hour.—Conrad Gesner, in his Epitome, pa. 604, says, that Richard Wallingford, an English abbot of St. Albans, who flourished in the year 1326, made a wonderful clock by a most excellent art, the like of which could not be produced by all Europe.—Moreri, under the word Horologe du Palais, observes, that Charles V, called the wise king of France, ordered at Paris the first large clock to be made by Henry de Vie, whom he sent from Germany, and set it upon the tower of his palace, in the year 1372.—John Froissart, in his Histoire et Chronique, vol. 2, ch. 28, says, the duke of Bourgogne had a clock, which sounded the hour, taken away from the city of Courtray, in the year 1382: and the same thing is said by Wm. Paradin, in his Annales de Bourgogne.

Clock-makers were first introduced into England in 1368, when Edward III granted a licence for three artists to come over from Delft in Holland, and practise their occupation in this country.

The water-clocks, or clepsydrae, and sun-dials, have both a much better claim to antiquity. The French annals mention one of the former kind, sent by Aaron king of Persia, to Charlemagne, about the year 807, which it would seem bore some resemblance to the modern clocks: it was of brass, and showed the hours by 12 little balls of the same metal, which at the end of each hour fell upon a bell, and made a sound. There were also figures of 12 cavaliers, which at the end of each hour came out through certain apertures, or windows, in the side of the clock, and shut them again, &c.

The invention of pendulum clocks is owing to the happy industry of the 17th century; and the honour of that discovery is disputed between Galileo and Huygens. The latter, who wrote an excellent volume on the subject, declares it was first put in practice in the year 1657, and the description of it printed in 1658. Becher, De Nova

Temporis dimetiendi Theoria, anno 1680, contends for Galileo; and relates, though at second-hand, the whole history of the invention; adding that one Treliar, clock-maker to the father of the then grand duke of Tuscany, made the first pendulum clock at Florence, under the direction of Galileo Galilei, a pattern of which was brought to Holland. And the Academy del Cimento expressly observes, that the application of the pendulum to the movement of a clock was first proposed by Galileo, and put in practice by his son Vicenzo Galilei, in 1649. But whoever may have been the inventor, it is certain that the invention never flourished till it came into the hands of Huygens, who insists, that if ever Galileo thought of such a thing, he never brought it to any degree of perfection. The first pendulum clock made in England was in the year 1662, by one Fromantil, a Dutchman.

Among the modern clocks, those of Strasburg and Lyons are very eminent for the richness of their furniture, and the variety of their motions and figures. In the former, a cock claps his wings, and proclaims the hour: the angel opens a door, and salutes the Virgin, &c. In the latter, two horsemen encounter, and beat the hour upon each other: a door opens, and there appears on the theatre the Virgin, with Jesus in her arms; the Magi, with their retinue, marching in order, and presenting their gifts; two trumpeters sounding all the while to proclaim the procession.

These however are far excelled by two that have lately been made by English artists, as a present from the East-India company to the emperor of China. These two clocks are in the form of chariots, in each of which a lady is placed, in a fine attitude, leaning her right hand on a part of the chariot, under which appears a clock of curious workmanship, little larger than a shilling, that strikes and repeats, and goes for eight days. On the lady's finger sits a bird, finely modelled, and set with diamonds and rubies, with its wings expanded in a flying posture, and actually flutters for a considerable time, on touching a diamond button below it; the body of the bird, in which are contained part of the wheels that animate it as it were, is less than the 16th part of an inch. The lady holds in her left-hand a golden tube little thicker than a large pin, on the top of which is a small round box, to which is fixed a circular ornament not larger than a sixpence, set with diamonds, which goes round in three hours in a constant regular motion. Over the lady's head is a double umbrella, supported by a small fluted pillar not thicker than a quill, and under the larger of which a bell is fixed at a considerable distance from the clock, with which it seems not to have any connexion; but from which a communication is secretly conveyed to a hammer, that regularly strikes the hour, and repeats the same at pleasure, by touching a diamond button fixed to the clock below. At the feet of the lady is a golden dog; before which, from the point of the chariot, are two birds fixed on spiral springs, the wings and feathers of which are set with stones of various colours, and they appear as if flying away with the chariot, which, from another secret motion, is contrived to run in any direction, either straight or circular, &c; while a boy, that lays hold of the chariot behind, appears also to push it forwards. Above the umbrella are flowers and ornaments of precious stones; and it terminates with a flying dragon set in the same manner. The whole is of gold, most curiously executed, and embellished with rubies and pearls.

The ingenious Dr. Franklin contrived a clock to show the hours, minutes, and seconds, with only three wheels and two pinions in the whole movement. The dial-plate had the hours engraven on it in spiral spaces along two diameters of a circle, containing four times 60 minutes. The index goes round in four hours, and points out the minutes from any hour by which it has passed to the next following hour. The small hand, in an arch at top, goes round once in a minute, and shows the seconds. The clock is wound up by a line going over a pulley, on the axis of the great wheel, like a common 30-hour clock. Many of these very simple machines have since been constructed, that measure time exceedingly well. This clock is subject, however, to the inconvenience of requiring frequent winding, by drawing up the weight; as also to some uncertainty as to the particular hour shown by the index.

Mr. Ferguson proposed to remedy these inconveniences by another construction, which is described in his Select Exercises, pa. 4. This clock will go a week without winding, and always shows the precise hour; but, as Mr. Ferguson acknowledges, it has two disadvantages which do not belong to Dr. Franklin's clock: when the minute hand is adjusted, the hour plate must also be set right, by means of a pin: and the smallness of the teeth in the pendulum wheel will cause the pendulum ball to describe but small arcs in its vibrations; and therefore the momentum of the ball will be less, and the times of the vibrations will be more affected by any unequal impulse of the pendulum wheel on the pallets. Beside, the weight of the flat ring, on which the seconds are engraven, will load the pivots of the axis of the pendulum wheel with a great deal of friction, which ought by all possible means to be avoided. To remedy this inconvenience, the seconds plate might be omitted:

Mr. Ferguson also contrived a clock, showing the apparent diurnal motions of the sun and moon, the age and phases of the moon, with the time of her coming to the meridian, and the times of high and low water; and all this by having only two wheels and a pinion added to the common movement. See his Select Exercises before mentioned. In this clock the figure of the sun serves as an hour index, by going round the dial-plate in 24 hours; and a figure of the moon goes round in 24 h. 50 $\frac{1}{2}$ min. the time of her going round in the heavens from any meridian to the same meridian again. A clock of this kind was adapted by Mr. Ferguson to the movement of an old watch. See also a description and drawing of an astronomical clock, showing the apparent daily motions of the sun, moon, and stars, with the times of their rising, southing, and setting; the places of the sun and moon in the ecliptic, and the age and phases of the moon for every day in the year, in the same book, p. 19.

There have been several treatises upon clocks; the principal of which are the following: Hieronymus Cardan, de Varietate Rerum, libri 17.—Conrade Dasypodius, Descriptio Horologii Astronomici Argentinensis in summa Templo erecti.—Guido Pancirollus, Antiqua desperita et nova reperta.—L'Usage du Cadran, ou de l'Horloge Physique Universelle, par Gahilée, Mathematicien du Duc de Florence.—Oughtred's Opuscula Mathematica.—Huygens's Horologium Oscillatorium.—Pendule perpetuelle, par l'Abbé de Hautefeuille.—J. J. Becheri Theoria et Experiencia de nova Temporis dimetandi Ratione et Horologiorum Constructione.—Clark's Oughtredus explicatus, ubi de Constructione Horologiorum.—Horological

Disquisitions.—Huygens's Posthumous Works.—Sully's Règle Artificielle du Temps, &c.—Servière's Recueil d'Ouvrages Curieux.—Derham's Artificial Clock-maker.—Camus's Traité des Forces Mouvantes.—Alexandre's Traité Général des Horologies.—Also Treatises and Principles of Clock-making, by Hatton, Cuning, &c., &c.

CLOUD, a visible collection of vapours, suspended in the atmosphere.

Though it be generally allowed that the clouds are formed from the aqueous vapours, which before were so closely united with the atmosphere as to be invisible; it is however not easy to account for the long continuance of some very opaque clouds without dissolving; or to assign the reason why the vapours, when they have once begun to condense, do not continue to do so till they at last fall to the ground in the form of rain or snow, &c. It is now known, that a separation of the latent heat from the water, of which vapour is composed, is attended with a condensation of that vapour in some degree; in such case, it will first appear as a smoke, mist, or fog; which, if interposed between the sun and earth, will form a cloud; and the same causes continuing to operate, the cloud will produce rain or snow. It is however abundantly evident that some other cause, besides mere heat or cold, is concerned in the formation of clouds, and the condensation of atmospherical vapours. This cause is esteemed in a great measure the electrical fluid: indeed electricity is now so generally admitted as an agent in all the great operations of nature, that it is no wonder to find the formation of clouds attributed to it; and this has accordingly been given by Beccaria as the cause of the formation of all clouds whatsoever, whether of thunder, rain, hail, or snow.

Büt whether the clouds are produced, that is, the atmospheric vapours rendered visible, by means of electricity or not, it is certain that they do often contain the electric fluid in prodigious quantities, and many terrible and destructive accidents have been occasioned by clouds very highly electrified. The most extraordinary instance of this kind perhaps on record happened in the island of Java, in the East-Indies, in August, 1772. On the 11th of that month, at midnight, a bright cloud was observed covering a mountain in the district called Cheribou, and several reports like those of a gun were heard at the same time. The people who dwelt on the upper part of the mountain not being able to fly fast enough, a great part of the cloud, eight or nine miles in circumference, detached itself under them, and was seen at a distance, rising and falling like the waves of the sea, and emitting globes of fire so luminous, that the night became as bright as day. The effects of it were astonishing; every thing was destroyed for 20 miles round; the houses were demolished; plantations were buried in the earth; and 2140 people lost their lives, besides 1500 head of cattle, and a vast number of horses, goats, &c. Another remarkable instance of the dreadful effects of electric clouds, which happened at Malta the 29th of October 1757, is also related in Brydone's Tour through Malta.

The height of the clouds is not usually great; the summits of high mountains being commonly quite free from them, as many travellers have experienced in passing these mountains. It is found that the most highly electrified clouds descend lowest, their height being often not more than 7 or 800 yards above the earth's surface; and sometimes thunder-clouds appear actually to touch the ground

with one of their edges; but the generality of clouds are suspended at the height of a mile, or little more, above the earth.

The motions of the clouds, though often directed by the wind, are not always so, especially when thunder is about to ensue. In this case they are seen to move very slowly, or even to appear quite stationary for some time. The reason of this probably is, that they are impelled by two opposite streams of air nearly of equal strength; and in such cases it appears that both the aerial currents ascend to a considerable height; for Messrs. Charles and Robert, while endeavouring to avoid a thunder-cloud, in one of their aerial voyages with a balloon, could find no alteration in the course of the current, though they ascended to the height of 4000 feet above the earth. In some cases the motions of the clouds evidently depend on their electricity, independent of any current of air whatever. Thus, in a calm and warm day, small clouds are often seen meeting each other in opposite directions, and setting out from such short distances, that it cannot be supposed that any opposite winds are the cause. Such clouds, when they meet, instead of forming a larger one, become much smaller, and sometimes entirely vanish; a circumstance most probably owing to the discharge of opposite electricities into each other. And this serves also to throw some light on the true cause of the formation of clouds; for if two clouds, the one electrified positively, and the other negatively, destroy each other on contact, it follows that any quantity of vapour suspended in the atmosphere, will, while it retains its natural quantity of electricity, remain invisible, but becomes a cloud when electrified either plus or minus.

The shapes of the clouds are also probably owing to their electricity; for in those seasons in which a great commotion has been excited in the atmospherical electricity, the clouds are seen assuming strange and whimsical forms, that are continually varying. This, as well as the meeting of small clouds in the air, and vanishing upon contact, is a sure indication of thunder.

The uses of the clouds are evident, as from them proceeds the rain that fructifies the earth, and without which, according to the present state of nature, the whole surface of the earth would soon become a mere desert. They are also useful as a screen interposed between the earth and the scorching rays of the sun, which are often so powerful as to destroy the grass and other tender vegetables. In the more secret operations of nature also, where the electric fluid is concerned, the clouds bear a principal share; and chiefly serve as a medium for conveying that fluid from the atmosphere into the earth, and from the earth into the atmosphere: in doing which, when electrified to a great degree, they sometimes produce very terrible effects; an instance of which is related above. See the articles ATMOSPHERICAL ELECTRICITY, EVAPORATION, RAIN, &c.

CLOUDS, in Artillery, are thin plates of iron nailed on that part of the axle-tree of a gun-carriage which comes through the nave, and through which the linspin goes.

CLUVIER, or CLUVERIUS, (PHILIP), a celebrated geographer, was born at Dantzig in 1580. After an education at home, he travelled into Poland, Germany, and the Netherlands, to improve himself in the knowledge of the law. But, when at Leyden, Joseph Scaliger persuaded him to give way to his genius for geography. In pursuance of this advice, Cluverius visited the greatest part of the European states. He was well skilled in many lan-

guages, speaking ten with facility, viz, Greek, Latin, German, French, English, Dutch, Italian, Hungarian, Polish, and Bohemian. On his return to Leyden, he taught there with great applause; and died in 1623, being only 43 years of age, justly esteemed the first geographer who had put his researches in order, and reduced them to certain principles. He was author of several ingenious works in geography, viz:

1. De Tribus Rheni Alveis.
2. Germania Antiqua.
3. Italia Antiqua, Sicilia, Sardinia, et Corsica.
4. Introductio in Universam Geographiam.

COASTING, is that part of Navigation in which the places are not far asunder, so that a ship may sail in sight of land, or within soundings, between them.

COCHLEA, one of the five Mechanical powers, otherwise called the Screw; being so named from the resemblance a screw bears to the spiral shell of a snail, in Latin Cochlea. See SCREW, and MECHANICAL POWERS.

COCK of a Dial, the pin, stile, or gnomon.

COEFFICIENTS, in Algebra, are numbers, or given quantities, usually prefixed to letters, or unknown quantities, by which it is supposed they are multiplied; and so, with such letters, or quantities, making a product, or coefficient production; whence the name.

Thus, in $3a$ the coefficient is 3, in br it is b , and in cr^2 it is c . If a quantity have no number prefixed, unity or 1 is understood; as a is the same as $1a$, and bc the same as $1bc$. The name coefficient was first given by Vieta.

In any equation so reduced as that its highest power or term has 1 for its coefficient; then the coefficient of the 2d term is equal to the sum of all the roots, both positive and negative; so that if the 2d term is wanting in an equation, the sum of the positive roots of that equation is equal to the sum of the negative roots, as they mutually balance and cancel each other. Also the coefficient of the 3d term of an equation is equal to the sum of all the rectangles arising by the multiplication of every two of the roots, how many ways soever they can be combined by twos; as once in the quadratic, 3 times in the cubic, 6 times in the biquadratic equation, &c. And the coefficient of the 4th term of an equation, is the sum of all the solids made by the continual multiplication of every three of the roots, how often soever such a ternary can be had; as once in a cubic, 4 times in a biquadratic, 10 times in an equation of 5 dimensions, &c. And thus it goes on infinitely.

COEFFICIENTS of the same Order, is a term sometimes used for the coefficients prefixed to the same unknown quantities, in different equations.

$$\begin{cases} ax + by + cz = m, \\ dx + ey + fz = n, \\ gx + hy + kz = p, \end{cases}$$

the coefficients a, d, g , are of the same order, being the coefficients of the same letter x ; also b, e, h , are of the same order, being the coefficients of y ; and so on.

Opposite COEFFICIENTS, such as are taken each from a different equation, and from a different order of coefficients. Thus, in the foregoing equations, a, e, k , or a, h, f , or d, b, k , &c, are opposite coefficients.

CELESTIAL. See CELESTIAL.

COFFER, in Architecture, a square depression or sinking, in each interval between the modillions of the Corinthian cornice; usually filled up with a rose; sometimes with a pomegranate, or other enrichment.

COFFER, in Fortification, denotes a hollow lodgment, athwart a dry moat, 6 or 7 feet deep, and 16 or 18 broad. The upper part of it is made of pieces of timber, raised 2 feet above the level of the moat; the elevation having hurdles laden with earth for its covering, and serving as a parapet with embrasures.

The coffer is nearly the same with the caponiere, excepting that this last is sometimes made beyond the counterscarp on the glacis, and the coffer always in the moat, taking up its whole breadth, which the caponiere does not. It differs from the traverse and gallery, in that these are made by the besiegers, and the coffer by the besieged.

The besieged commonly make use of coffers to repulse the besiegers, when they endeavour to pass the ditch. And, on the other hand, the besiegers, to save themselves from the fire of these coffers, throw up the earth on that side towards the coffer.

COFFER-DAMS, or Batardeaux, in Bridge-building, are inclosures formed for laying the foundation of piers, and for other works in water, to exclude the surrounding water, and so prevent it from interrupting the workmen.

These inclosures are sometimes single, and sometimes double, with clay rammed between them; sometimes they are made with piles driven close together, and sometimes the piles are notched or dove-tailed into one another; but the most usual method is, to drive piles with grooves in them, at the distance of five or six feet from each other, and then boards are let down between them, after which the water is pumped out.

COGESHALL'S Sliding-Rule, an instrument used in Gauging, and so called from its inventor. See the description and use under *SLIDING-RULE*.

COHESION, in Natural Philosophy, as distinguished from adhesion, is that species of attraction which, uniting particle to particle, retains together the component parts of the same mass or kind. Or it is that action or power by which the homogeneous particles of bodies are kept attached to each other.

This power was first considered by Newton as one of the properties essential to all matter, and the cause of all that variety observed in the texture of different terrestrial bodies. He does not attempt to investigate the nature of this power, but wisely contents himself with calling it a mutual attraction peculiar to the particles of matter. His words are as follow: "The particles of all hard homogeneous bodies, which touch one another, cohere with a great force; to account for which, some philosophers have recourse to a kind of hooked atoms, which in effect is nothing else but to beg the thing in question. Others imagine that the particles of bodies are connected by rest, i.e. in effect by nothing at all; and others by conspiring motions, i.e. by a relative rest among themselves. For myself, it rather appears to me, that the particles of bodies cohere by an attractive force, whereby they tend mutually toward each other: which force, in the very point of contact, is very great; at little distances is less, and at a little farther distance is quite insensible."

It is uncertain in what proportion this force decreases as the distance increases: Desaguliers conjectures, from some phenomena, that it decreases as the biquadratic or 4th power of the distance, so that at twice the distance it acts 16 times more weakly, &c.

"Now if compound bodies be so hard, as by experience we find some of them to be, and yet have a great many hidden pores within them, and consist of parts only laid

together; no doubt those simple particles which have no pores within them, and which were never divided into parts, must be vastly harder. For such hard particles, gathered into a mass, cannot possibly touch in more than a few points; and therefore much less force is required to sever them, than to break a solid particle, whose parts touch throughout all their surfaces, without any intermediate pores or interstices. But how such hard particles, only laid together, and touching only in a few points, should come to cohere so firmly, as in fact we find they do, is inconceivable; unless there be some cause, whereby they are attracted and pressed together. Now the smallest particles of matter may cohere by the strongest attractions, and constitute larger, whose attracting force is feebler: and again, many of these larger particles cohering, may constitute others still larger, whose attractive force is still weaker; and so on for several successions, till the progression end in the biggest particle, on which the operations in chemistry, and the colours of natural bodies depend; and which by cohering compose bodies of a sensible magnitude."

Again, the opinion maintained by many, is that which is so strongly defended by J. Bernoulli, De Gravitate Ætheris; who attributes the cohesion of the parts of matter to the uniform pressure of the atmosphere: confirming this opinion by the known experiment of two polished marble planes, which cohere very strongly in the open air, but easily drop asunder in an exhausted receiver. However, if two plates of this kind be smeared with oil, to fill up the pores in their surfaces, and prevent the lodgment of air, and one of them be gently rubbed upon the other, they will adhere so strongly, even when suspended in an exhausted receiver, that the weight of the lower plate will not be able to separate it from the upper one. And though this theory might serve tolerably well to explain the cohesion of compositions, or greater collections of matter; yet it falls far short of accounting for that first cohesion of the atoms, or primitive corpuscles, of which the particles of hard bodies are composed; for a body does not fall in pieces in the exhausted receiver.

Again, some philosophers have positively asserted, that the powers, or means, are immaterial, by which matter coheres; and, in consequence of this supposition, they have so refined upon attractions and repulsions, that their systems appear but little short of scepticism, or denying the existence of matter altogether. A system of this kind is adopted by Dr. Priestley, from Messrs. Boscovich and Michell, to solve some difficulties concerning the Newtonian doctrine of light. See his History of Vision, vol. 1, pa. 392. "The easiest method," says Priestley, "of solving all difficulties, is to adopt the hypothesis of Mr. Boscovich, who supposes that matter is not impenetrable, as has been perhaps universally taken for granted; but that it consists of physical points only, endowed with powers of attraction and repulsion in the same manner as solid matter is generally supposed to be: provided therefore that any body moves with a sufficient degree of velocity, or has a sufficient momentum to overcome any powers of repulsion that it may meet with, it will find no difficulty in making its way through any body whatever; for nothing else will penetrate each other but powers, such as we know do in fact exist in the same place, and counterbalance or over-rule each other. The most obvious difficulty, and indeed almost the only one, that attends this hypothesis, as it supposes the mutual penetrability of

matter, arises from the idea of the nature of matter, and the perplexity we meet with in attempting to force two bodies into the same place. But it is demonstrable, that the first obstruction arises from no actual contact of matter, but from mere powers of repulsion. This difficulty we can overcome; and having got within one sphere of repulsion, we fancy that we are now impeded by the solid matter itself. But the very same is the opinion of the generality of mankind with respect to the first obstruction. Why, therefore, may not the next be another sphere of repulsion, which may only require a greater force than we can apply to make it yield without disordering the arrangement of the constituent particles; but which may be overcome by a body moving with the astonishing velocity of light?"

Other philosophers have supposed that the powers, both of gravitation and cohesion, are material; and that they are only different actions of the ethereal fluid, or elementary fire. In proof of this doctrine, they allege the experiment with the Magdeburg hemispheres, as they are called. The pressure of the atmosphere, we know, is, in this case, capable of producing a very strong cohesion; and if there be in nature any fluid more penetrating, as well as more powerful in its effects, than the air we breathe, it is possible that what is called the attraction of cohesion may in some measure be an effect of the action of that fluid. Such a fluid as this is the element of fire. Its activity is such as to penetrate all bodies whatever: and in the state in which it is commonly called fire, it acts according to the quantity of solid matter contained in the body. In this state it is capable of dissolving the strongest cohesions observed in nature. Fire, therefore, being able to dissolve cohesions, must also be capable of causing them, provided its power be exerted for that purpose, which possibly it may be, when we consider its various modes or appearances, viz, as fire or heat, in which state it consumes, destroys, and dissolves; or as light, when it seems deprived of that destructive power; and as the electric fluid, when it attracts, repels, and moves bodies, in a great variety of ways. In the Philos. Trans. for 1777 this hypothesis is noticed, and in some measure adopted by Mr. Henley. "Some gentlemen (he observes) have supposed that the electric matter is the cause of the cohesion of the particles of bodies. If the electric matter be, as I suspect, a real elementary fire inherent in all bodies, that opinion may probably be well founded; and perhaps the soldering of metals, and the cementation of iron, by fire, may be considered as strong proofs of the truth of their hypothesis."

But whatever the cause of cohesion may be, its effects are evident and certain. The different degrees thereof, constitute bodies of different forms and properties. Thus, Newton observes, the particles of fluids, which do not cohere too strongly, and are small enough to render them susceptible of those agitations which keep liquors in a fluor, are most easily separated and rarefied into vapour, and make what the chemists call volatile bodies; being rarefied with an easy heat, and again condensed with a moderate cold. Those that have grosser particles, and so are less susceptible of agitation, or cohere by a stronger attraction, are not separable without a greater degree of heat; and some of them not without fermentation; and these constitute what the chemists call fixed bodies.

Air, in its fixed state, possesses the interstices of solid

substances, and probably serves as a bond of union to their constituent parts; for when these parts are separated, the air is discharged, and recovers its elasticity. And this kind of attraction is evinced by a variety of familiar experiments; as, by the union of two contiguous drops of mercury; by the mutual approach of two pieces of cork, floating near each other in a basin of water; by the adhesion of two leaden balls, whose surfaces are scraped and joined together with a gentle twist, which is so considerable, that, if the surfaces are about a quarter of an inch in diameter, they will not be separated by a weight of 100 lb. by the ascent of oil or water between two glass planes, so as to form the hyperbolic curve, when they are made to touch on one side, and kept separate at a small distance on the other; by the depression of mercury, and by the rise of water in capillary tubes, and on the sides of glass vessels; also in sugar, sponge, and all porous substances. And where this cohesive attraction ends, a power of repulsion begins.

To determine the force of Cohesion, in a variety of different substances, many experiments have been made, and particularly by Professor Muschenbroek. The adhesion of polished planes, about two inches in diameter, heated in boiling water, and smeared with grease, required the following weights to separate them:

Plane of Glass	Cold Grease	Hot Grease
Brass	130 lb	300 lb
Copper	150	800
Marble	200	850
Silver	225	600
Iron	150	250
	300	950

But when the brass planes were made to adhere by other sorts of matter, the results were as in the following table:

With Water	-	-	12 oz
Oil	-	-	18
Venice Turpentine	-	-	24
Tallow Candle	-	-	800
Rosin	-	-	850
Pitch	-	-	1400

In estimating the Absolute Cohesion of solid pieces of bodies, he applied weights to separate them according to their length: his pieces of wood were long square parallelopipeds, each side of which was .26 of an inch, or about $\frac{1}{4}$, and they were drawn asunder by the following weights:

Fir	-	-	600 lb
Elm	-	-	950
Alder	-	-	1000
Linden-tree	-	-	1000
Oak	-	-	1150
Beech	-	-	1250
Ash	-	-	1250

He tried also wires of metal, 1-10th of a Rhineland inch in diameter: the metals and weights were as follows:

Of Lead	-	-	29 $\frac{1}{2}$ lb
Tin	-	-	40 $\frac{1}{2}$
Copper	-	-	29 $\frac{1}{2}$
Yellow Brass	-	-	360
Silver	-	-	370
Iron	-	-	450
Gold	-	-	500

He then tried the Relative Cohesion, or the force with which bodies resist an action applied to them in a direction

perpendicular to their length. For this purpose he fixed pieces of wood by one end into a square hole in a metal plate, and hung weights towards the other end, till they broke at the hole: the weights and distances from the hole are exhibited in the following table:

	Distance	Weight
Pine	- 9½ inc.	- 36½ oz.
Fir	- 9	- 40
Beech	- 7	- 56½
Elm	- 9	- 44
Oak	- 8½	- 48
Alder	- 9½	- 48

See his *ELEM. NAT. PHILOS.* cap. 19.

The inquisitive reader may further consult Ritter on Cohesion; Gilbert's Journal, iv, 1; Benzenberg on Cohesion, xvi, 76; Fontana on Solidity and Fluidity, Soc. Ital. i, 89; and Dr. T. Young on the Cohesion of Fluids, in the *Philos. Trans.* 1805, or in the 2d vol. of his *Nat. Philos.*

COIGNET (MICHAEL), a writer on navigation, and a native of Antwerp, who flourished in the latter part of the 16th century, and died in 1623. He published a work on navigation in the Flemish language; which was afterwards enlarged, and published in French, under the title of "Instruction nouvelle des Points plus excellents et nécessaires touchant l'Art de Naviger." This served as a supplement to Medina's book on the same subject, whose mistakes are well exposed by Coignet. In treating of the sun's declination, he took notice of the gradual decrease in the obliquity of the ecliptic, a point long disputed, but now settled from the theory of attraction, as well as long observation. He also described the cross-staff with three transverse pieces, which he mentioned as being then in common use among mariners; but he preferred that of Gemma Frisius. He mentioned likewise some instruments of his own invention, which however are now quite disused. As the old sea-table, above noticed, erred more and more in advancing towards the poles, he set down another, to be used by such as sailed beyond the 60th degree of latitude. At the end of the book is delivered a method of sailing on a parallel of latitude, by means of a ring dial, and a 24-hour glass; on which the author very much values himself.

COLD, the privation of heat, or the opposite to it.

As it is supposed that heat consists in a particular motion of the parts of a hot body, hence the nature of cold, which is its opposite, is deduced; for it is found that cold extinguishes, or rather abates heat; hence it would seem to follow, that those bodies are cold, which check and restrain the motion of the particles in which heat consists.

In general, cold contracts most bodies, and heat expands them: though there are some instances to the contrary, especially in the extreme cases or states of these qualities of bodies. Thus, though iron, in common with other bodies, expand with heat, yet, when melted, it is always found to expand in cooling again. So also, though water always is found to expand gradually as it is heated, and to contract as it cools, yet in the act of freezing, it suddenly expands again, and that with a most enormous force, capable of rending rocks, or bursting the very thick shells of metal, &c. A computation of the force of freezing water has been made by the Florentine Academicians, from the bursting of a very strong brass globe or shell, by freezing water in it; when, from the known thickness and tenacity of the metal, it was found that the

expansive power of a spherule of water only one inch in diameter, was sufficient to overcome a resistance of more than 27,000 pounds, or 13 tons and a half. See also experiments on bursting thick iron mortar-shells by freezing water in them, by Major Edward Williams of the Royal Artillery, in the *Edinb. Philos. Trans.* vol. 2.

Such a prodigious power of expansion, almost double that of the most powerful steam-engines, and exerted in so small a mass, seemingly by the force of cold, was thought a very powerful argument in favour of those who supposed that cold, like heat, is a positive substance. Dr. Black's discovery of latent heat, however, has now afforded a very easy and natural explication of this phenomenon. He has shown, that, in the act of congelation, water is not cooled more than it was before, but rather becomes warmer: that as much heat is discharged, and passes from a latent to a sensible state, as, had it been applied to water in its fluid state, would have heated it to 135°. In this process, the expansion is occasioned by a great number of minute bubbles suddenly produced. Formerly these were conjectured to be cold in the abstract; and to be so subtle, that, insinuating themselves into the substances of the fluid, they augmented its bulk, at the same time that, by impeding the motion of its particles on each other, they changed it from a fluid to a solid. But Dr. Black shows that these are only air extricated during the congelation; and to the extrication of which he ascribes the great expansive force exerted by freezing water. The only question therefore now remaining, is, by what means this air comes to be extricated, and to take up more room than it naturally does in the fluid. To this it may be answered, that perhaps part of the heat which is discharged from the freezing water, combines with the air in its unelastic state, and, by restoring its elasticity, gives it that extraordinary force, as is seen also in the case of air suddenly extricated in the explosion of gunpowder.

Cold also usually tends to make bodies electric, which are not so naturally, and to increase the electric properties of such as are so. And it is farther found, that all substances do not transmit cold with equal facility; but that the best conductors of electricity, viz, metals, are also the best conductors of cold. It may farther be added, that when cold has been carried to such an extremity as to render any body an electric, it then ceases to conduct the cold so well as before. This is exemplified in the practice of the Laplanders and Siberians; where, to exclude the extreme cold of the winters from their habitations the more effectually, and to admit at the same time a small portion of light, they cut pieces of ice, which in the winter season must always be electric in those countries, and place them in their windows; which they find to be much more effectual in keeping out the cold, than any other substance.

Cold is the destroyer of all vegetable life, when increased to an excessive degree. It is found that many garden plants and flowers, which seem to be very stout and hardy, go off at a little increase of cold beyond the ordinary standard. And in severe winters, nature has provided the best natural defence for the corn-fields and gardeus, by a covering of snow, which preserves such parts green and healthy as are under it, while such as are not covered by it are either killed or greatly injured.

Dr. Clarke is of opinion, that cold is owing to certain nitrous, and other saline particles, endued with particular

figures proper to produce such effects. Hence, sal-ammoniac, saltpetre, or salt of urine, and many other volatile and alkalize salts, mixed with water, very much increase its degree of cold. In the Philos. Trans. number 274, M. Geoffroy relates some remarkable experiments with regard to the production of cold. Four ounces of sal-ammoniac dissolved in a pint of water, made his thermometer descend 2 inches and $\frac{1}{2}$ in less than 15 minutes. An ounce of the same salt put into 4 or 5 ounces of distilled water, made the thermometer descend 2 inches and $\frac{1}{2}$. Half an ounce of sal-ammoniac mixed with 3 ounces of spirit of nitre, made the thermometer descend 2 inches and $\frac{1}{2}$; but, on using spirit of vitriol instead of nitre, it sunk 2 inches and $\frac{1}{2}$. In this last experiment it was remarked, that the vapours raised from the mixture had a considerable degree of heat, though the liquid itself was so extremely cold. Four ounces of saltpetre mixed with a pint of water, sank the thermometer an inch and $\frac{1}{2}$; but a like quantity of sea salt sank it only $\frac{1}{2}$ of an inch. Acids always produced heat, even common salt with its own spirit. Volatile alkaline salts produced cold in proportion to their purity, but fixed alkalies heat.

But a far greater degree of cold produced by the mixture of salts and aqueous fluids, was that shown by Homberg; who gives the following receipt for making the experiment: Take a pound of corrosive sublimate, and as much sal-ammoniac; powder them separately, and mix the powders well; put the mixture into a phial, pouring upon it a pint and a half of distilled vinegar, shaking all well together. This composition becomes so cold, that it can scarce be held in the hand in summer; and it happened, as M. Homberg was making the experiment, that the matter froze. The same thing once happened to M. Geoffroy, in making an experiment with sal-ammoniac and water, but it never was in his power to make it succeed a second time.

If, instead of making these experiments with fluid water, it be taken in its congealed state of ice, or rather snow, degrees of cold will be produced greatly superior to any that have yet been mentioned. A mixture of snow and common salt sinks a Fahrenheit's thermometer to 0; potashes and pounded ice sank it 8 degrees farther; two affusions of spirit of salt on pounded ice, sank it 14 $\frac{1}{2}$ below 0; and by repeated affusions of spirit of nitre M. Fahrenheit sank it to 40° below 0. This is the ultimate degree of cold which the mercurial thermometer will measure; for the mercury itself begins then to congeal; and therefore recourse must afterwards be had to spirit of wine, naphtha, or some other fluid that will not congeal. The greatest degree of cold hitherto produced by artificial means, has been 80° below 0; which was done at Hudson's Bay by means of snow and vitriolic acid, the thermometer standing naturally at 20° below 0. Indeed greater degrees of cold than this have been supposed: Mr. Martin, in his Treatise on Heat, relates, that at Kirenga in Siberia, the mercurial thermometer sunk to 118° below 0; and Professor Braun at Petersburg, when he made the first experiment of congealing quicksilver, fixed the point of congelation at 350° below 0; but from later experiments it has been more accurately determined, that 40° below 0 is the freezing point of quicksilver.

The most remarkable experiment however was made by Mr. Walker of Oxford, with spirit of nitre poured on Glauber's salt, the effect of which was found to be similar to that of the same spirit poured on ice or snow; and the

addition of sal-ammoniac rendered the cold still more intense. The proportions of these ingredients recommended by Mr. Walker, are concentrated nitrous acid two parts by weight, water one part; of this mixture, cooled to the temperature of the atmosphere, 18 ounces; and of Glauber's salt, a pound and a half avoidupoise; and of sal-ammoniac, 12 ounces. On adding the Glauber's salt to the nitrous acid, the thermometer fell 52°, viz., from 50 to -2; and on the addition of the sal-ammoniac it fell to -9. Thus Mr. Walker was able to freeze quicksilver without either ice or snow, when the thermometer stood at 45°, viz., by putting the ingredients in 4 different pans, and inclosing these within each other.

Excessive degrees of cold also occur naturally in many parts of the globe in the winter season.

Though the thermometer in this country seldom descends so low as 0, yet in the winter of 1780, Mr. Wilson of Glasgow observed, that a thermometer laid on the snow sunk to 25° below 0; and Mr. Derham, in the year 1708, observed in England, that the mercury stood within one-tenth of an inch of its station when plunged into a mixture of snow and salt. At Petersburg, in 1732, the thermometer stood at 28° below 0; and when the French academicians wintered near the polar circle, they observed the thermometer at 33° below 0; and in the Asiatic and American continents still greater degrees of cold are often observed. Lately, Professor Leslie, of Edinburgh, has frozen water, merely by evaporation in the exhausted receiver of an air-pump; and, it is said, he can freeze mercury in the same way. Mercury has also been frozen by Dr. Marcell, by the evaporation of ether. See Nicholson's Journal, v. 34, pa. 119; also the article FREEZING in this Dictionary. Further, a paper of Dr. Marcell's was read at the Royal Society, July 8, 1813, on the intense degree of cold produced by the sulphuret of carbon. From the author's experiments it appears that this liquor is the most evaporable of all known fluids, or at least to produce, by its evaporation, the most intense degree of cold. If the bulb of a spirit-thermometer, closely enveloped in fine flannel, or cotton wool, be moistened with the fluid, its temperature falls to about 0; but if the thermometer be exposed to the effect of a vacuum, by being enclosed in the receiver of a good air-pump, it sinks to -80°, in a minute or two. The congelation of mercury in glass tubes may therefore be most quickly and easily performed by this process at all seasons, and under any atmospheric temperature.

In the last bulletin of the retreat of the French from Moscow, in November and December 1812, the cold, there stated at 16 and 18 below freezing, is perhaps to be understood as being on the scale of Reaumur. The thermometer most in use through England is Fahrenheit's; and upon that scale the cold above mentioned by the French would be from 8 to 11 below zero; a degree in England very rarely known, but common enough amidst the horrors of Russia; where, in 1773, the Empress Catharine made the famous experiment on the ordnance shell, of the largest diameter, 18 inches. The shell was filled with water, in her presence, as she states, and in less than an hour the whole was so frozen as to burst, and with no small explosion!—“Avec beaucoup de fracas!” Some few years before, there had been another curious experiment by Prince Orloff, who, in a foundation for a massy brick coach gateway to his court-yard, in a soil so loose and wet, that piles must have been driven, filled so many corresponding cavities with water, on which, when turned by the frost into

columns, he raised the projected superstructure ! And at that time (1773) it had lasted four years, and so might be likely to last for ever ! The words of the report are, "Une porte cochère voutée en briques, et très solide ! Elle existe depuis quatre ans ; et elle existera, je crois, jusqu'à ce qu'on l'abatte!"

The effects of these extreme degrees of cold are very surprising. Trees are burst, rocks rent, and rivers and lakes frozen several feet deep; metallic substances blister the skin, like red-hot iron: the air, when drawn in by breathing, hurts the lungs, and excites a cough; even the effects of fire in a great measure seems to cease; and it is observed, that though metals are kept for a considerable time before a strong fire, they will still freeze water when thrown upon them. When the French mathematicians wintered at Tornio in Lapland, the external air, when suddenly admitted into their rooms, converted the moisture of the air into whirls of snow; their breasts seemed to be rent when they breathed it, and the contact thereof was intolerable to their bodies; and the spirit of wine, which had not been highly rectified, burst some of their thermometers by the congelement of the aqueous part.

Extreme cold often proves fatal to animals in those countries where the winters are very severe; thus 7000 Swedes perished at once in attempting to pass the mountains which divide Norway from Sweden. But it is not necessary that the cold, in order to destroy human life, should be so very intense as has just been mentioned; it is only requisite to be a little below 32° of Fahrenheit, or the freezing point, accompanied with snow or hail, from which shelter cannot be obtained. The snow which falls upon the clothes, or the uncovered parts of the body, then melts, and by a continual evaporation carries off the animal heat to such a degree, that a sufficient quantity is not left for the support of life. In such cases, the person first feels himself extremely chill and uneasy; he turns listless, unwilling to walk or use exercise to keep himself warm, and at last turns drowsy, sits down to refresh himself with sleep, but awakes no more. See FREEZING.

A striking illustration of these effects of cold is related by captain Cook, in an occurrence which took place during a botanical excursion of Sir Joseph Banks and Dr. Solander among the hills of Terra del Fuego. The party, consisting of 11 persons, were overtaken by darkness, and obliged to spend the night on the hills, during extreme cold. Dr. Solander, who had more than once crossed the mountains which divide Sweden from Norway, well knew that extreme cold, especially when joined with fatigue, produces a torpor and sleepiness that are almost irresistible; he therefore conjured the company to keep moving, whatever pains it might cost them, and whatever relief they might be promised by an inclination to rest: "Whoever sits down," said he, "will sleep; and whoever sleeps, will wake no more." Thus at once admonished and alarmed, they set forward; but while they were still upon the naked rock, and before they had got among the bushes, the cold became suddenly so intense, as to produce the effect that had been most dreaded; Dr. Solander himself was the first who found the inclination, against which he had warned others, irresistible, and insisted upon being suffered to lie down. Mr. Banks entreated and remonstrated in vain; down he lay upon the ground, though it was covered with snow; and it was with great difficulty that his friend kept him from sleeping. Richmond also, one of the black servants, began to linger, having suffered from the cold in the

same manner as the Doctor. Mr. Banks therefore sent 5 of the company forward to get a fire ready at the first convenient place they could find; and himself, with 4 others, remained with the Doctor and Richmond, whom partly by persuasion and entreaty, and partly by force, they brought in; but when they had got through the greater part of the birch and swamp, they both declared they could go no farther. Mr. Banks had recourse again to entreaty and expostulation, but they produced no effect. When Richmond was told that if he did not go on he would in a short time be frozen to death, he answered that he desired nothing but to lie down and die. The Doctor did not so explicitly renounce his life; he said he was willing to go on, but that he must first take some sleep, though he had before told the company that to sleep was to perish. Mr. Banks and the rest found it impossible to carry them, and there being no remedy, they were both suffered to sit down, being partly supported by the bushes; and in a few minutes they fell into a profound sleep. Soon after some of the people who had been sent forward returned with the welcome news, that a fire was kindled about a quarter of a mile farther on the way. Mr. Banks then endeavoured to wake Dr. Solander, and happily succeeded; but, though he had not slept five minutes, he had almost lost the use of his limbs, and the muscles were so shrunk, that his shoes fell from his feet;—he consented to go forward with such assistance as could be given him; but no attempts to relieve poor Richmond were successful. He, together with another black left with him, died. Several others began to lose their sensibility, having been exposed to the cold and snow near an hour and a half, but the fire recovered them. See Captain Cook's first Voyage; also Rees's Cyclopaedia, art. Cold.

COLLECTOR, in Electricity, is a small appendage to the prime conductor of the electrical machine, and generally consisting of pointed wires, affixed to that end of the prime conductor which stands contiguous to the glass globe, or cylinder, or other electric of the machine. Its office is to receive the electricity, whether positive or negative, from the excited electric, much more readily than the blunt end of the prime conductor would be able to receive it, without that appendage.

COLLEGE (ROYAL MILITARY), was instituted in 1799, under the direction of 12 commissioners, a governor, and professor of mathematics. It consists of two departments; the senior, established first at High Wycombe, and the junior at Great Marlow, in Buckinghamshire, each under the care of a commandant, superintendent, and adjutant, and under the instruction of a number of able masters in different branches of science. But in the year 1813 the senior department has been removed to Farnham, and the junior to Sandhurst, near Bagshot, Surrey. The pupils in the senior department are young officers who have received their commissions; those in the junior department are gentlemen cadets, amounting to about 3 or 400 in number, are educated and fitted for commissions in the army, each cadet paying a certain annual sum, towards the expense of his education and maintenance, &c.

COLLEGE, Naval, the new name of the Naval Academy at Portsmouth. See ACADEMY.

COLLIMATION, *Line of*, in a telescope, is a line passing through the intersection of those wires that are fixed in the focus of the object-glass, and the centre of the same glass.

COLLINS (JOHN), an eminent accountant and mathe-

matician, was born at Wood Eaton near Oxford, March 5, 1624. He received his education from his father, a dissenting minister, and at 16 years of age was put apprentice to a bookseller at Oxford; but soon after the commencement of the civil wars he became a clerk of the Prince of Wales's kitchen. In this situation he was under the superintendence of Mr. Marr, a good mathematician, and famous for the dials with which he adorned the king's gardens. From hence he travelled abroad, to prosecute his favourite study; and on his return he took upon him the profession of an accountant, and published, in the year 1652, a large work entitled, *An Introduction to Merchants Accompts*; which was followed by several other publications on different branches of accounts. In 1658, he published a treatise called *The Sector on a Quadrant*; containing the description and use of four several quadrants, each accommodated to the making of sun-dials, &c.; to which he afterwards added an appendix concerning reflected dialling, from a glass placed reclining.—In 1659, he published his *Geometrical Dialling*; and the same year also his *Mariner's Plain Scale* new plained.—Collins now became a Fellow of the Royal Society in London, to which he made various communications, particularly some ingenious chronological rules for the calendar, printed in the *Philos. Trans.* number 46, for April 1669: also a curious dissertation concerning the resolution of equations in numbers, printed also in the *Trans.* for March 1671: an elegant construction of the curious problem, Having given the mutual distances of three objects in a plane, with the angles made by them at a fourth place in that plane, to find the distance of this place from each of the three former, vol. 6, pa. 2093: and thoughts about some defects in algebra, vol. 14, pa. 375.

Collins wrote also several commercial tracts, highly acceptable to the public; viz, *A Plea for bringing over Irish cattle, and keeping out the fish caught by foreigners*:—*For the promotion of the English fishery*:—*For the working of the Tin-mines*:—*A discourse on Salt and Fishery*. He was frequently consulted in nice and critical cases of accounts, of commerce, and engineering. On one of these occasions, being appointed to inspect the ground for cutting a canal or river between the Isis and the Avon, he contracted a disorder by drinking cider when he was too warm, which ended in his death the 10th of November 1683, at 59 years of age.

Mr. Collins was a very useful man to the sciences, keeping up a constant correspondence with the most learned men, both at home and abroad, and promoting the publication of many valuable works, which, but for him, would never have been introduced to the public; particularly Dr. Barrow's optical and geometrical Lectures; his abridgment of the Works of Archimedes, Apollonius, and Theodosius; Branker's translation of Rhronius's Algebra, with Dr. Pell's additions, &c.; which were procured by his frequent solicitations.

After a considerable time had elapsed, his papers were all delivered into the hands of the learned and ingenious Mr. William Jones, F. R. S., among which were found manuscripts, on mathematical subjects, of Briggs, Oughtred, Barrow, Newton, Pell, and many others. From a variety of letters from these, and many other celebrated mathematicians, it appears that Collins spared neither pains nor expense to procure what tended to promote real science: and even many of the late discoveries in physical knowledge are indebted to him for their improvement; for

while he excited some to make known every new and useful invention, he employed others to improve them. Sometimes he was peculiarly useful, by showing where the defect was in any useful branch of science, pointing out the difficulties attending the inquiry, and at other times setting forth the advantages, and keeping up a spirit and warm desire for improvement. Mr. Collins was also as it were the register of all the new improvements made in the mathematical sciences; the magazine to which the curious had frequent recourse: in so much that he acquired the appellation of the English Mersenneus. If some of his correspondents had not obliged him to conceal their communications, there could have been no dispute about the priority of the invention of a method of analysis, the honour of which evidently belongs to Newton; as appears undeniably from the papers printed in the *Commercium Epistolicum* D. Joannis Collins et aliorum de Analysis promota; jussu Societatis Regiae in lucem editum, 1712; a work that was composed from the letters in the possession of our author.

COLLINS'S Quadrant. See *Quadrant*.

COLLISION, is the percussion or striking of bodies against each other. Striking bodies are considered either as elastic, or non-elastic. They may also be either both in motion, or one of them in motion and the other at rest. When non-elastic bodies strike, they adhere together as one mass; which, after collision, either remains at rest, or moves forward as one body. But when elastic bodies strike, they always separate after the stroke. The principal theorems relating to the collision of bodies, are the following:

1. If any body impinge or act obliquely on a plane surface; the force or energy of the stroke, or action, is as the sine of the angle of incidence. Or the force upon the surface, is to the same when acting perpendicularly, as the sine of incidence is to the radius.
2. If one body act on another, in any direction, and by any kind of force; the action of that force on the second body is made only in a direction perpendicular to the surface on which it acts.
3. If the plane, acted on, be not absolutely fixed, it will move, after the stroke, in the direction perpendicular to its surface.

4. If a body *a* strike another body *b*, which is either at rest, or else in motion, either towards *a* or from it; then the momenta, or quantities of motion, of the two bodies, estimated in any one direction, will be the very same after the stroke that they were before it.

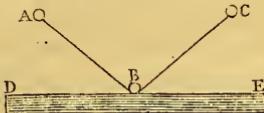

Thus, first, if *a* with a momentum of 10, strike *b* at rest, and communicate to it a momentum of 4, in the direction *AB*. Then there will remain in *a* only a momentum of 6 in that direction: which together with the momentum of *b*, viz 4, makes up still the same momentum between them as before.—But if *b* were in motion before the stroke, with a momentum of 5, in the same direction, and receive from *a* an additional momentum of 2: then the motion of *a* after the stroke will be 8, and that of *b*, 7; which together make 15, the same as 10 and 5, the motions before the stroke.—Lastly, if the bodies move in opposite directions, and meet each other, namely *a* with a motion of 10, and *b*, of 5; and *a* communicate to *b* a motion of 6 in the direction *AB* of its motion: then, before the stroke, the whole motion from both, in the direction *AB*, is 10—5, or

5: but after the stroke the motion of a is 4 in the direction AB , and the motion of b is $6 - 5$, or 1, in the same direction AB ; therefore the sum $4 + 1$, or 5, is still the same motion from both as it was before.

5. If a hard and fixed plane be struck either by a soft or a hard unelastic body; the body will adhere to it. But if the plane be struck by a perfectly elastic body, it will rebound from it with the same velocity with which it struck the plane.

6. The effect of the blow of the elastic body, upon the plane, is double to that of the non-elastic one; the velocity and mass being the same in both.

7. Hence, non-elastic bodies lose, by their collision, but half the motion that is lost by elastic bodies; the masses and velocities being equal.

8. If an elastic body a impinge upon a firm plane DE at the point B , it will rebound from it in an angle equal to that in which it struck it; or the angle of incidence will be equal to the angle of reflection: namely, the angle $ABD = CBE$.

9. If the non-elastic body b , moving with the velocity v in the direction bb , and the body b with the velocity v , strike each other, the direction of the motion being in the line ac ; then they will move after the stroke with a common velocity, which will be more or less according as, before the stroke, b moved towards B , or from B , or was at rest; and that common velocity, in each of these cases, will be as follows: viz,

$$\frac{bv+ bv}{b+b} \text{ when } b \text{ moved from } B,$$

$$\frac{bv - bv}{b+b} \text{ when } b \text{ moved towards } B,$$

$$\frac{bv}{b+b} \text{ when } b \text{ was at rest.}$$

For example, if the bodies or weights, b and b , be 5lb and 3lb; and their velocities v and v , 60 feet and 40 feet per second; then 300 and 120 will be their momenta bv and bv , and $8 = b + b$ the sum of the weights. Consequently the common velocity after the stroke, in the three cases above-mentioned, will be thus, viz,

$$\frac{300 + 120}{8} = \frac{420}{8} \text{ or } 52\frac{1}{2} \text{ in the first case,}$$

$$\frac{300 - 120}{8} = \frac{180}{8} \text{ or } 22\frac{1}{2} \text{ in the second case,}$$

$$\frac{300}{8} = \text{--- or } 37\frac{1}{2} \text{ in the third case.}$$

10. If two perfectly elastic bodies impinge on each other; their relative velocity is the same both before and after the impulse; that is, they will recede from each other with the same velocity with which they approached and met.

It is not meant however by this theorem, that each body will have the very same velocity after the impulse as it had before; for that will be varied according to the relation of the masses of the two bodies; but that the velocity of the one, after the stroke, will be so much increased, and the other decreased, as to have the same difference as before,

in one and the same direction. So, if the elastic body b move with the velocity v , and overtake the elastic body b , moving the same way, with the velocity v ; then their relative velocity, or that with which they strike, is only $v - v$; and it is with this same velocity that they separate from each other after the stroke: but if they meet each other, or the body b move contrary to the body b ; then they meet and strike with the velocity $v + v$, and it is with the same velocity that they separate again, and recede from each other after the stroke: in like manner, they would separate with the velocity v of b , if b were at rest before the stroke. Also the sum of the velocities of the one body, is equal to the sum of the others. But whether they move forwards or backwards after the impulse, and with what particular velocities, are circumstances that depend on the various masses and velocities of the bodies before the stroke, and are as specified in the next theorem.

11. If the two elastic bodies b and b move directly towards each other, or directly from each other, the former with the velocity v , and the latter with the velocity v ; then, after their meeting and impulse, the respective velocities of b and b in the direction bc , in the three cases of motion, will be as follow: viz,

$$\frac{2bv + (b - b)v}{b+b} \text{ the velocity of } b,$$

$$\frac{2bv + (b - b)v}{b+b} \text{ the velocity of } b,$$

when the bodies both moved towards c before the stroke; and

$$\frac{-2bv + (b - b)v}{b+b} \text{ the velocity of } b,$$

$$\frac{2bv + (b - b)v}{b+b} \text{ the velocity of } b,$$

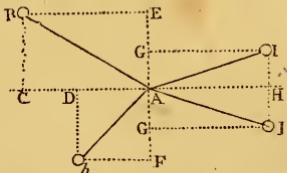

when b moved towards c , and b towards b before the stroke; also,

$$\frac{b-b}{b+b} \times v \text{ the velocity of } b,$$

$$\frac{2b}{b+b} \times v \text{ the velocity of } b,$$

when b was at rest before the stroke.

12. The motions of bodies after impact, that strike each other obliquely, are thus determined.

Let the two bodies b , b' , move in the oblique directions ba , $b'a$, and strike each other at A , with velocities which are in proportion to the lines ba , $b'a$. Let CAN represent the plane in which the bodies touch in the point of concourse; to which draw the perpendiculars bc , $b'd$, and complete the rectangles ce , df . Now the motion in ba is resolved into the two bd , da ; of which the antecedents bc , bd are the velocities with which they directly meet, and the consequents ca , da are parallel, and therefore by these the bodies do not impinge on each other, and consequently the motions according to these directions will not be changed by the impulse; so that the velocities with which the bodies meet, are as bc or ea , and bd or fa .

The motions therefore of the bodies *b*, *b*, directly striking each other with the celerities *EA*, *FA*, will be determined by art. 11 or 9, according as the bodies are elastic or non-elastic; which being done, let *AG* be the velocity, so determined, of one of them, as *A*; and since there remains also in the same body a force of moving in the direction parallel to *BE*, with a velocity as *BE*, make *AH* equal to *BE*, and complete the rectangle *GN*: then the two motions in *AN* and *AG*, or *HN*, are compounded into the diagonal *AI*, which therefore will be the path and celerity of the body *B* after the stroke. And after the same manner is the motion of the other body *b* determined after the impact.

13. The state of the common centre of gravity of bodies is not affected by the collision or other actions of those bodies on each other. That is, if it were at rest before their collision, so will it be also at rest after collision: and if it were moving in any direction, and with any velocity, before collision; it will do the very same after collision.

See more on this subject under the article PERCUSSION.

COLONNADE, a peristyle of a circular figure; or a series of columns disposed in a circle, and insulated within-side.

COLOUR, a property inherent in light, by which, according to the various sizes of its parts, or from some other cause, it excites different vibrations in the optic nerve; which, propagated to the sensorium, affect the mind with different sensations. See the doctrine of colours fully explained under Chromatics. See also OPTICS, ACHROMATIC, and TELESCOPE.

COLSON (John), a respectable mathematician, who flourished about the beginning of the 18th century, and who appears to have been a Cambridge scholar. - We first notice him as author of some papers in the Philos. Trans. viz. one in vol. 25 (an. 1707) on The Universal Resolution of Cubic and Biquadratic Equations; a second in vol. 34, on Negative-Affirmative Arithmetic; and 3dly, in vol. 39, on the Construction and Use of Spherical Maps. He was also author of several separate works; as, The British Hemisphere, being a map of a new contrivance, in the form of a half globe, of about 15 inches in diameter, but comprehending the whole known surface of the habitable earth, the city of London being the centre or vertex of the map. In 1736 he published a translation from the Latin of Sir Isaac Newton's Method of Fluxions and Infinite Series, with a large comment on the whole work, consisting of annotations, illustrations, and supplements. At the date of this publication Mr. Colson was in the situation of master of Sir Joseph Williamson's free mathematical school at Rochester, and a F. R. S. Three years after this we find he succeeded Mr. Sanderson as Lucasian Professor of Mathematics at Cambridge, a situation which he held for 20 years, after which he was succeeded, in 1759, by Dr. Waring; though Mr. Colson lived till Dec. 20, 1760. The character of our author seems to have been chiefly that of minute precision and patient laborious industry. His paper on the solution of cubic and biquadratic equations above-mentioned, is founded nearly on the idea of the solution by Descartes, by assuming the biquadratic as equal to the product of two quadratics with indeterminate coefficients. The construction of the equations also, by means of the circle and parabola, is in imitation of the like constructions of Descartes in his Geometry, and of Mr. Baker in his Geometrical Key. Mr. Colson, it seems, was so well pleased with the Analytical Institutions of the Sig-

nora Agnesi, that he made an entire translation of that lady's work, from the Italian, the copy of which was found among his papers, and published at the expense of Mr. Baron Maseres in 2 volumes 4to.

COLUMBA Noachi, Noah's Dove, a small constellation in the southern hemisphere, consisting of 10 stars.

COLUMN, in Architecture, a round pillar, made to support or adorn a building.

The column is the principal part of an architectonical order, and is composed of three parts, the base, the shaft, and the capital; each of which is subdivided into a number of lesser parts, called members, or mouldings.

Columns are different according to the different orders in which they are used; and also according to their matter, construction, form, disposition, and purpose. The proportion of the length of each to its diameter, and the diminution of the diameter upwards, are diversly stated by different authors. The medium of them is nearly as follows:

The Tuscan is the simplest and shortest of all: its height $\frac{3}{4}$ diameters, or 7 modules; and it diminishes $\frac{1}{4}$ part of its diameter.

The Doric is more delicate, and adorned with flutings; its height $7\frac{1}{2}$ or 8 diameters.

The Ionic is more delicate still, being 9 diameters long. It is distinguished from the rest by the volutes, or curled scrolls in its capital, and by its base, which is peculiar to it.

The Corinthian is the richest and most delicate of all the columns, being 10 diameters in length, and adorned with two rows of leaves, and stalks or stems, from whence spring out small volutes.

The Composite column is also 10 diameters long, its capital adorned with rows of leaves like the Corinthian, and with angular volutes like the Ionic.

COLURES, are two great circles imagined to intersect at right angles in the poles of the world, and to pass, the one through the equinoctial points Aries and Libra, and the other through the solstitial points Cancer and Capricorn; whence they are called the Equinoctial and Solstitial Colures. By thus dividing the ecliptic into four equal parts, they mark the four seasons, or quarters of the year.

It is a matter of dispute over what part of the back of Aries the equinoctial colure passed in the time of Hipparchus. Newton, in his Chronology, takes it to have been over the middle of this constellation. Souciet insists that it passed over the dodecatemorion of Aries, or midway between the rump and first of the tail. There are some observations in the Philos. Trans. number 466, concerning the position of this colure in the ancient sphere, from a draught of the constellation Aries, in the Aratæa published at Leyden and Amsterdam in 1652, which appears to confirm Newton's opinion; but the antiquity and authority of the original draught may still be questioned.

COMA BERENICES, Berenice's Hair, a modern constellation of the northern hemisphere; composed of unformed stars between the Lion's tail and Bootes.

It is said that this constellation was formed by Conon, an astronomer, to console the queen of Ptolemy Euergetes, for the loss of a lock of her hair, which was stolen out of the temple of Venus, where she had dedicated it on account of a victory obtained by her husband.

The stars in this constellation are, in Tycho's catalogue 14, in Hevelius's 21, and in the Britannic catalogue 43.

COMBINATIONS, denote the alternations or varia-

tions of any number of quantities, letters, sounds, or the like, in all possible ways. Mersenne gives the combinations of all the notes and sounds in music, as far as 64; the sum of which amounts to a number expressed by 90 places of figures. And the number of possible combinations of the 24 letters of the alphabet, taken first two by two, then three by three, and so on, according to Prestet's calculation, amounts to

1391724288887252999425128493402200.

Father Truchet, in Mém. de l'Acad., shows, that two square pieces, each divided diagonally into two colours, may be arranged and combined 64 different ways, so as to form as many different kinds of chequer-work: a circumstance worthy the attention of masons, pavours, &c.

Doctrine of COMBINATIONS.

I. Having given any number of things, with the number in each combination; to find the number of combinations.

1. When only two are combined together.

One thing admits of no combination.

Two, a and b , admit of one only, viz. ab .

Three, a , b , c , admit of three, viz. ab , ac , bc .

Four admit of six, viz. ab , ac , ad , bc , bd , cd .

Five admit of ten, viz. ab , ac , ad , ae , bc , bd , be , cd , ce .

Whence it appears that the numbers of combinations, of two and two only, proceed according to the triangular numbers 1, 3, 6, 10, 15, 21, &c., which are produced by the continual addition of the arithmetical series 0, 1, 2, 3, 4, 5, &c. So that if n be the number of things, then the general formula for expressing the sum of all their combinations by twos, will be $\frac{n \cdot (n-1)}{2}$.

Thus, if $n = 2$; this becomes $\frac{2 \cdot 1}{2} = 1$.

If $n = 3$; it is $\frac{3 \cdot 2}{2} = 3$.

If $n = 4$; it is $\frac{4 \cdot 3}{2} = 6$. &c.

2. When three are combined together; then

Three things admit of one order, abc .

Four admit of 4; viz. abc , abd , acd , bcd .

Five admit of 10; viz. abc , abd , abe , acd , ace , ade , bcd , bde , cde . And so on according to the first pyramidal numbers 1, 4, 10, 20, &c., which are formed by the continual addition of the former, or triangular numbers 1, 3, 6, 10, &c. And the general formula for any number n of combinations, taken by threes, is, $\frac{n}{1} \times \frac{n-1}{2} \times \frac{n-2}{3}$.

So, if $n = 3$; it is $\frac{3 \cdot 2 \cdot 1}{1 \cdot 2 \cdot 3} = 1$.

If $n = 4$; it is $\frac{4 \cdot 3 \cdot 2}{1 \cdot 2 \cdot 3} = 4$.

If $n = 5$; it is $\frac{5 \cdot 4 \cdot 3}{1 \cdot 2 \cdot 3 \cdot 4} = 10$. &c.

Proceeding thus, it is^{is} found that a general formula for any number n of things, combined by m at each time, is $s = \frac{n}{1} \times \frac{n-1}{2} \times \frac{n-2}{3} \times \frac{n-3}{4} \&c.$, continued to m factors, or terms, or till the last factor in the denominator be m .

So, in 6 things, combined by 4's, the number of combinations is $\frac{6 \cdot 5 \cdot 4 \cdot 3}{1 \cdot 2 \cdot 3 \cdot 4} = 15$.

3. By adding all these series together, their sum will be the whole number of possible combinations of n things combined both by twos, by threes, by fours, &c. And as the said series are evidently the coefficients of the power n of a binomial, wanting only the first two 1 and n ; there-

fore the said sum, or whole number of all such combinations, will be

$(1+1)^n - n - 1$, or $2^n - n - 1$. Thus if the number of things be 5; then $2^5 - 5 - 1 = 32 - 6 = 26$.

II. To find the number of Changes and Alterations which any number of quantities can undergo, when combined in all possible varieties of ways, with themselves and each other, both as to the things themselves, and the Order or Position of them.

One thing admits but of one order or position.

Two things may be varied four ways; thus, aa , ab , ba , bb .

Three quantities, taken by twos, may be varied nine ways; thus, aa , ab , ac , ba , ca , bb , bc , cb , cc .

In like manner four things, taken by twos, may be varied, 4^2 or 16 ways; and 5 things, by twos, 5^2 or 25 ways; and, in general, n things, taken by twos, may be changed or varied n^2 different ways.

For the same reason, when taken by threes, the changes will be n^3 ; and when taken by fours, they will be n^4 ; and so generally, when taken by n 's, the changes will be n^n .

Hence, then, adding all these together, the whole number of changes, or combinations in n things, taken both by 2's, by 3's, by 4's, &c., to n 's, will be the sum of the geometrical series, $n + n^2 + n^3 + n^4 + \dots + n^n$, which sum is $= \frac{n^n - 1}{n - 1}$.

For example, if the number of things n be 4; this gives $\frac{4^n - 1}{4 - 1} \times 4 = \frac{255}{3} \times 4 = 340$.

And if n be 24, the number of letters in the alphabet; the theorem gives

$$\frac{24^{24} - 1}{24 - 1} \times 24 = (24^{24} - 1) \times \frac{24}{23} =$$

1391724288887252999425128493402200. In so many different ways, therefore, may the 24 letters of the alphabet be varied or combined among themselves, or so many different words may be made out of them.

COMBUST, or COMBUSTION, is said of a planet when it is in conjunction with the sun, or not distant from it above half their disc. But according to Argol, a planet is Combust, or in Combustion, when it is within $8\frac{1}{2}$ of the sun.

COMBUSTION, in Chemical and Natural Philosophy, term denoting the decomposition of certain substances accompanied by light and heat.

When a stone or a brick is heated, it undergoes no change, except an augmentation of temperature; and when left to itself it soon cools again, and becomes as at first. But with combustible bodies the case is very different. When heated to a certain degree in the open air, they suddenly become much hotter of themselves; continue for a considerable time intensely hot, sending out a copious stream of caloric and light to the surrounding bodies. This emission after a certain period begins to diminish, and at last ceases altogether. The combustible has now undergone a complete change; it is converted into a substance possessing very different properties, and no longer capable of combustion. Thus, when charcoal is kept for some time at the temperature of about 800° , it kindles, becomes intensely hot, and continues to emit light and caloric for a long time. When the emission ceases, the charcoal has all disappeared, except an inconsiderable residuum of ashes; being almost entirely converted into carbonic acid gas, which makes its escape, unless the experiment be conducted in proper vessels. If it be collected, it is found to exceed greatly in weight the whole of the charcoal consumed.

Previous to the 17th century, the theory of combustion was but little understood or attended to. Since that period the labours of Bacon and Boyle, and Hooke and Mayow, together with those of Stahl and Lavoisier, have thrown much light on the subject, particularly the theory of Lavoisier, which is by far the most rational that have yet been offered to the public. He corrects the errors of his predecessors, and has advanced before them one very important step; but many new steps are still wanting to render his theory of combustion complete. It explains indeed, in a satisfactory manner, why during the process of combustion the burning body gradually wastes away; but it gives no explanation of the constant emission of heat and light, though a circumstance as worthy of attention as the wasting of the body.

Dr. Thomson, admitting the truth and accuracy of the Lavoisian theory as far as it proceeds, divides the bodies which occupy the attention of chemists into:—1. Combustibles; 2. Supporters of combustion; and 3. Incombustibles.

The *combustibles*, or those bodies which in common language are said to burn, may be divided into, 1. Simple combustibles; 2. Compound combustibles; and 3. Combustible oxides. Simple combustibles are, sulphur, phosphorus, carbon, hydrogen, and all the metals, except perhaps gold, silver, and mercury. Compound combustibles consist of compounds formed by the simple combustibles uniting together two and two; and combustible oxides are composed of one or more simple combustibles combined with a dose of oxygen. These oxides may be arranged under two heads: viz., those containing only a single base combined with oxygen may therefore be termed simple combustible oxides; and those containing more than one base may therefore be termed compound combustible oxides. The simple combustible oxides are only four in number: namely, oxide of sulphur, oxide of phosphorus, charcoal, and carbonic oxide gas. All the simple combustible oxides are by combustion converted into acids. The compound combustible oxides include by far the greater number of combustible bodies; for almost all the animal and vegetable substances belong to them, and the double base is usually carbon and hydrogen.

The *supporters* of combustion are a set of bodies which are not of themselves, strictly speaking, capable of undergoing combustion, but which are absolutely necessary for the process. All the supporters known at present are six; viz.,—1. Oxygen gas; 2. Air; 3. Gaseous oxide of azote; 4. Nitrous gas; 5. Nitric acid; and 6. Oxy-muriatic acid. There are other substances to which the author gives the name of *partial supporters*; but all supporters contain one common principle, namely, oxygen.

The *incombustible bodies* are neither capable of undergoing combustion themselves, nor of supporting the combustion of bodies that are. Of course they are not immediately connected with combustion; but they are noticed here because some of the alkalies and earths which belong to this class possess certain properties in common with combustibles, and are capable of exhibiting phenomena somewhat analogous to combustion; phenomena which Dr. Thomson describes under the title of *semi-combustion*.

From these observations it is obvious, that in every case of combustion there must be present a *combustible* and a *supporter*; and Lavoisier ascertained beyond a doubt, that, during the process, the combustible always unites with the oxygen of the supporter. This new compound Dr. Thom-

son calls a *product of combustion*; and maintains that every such product is either water, or an acid, or a metallic oxide. He admits indeed that other bodies sometimes make their appearance during combustion; but affirms that these, on examination, will be found neither to be products, nor to have undergone combustion. See Nicholson's Journal, vol. 2, 2d series; also Dr. Thomson's Chemistry.

COMET, a heavenly body in the planetary region, appearing suddenly, and again disappearing; and during the time of its appearance moving in a proper, though very eccentric orbit, like a planet.

Comets are vulgarly called Blazing Stars, and have this to distinguish them from other stars, that they are usually attended with a long train of light, tending always opposite to the sun, and being of a fainter lustre, the farther it is from the body of the comet. And hence arises a popular division of comets, into three kinds, viz., bearded, tailed, and hairy comets; though in reality, this division rather relates to the several circumstances of the same comet, than to the phenomena of several. Thus, when the comet is eastward of the sun, and moves from him, it is said to be bearded, because the light precedes it in the manner of a beard: when the comet is westward of the sun, and sets after him, it is said to be tailed, because the train of light follows it in the manner of a tail: and lastly, when the sun and comet are diametrically opposite, the earth being between them, the train is hid behind the body of the comet, excepting the extremities, which, being broader than the body of the comet, appear as it were around it, like a border of hair, or coma, from which it is called hairy, and a comet. But there have been comets whose disc was as clear, round, and well defined, as that of Jupiter, without either tail, beard, or coma.

Of the Nature of Comets.—Philosophers and astronomers, of all ages, have been much divided in their opinions as to the nature of comets. Their strange appearance has always been matter of terror to the vulgar, who have uniformly considered them as evil omens, and forrunners of war, pestilence, &c. Diodorus Siculus and Apollonius Myndius, in Seneca, inform us, that many of the Chaldeans held them to be lasting bodies, having stated revolutions as well as the planets, but in orbits vastly more extensive; on which account they are only visible while near the earth, but disappear again when they go into the higher regions. Others were of opinion, that the comets were only meteors raised very high in the air, which blaze for a while, and disappear when the matter of which they consist is consumed or dispersed.

Some of the Greeks, before Aristotle, supposed that a comet was a vast heap or assemblage of very small stars meeting together, by reason of the inequality of their motions, and so uniting into a visible mass, by the union of all their small lights; which must again disappear, as those stars separated, and each proceeded in its course. Pythagoras, however, accounted them a kind of planets or wandering stars, disappearing in the superior parts of their orbits, and becoming visible only in the lower parts of them.

But Aristotle held, that comets were only a kind of transient fires, or meteors, consisting of exhalations raised to the upper region of the air, and there set on fire; far below the course of the moon.

Seneca, who lived in the first century, and who had seen two or three comets himself, plainly intimates that he thought them above the moon; and argues strongly against

those who supposed them to be meteors, or maintained other absurd opinions concerning them; declaring his belief that they were not fires suddenly kindled, but the eternal productions of nature. He points out also the only way to arrive at a certainty on this subject, viz, by collecting a number of observations concerning their appearance, in order to discover whether they return periodically or not. "For this purpose," he observes, "one age is not sufficient; but the time will come when the nature of comets and their magnitudes will be demonstrated, and the routes they take, so different from the planets, explained. Posterity will then wonder, that the preceding ages should be ignorant of matters so plain and easy to be known."

For a long time this prediction of Seneca seemed not likely to be fulfilled; and Tycho Brahe was the first among the moderns, who restored the comets to their true rank in the creation; for after diligently observing the comet of 1577, and finding that it had no sensible diurnal parallax, he assigned it its true place in the planetary regions. See his book *De Cometa anni 1577.*

Before this, however, there were various opinions concerning them. In the dark and superstitious ages, comets were held to be forerunners of every kind of calamity, and it was supposed they had different degrees of malignity, according to the shape they assumed; whence also they were differently denominated. Thus, it was said that some were bearded, others hairy; that some represented a beam, sword, or spear; others a target, &c; whereas modern astronomers acknowledge only one species of comets, and account for their different appearances from their different situations with respect to the sun and the earth.

Kepler, in other respects a very great genius, indulged the most extravagant conjectures, not only concerning comets, but the whole system of nature in general. The planets he imagined were huge animals swimming round the sun; and the comets monstrous and uncommon animals generated in the celestial spaces.

A still more ridiculous opinion, if possible, was that of John Bodin, a learned Frenchman in the 16th century; who maintained that comets "are spirits, which having lived on the earth innumerable ages, and being at last arrived on the confines of death, celebrate their last triumph, or are recalled to the firmament like shining stars! This is followed by famine, plague, &c, because the cities and people destroy the governors and chiefs who appease the wrath of God."—Others again have denied even the existence of comets, and maintained that they were only false appearances, occasioned by the refraction or reflection of light.

Hevelius, from a great number of observations, proposed it as his opinion, that the comets, like the solar maculae or spots, are formed or condensed out of the grosser exhalations of his body; in which he differs but little from the opinion of Kepler.

James Bernoulli, in his *Systema Cometarum*, imagined that comets were no other than the satellites of some very distant planet, which was itself invisible to us on account of its distance, as were also the satellites unless when in a certain part of their orbits.

Descartes advances another opinion: He conjectures that comets are only stars, formerly fixed, like the rest, in the heavens; but which becoming gradually covered with maculae or spots, and at length wholly deprived of

their light, cannot keep their places, but are carried off by the vortices of the circumjacent stars; and in proportion to their magnitude and solidity, moved in such a manner, as to be brought nearer the orb of Saturn; and thus coming within reach of the sun's light, rendered visible.

But the absurdity of all these hypotheses now abundantly appears from the observed phenomena of comets, and from the doctrine of Newton, which is as follows:

The comets, he says, are compact, solid, fixed, and durable bodies; in fact a kind of planets, which move in very oblique and eccentric orbits, every way with the greatest freedom; persevering in their motions, even against the course and direction of the planets: and their tail is a very thin and slender vapour, emitted by the head or nucleus of the comet, ignited or heated by the sun. This theory of the comets at once solves their principal phenomena, which are as below.

The Principal Phenomena of the Comets.

1. First then, those comets which move according to the order of the signs, do all, a little before they disappear, either advance slower than usual, or else go retrograde, if the earth be between them and the sun; but more swiftly, if the earth be placed in a contrary part. On the other hand, those which proceed contrary to the order of the signs, move more swiftly than usual, if the earth be between them and the sun; and more slowly, or else retrograde, when the earth is in a contrary part.—For since this course is not among the fixed stars, but among the planets; as the motion of the earth either conspires with them, or goes against them; their appearance, with respect to the earth, must be changed; and, like the planets, they must sometimes appear to move swifter, sometimes slower, and sometimes retrograde.

2. So long as their velocity is increased, they nearly move in great circles; but towards the end of their course, they deviate from those circles; and when the earth proceeds one way, they go the contrary way. Because, in the end of their course, when they recede almost directly from the sun, that part of the apparent motion which arises from the parallax, must bear a greater proportion to the whole apparent motion.

3. The comets move in ellipses, having one of their foci in the centre of the sun; and by radii drawn to the sun, describe areas proportional to the times. Because they do not wander precariously from one fictitious vortex to another; but, making a part of the solar system, return perpetually, and run a constant round. Hence, their elliptic orbits being very long and eccentric, they become invisible when in that part which is most remote from the sun. And from the curvity of the paths of comets, Newton concludes, that when they disappear, they are much beyond the orbit of Jupiter; and that in their perihelion they frequently descend within the orbits of Mars and the inferior planets.

4. The light of their nuclei, or bodies, increases as they recede from the earth towards the sun; and on the contrary, it decreases as they recede from the sun. Because, as they are in the regions of the planets, their access towards the sun bears a considerable proportion to their whole distance.

5. Their tails appear the largest and brightest, immediately after their transit through the region of the sun, or after their perihelion. Because then, their heads being the most heated, will emit the most vapours.—From the light of the nucleus we infer their vicinity to the earth,

and that they are by no means in the region of the fixed stars, as some have imagined; since, in that case, their heads would be no more illuminated by the sun, than the planets are by the fixed stars.

6. The tails always decline from a just opposition to the sun towards those parts which the nuclei or bodies pass over, in their progress through their orbits. Because all smoke, or vapour, emitted from a body in motion, tends obliquely upwards, still receding from that part towards which the smoking body proceeds.

7. This declination, *ceteris paribus*, is the smallest when the nuclei approach nearest the sun: and it is also less near the nucleus, or head, than towards the extremity of the tail. Because the vapour ascends more swiftly near the head of the comet, than in the higher extremity of its tail; and also when the comet is nearer the sun, than when it is farther off.

8. The tails are somewhat brighter, and more distinctly defined in their convex, than in their concave part. Because the vapour in the convex part, which goes first, being somewhat nearer and denser reflects the light more copiously.

9. The tails always appear broader at their upper extremity, than near the centre of the comyt. Because the vapour in a free space continually rarefies and dilates.

10. The tails are always transparent, and the smallest stars appear through them; because they consist of infinitely thin vapour.

The Phases of Comets.—The nuclei, which are also called the heads, and bodies, of comets, viewed through a telescope, exhibit faces very different from those of the fixed stars or planets. They are liable to apparent alterations, which Newton ascribes to changes in the atmosphere of comets: and this opinion was confirmed by observations of the comet in 1744; *Hist. Acad. Scienc.* 1744. Sturmius says that, observing the comet of 1680 with a telescope; it appeared like a coal dimly glowing, or a rude mass of matter illuminated with a dusky fumid light, less sensible towards the extremes than in the middle; whereas a star appears with a round disc, and a vivid light.

Of the comet of 1664, Hevelius observes, that its body was of a yellowish colour, very bright and conspicuous, but without any glittering light: in the middle was a dense ruddy nucleus, almost equal to Jupiter, encompassed by a much fainter, thinner matter. February 5th, its head was somewhat larger and brighter, and of a gold colour; but its light more dusky than that of the stars: at here the nucleus appeared divided into several parts. Feb. 6th, the disc was lessened; the parts of the nucleus still existed, though less than before: one of them, on the lower part of the disc, on the left, much denser and brighter than the rest; its body round, and representing a very lucid small star: the nucleus still encompassed with another kind of matter. Feb. 10th, the head somewhat more obscure, and the nucleus more confused, but brighter at top than bottom. Feb. 13th, the head diminished much both in size and splendor. March 2d, its roundness a little impaired, and its edges lacerated, &c. March 28th, very pale, and exceeding thin; its matter much dispersed; and no distinct nucleus at all appearing.

Weigelius, who saw the comet of 1664, as also the moon, and a small cloud in the horizon illuminated by the sun at the same time, observed, that through the telescope the moon appeared of a continued luminous surface: but the comet very different; being exactly like the small cloud.

And from these observations it was that Hevelius formed his opinion, that comets are like maculae or spots formed out of the solar exhalations.

Of the Magnitude of Comets.—The estimates that have been given of the magnitude of comets by Tycho Brahé, Hevelius, and other astronomers, are not very accurate; as it does not appear that they distinguished between the nucleus and the surrounding atmosphere. Thus Tycho computes that the true diameter of the comet in 1577, was in proportion to the diameter of the earth, as 3 to 14; and Hevelius made the diameter of the comet of 1652, to that of the earth, as 52 to 100. But the diameter of the atmosphere is often 10 or 15 times as great as that of the nucleus: the former, in the comet of 1682, was measured by Flamsteed, and found to be 2', when the diameter of the nucleus alone was only 11 or 12''. Though some comets, estimated by a comparison of their distance and apparent magnitude, have been reckoned much larger than the moon, and even equal to some of the primary planets. The diameter of that of 1744, when at the distance of the sun from us, measured about 1', which makes its diameter about three times that of the earth: at another time the diameter of its nucleus was nearly equal to that of the planet Jupiter.

Of the Tails of Comets.—There have been various conjectures about the nature of the tails of comets, the principal of which are those of Newton, and his followers. Newton shows that the atmospheres of comets will furnish vapour sufficient to form their tails. This he argues from their wonderful rarefaction in our air at a distance from the earth; which is such that a cubic inch of common air, expanded to the rarity of that at the distance of half the earth's diameter, or 4000 miles, would fill a space larger than the whole region of the stars. Since then the coma, or atmosphere of a comet, is ten times higher than the surface of the nucleus, from the centre; the tail, ascending still much higher, must necessarily be immensely rare: so that it is no wonder the stars are visible through it.

Now the ascent of vapours into the tail of the comet, he supposes to be occasioned by the rarefaction of the matter of the atmosphere at the time of the perihelion. Smoke, it is observed, ascends the chimney by the impulse of the air in which it floats; and air, rarefed by heat, ascends by the diminution of its specific gravity, carrying up the smoke along with it: in the same manner then it may be supposed that the tail of a comet is raised by the sun.

The tails therefore thus produced in the perihelions of comets, will go off along with their head, into remote regions; and either return from thence, together with the comets, after a long series of years; or rather be there lost, and vanish by little and little; and the comet be left bare; till at its return, descending towards the sun, some short tails are again gradually produced from the head; which afterwards, in the perihelion, descending into the sun's atmosphere, will be immensely increased.

Newton farther observes, that the vapours, when thus dilated, rarefied, and diffused through all the celestial regions, may probably, by means of their own gravity, be gradually attracted down to the planets, and become intermingled with their atmospheres. He adds that this intermixture may be useful and necessary for the conservation of the water and moisture of the planets, dried up or consumed in various ways. And I suspect, adds our author, that the spirit, which makes the finest, subtlest, and

best part of our air, and which is absolutely requisite for the life and being of all things, is derived principally from the comets.—On this principle there may appear to be some foundation for the popular opinion of presages from comets; since the tail of a comet thus intermingled with our atmosphere, may produce changes very sensible in animal and vegetable bodies.

It may here be added, that another use which Newton conjectures comets may be designed to serve, is that of recruiting the sun with fresh fuel, and repairing the consumption of his light by the streams continually sent forth in every direction from that luminary. In support of this conjecture he observes, that comets in their perihelion may suffer a diminution of their projectile force, by the resistance of the solar atmosphere; so that by degrees their gravitation towards the sun may be so far increased, as to precipitate their fall into his body.

Various opinions have been entertained respecting the generation of the tails of comets. Apian, Tycho Brahe, and some others, think they are produced by the sun's rays transmitted through the nucleus of the comet, which they supposed was transparent, and there refracted as in a glass lens, so as to form a beam of light behind the comet. Descartes accounted for the phenomenon of the tail by the refraction of light from the head of the comet to the spectator's eye. Maran supposes that the tails are formed from the luminous matter composing the sun's atmosphere: and M. De Lalande combines this hypothesis with that of Newton recited above. But Mr. Rowning, not satisfied with Newton's opinion, accounts for the tails of comets in the following manner: It is well known, says he, that when the sun's light passes through the atmosphere of any body, as the earth, that which passes on one side, is by the refraction made to converge towards that which passes on the opposite side; and this convergency is not wholly effected either at the entrance of the light into the atmosphere, or at its egression from it; but beginning at its entrance, it increases in every point of its progress: It is also agreed, that the atmospheres of the comets are very large and dense: he therefore supposes that by such time as the light of the sun has passed through a considerable part of the atmosphere of the comet, the rays are so far refracted towards each other, that they then begin sensibly to illuminate it, or rather the vapours floating in it; and so render that part they have yet to pass through, visible to us: and that this portion of the atmosphere of a comet thus illuminated, appears to us in form of a beam of the sun's light, and passes under the denomination of a comet's tail. Rowning's Nat. Philos. part 4. chap. 11.

M. Euler, Mem. Berlin, tom. 2, pa. 117, thinks there is a great affinity between the tails of comets, the zodiacal light, and the aurora borealis, and that the common cause of all of them, is the action of the sun's light on the atmospheres of the comets, of the sun, and of the earth. He supposes that the impulse of the rays of light on the atmosphere of a comet, may drive some of the finer particles of that atmosphere far beyond its limits; and that this force of impulse combined with that of gravity towards the comet, would produce a tail, which would always be in opposition to the sun, if the comet did not move. But the motion of the comet in its orbit, and about an axis, must vary the position and figure of the tail, giving it a curvature, and deviation from a line join-

ing the centres of the sun and comet; and that this deviation will be greater, as the orbit of the comet has the greater curvature, and as the motion of the comet is more rapid. It may even happen, that the velocity of the comet, in its perihelion, may be so great, that the force of the sun's rays may produce a new tail, before the old one can follow; in which case the comet might have two or more tails. The possibility of this is confirmed by the comet of 1744, which was observed to have several tails while it was in its perihelion.

Dr. Hamilton urges several objections against the Newtonian hypothesis; and concludes that the tail of a comet is formed of matter which has not the power of refracting or reflecting the rays of light; but that it is a lucid or self-shining substance: and from its similarity to the aurora borealis, that it is produced by the same cause, and is properly an electrical phenomenon. Dr. Halley likewise was doubtless inclined to this hypothesis, when he said, that the streams of light in an aurora borealis so much resembled the long tails of comets, that at first sight they might well be taken for such: and that this light seems to have a greater affinity to that which the effluvia of electric bodies emit in the dark. Philos. Trans. No. 347. Hamilton's Philos. Essays, pa. 91.

The Motion of Comets.—If it be supposed that the paths of comets are perfectly parabolical, as some have imagined, it will follow that, being impelled towards the sun by a centripetal force, they descend as from spaces infinitely distant; and that by their falls they acquire such a velocity as will carry them off again into the remotest regions, never more to return. But the frequency of their appearance, and their degree of velocity, which does not exceed what they might acquire by their gravity towards the sun, seem to put it past doubt that they move like the planets, in elliptic orbits, though exceedingly eccentric; and so return again after very long periods.

The apparent velocity of the comet of 1472, as observed by Regiomontanus, was such as to carry it through 40° of a great circle in 24 hours: and it was observed that the comet of 1770 moved through more than 45° in the last 25 hours.

Respecting the return of comets there have been different opinions. Newton, Flamsteed, Halley, and other English astronomers, appear quite satisfied of the return of these bodies. Cassini and some of the French think it highly probable; but De la Hire and others oppose it. Those on the affirmative side suppose that the comets describe orbits prodigiously eccentric, insomuch that we can observe them only in a very small part of their revolution: out of this, they are lost in the immensity of space; hid not only from our eyes, but our telescopes; that small part of their orbit next us passing sometimes within those of all the inferior planets.

Cassini gives the following reasons in favour of the return of comets. 1. It is found that they move a considerable time in the arch of a great circle, when referred to the fixed stars, that is, a circle whose plane passes through the centre of the earth; deviating but a little from it chiefly towards the end of their appearance; a deviation however common to them with the planets.—2. Comets, as well as planets, appear to move so much the faster as they are nearer the earth; and when they are at equal distances from their perigea, their velocities are nearly the same. By subtracting from their motion the

apparent inequality of velocity occasioned by their different distance from the earth, their equal motion might be found: but we should not still be certain that this is their true motion; because they might have considerable inequalities, not distinguishable in that small part of their orbit visible to us. It is rather probable that their real motion, as well as that of the planets, is unequal in itself; and hence we have a reason why the observation made during the appearance of a comet, cannot give the just period of its revolution.—3. There are no two different planets whose orbits cut the ecliptic in the same angle, and whose nodes are in the same points of the ecliptic, and having the same apparent velocity in their perige: consequently, two comets seen at different times, yet agreeing in all those three circumstances, can only be one and the same comet. Not that this exact agreement, in these circumstances, is absolutely necessary to determine their identity: for the moon herself is irregular in all of them, so that it appears there may be cases in which the same comet, at different periods of revolution, may disagree in these points.

As to the objections against the return of comets, the principal is that of the unfrequency of their appearance, with regard to the number of revolutions assigned to them. In 1702 there was a comet, or rather the tail of one, seen at Rome, which M. Cassini takes to be the same with that observed by Aristotle, and again lately in the year 1668; which would imply a period of 34 years: Now, it may appear strange that a star which has so short a revolution, and of consequence such frequent returns, should be so seldom seen. Again, in April of the same year 1702, a comet was observed by Messrs. Bianchini and Maraldi, which the latter supposed was the same with that of 1664, both on account of its motion, velocity, and direction. M. de la Hire thought it had some relation to another he had observed in 1698, which Cassini refers to that of 1652; which would make it a period of 43 months, and the number of revolutions between 1652 and 1692, 14: now, it is hard to suppose, that in this age, when the heavens are so narrowly watched, a star should make 14 revolutions unperceived; especially such a star as this, which might appear above a month together; and consequently be often disengaged from the crepuscula. For this reason M. Cassini is very reserved in maintaining the hypothesis of the return of comets, and only proposes those for planets where the motions are easy and simple, and are solved without straining, or allowing any irregularities.

M. de la Hire proposes one general difficulty against the whole system of the return of comets, which would seem to prevent any comet from returning as a planet; which is this; that by the disposition necessarily given to their courses, they ought to appear as small at first as at last; and always increase till they arrive at their nearest proximity to the earth; or if they should chance not to be observed, as soon as they are capable of being seen, it is yet hardly possible but they must often show themselves before they have arrived at their full magnitude and brightness: but, adds he, none were ever yet observed till they had arrived at it. However, the appearance of a comet in the month of October 1723, while at a great distance,

so as to be too small and dim to be viewed without a telescope, as well as the observations of several others since, may serve to remove this obstacle, and set the comets still on the same footing with the planets.

It is a conjecture of Newton, that as those planets which are nearest to the sun, and revolve in the least orbits, are the smallest; so among the comets, such as in their perihelion come nearest the sun, are the smallest, and revolve in the least orbits.

Of the Writings and Lists of Comets.

There have been many writings on the subject of comets, beside the notices of historians as to the appearance of certain particular ones.

Regiomontanus first showed how to find the magnitudes of comets, their distance from the earth, and their true place in the heavens. His 16 problems De Cometæ Magnitudine, Longitudine, ac Loco, are to be found in a book published in the year 1544, with the title of *Scripta Joannis Regiomontani*.

Peter Apian observed and wrote on the comets of 1631, 1632, &c. Other writers are Tycho Brahe, in his *Progymnasmata Astronomiae Instauratae*.—Kepler, of the comet in the year 1607, and de *Cometis Libelli tres*.—Riciolus, in his *Almagestum Novum*, published 1651, enumerates 154 comets cited by historians down to the year 1618.—Hevelius's *Prodromus Cometiticus*, containing the history of the comet of the year 1664. Also his *Cometographia*.—Lubienietz, in a large folio work expressly on this subject, published 1667, extracts, with immense labour, from the passages of all historians, an account of 415 comets, ending with that of 1665.—Dr. Hooke, in his *Posthumous works*.—M. Cassini's little *Tract of Comets*.—Sturmius's *Dissertatio de Cometarum Natura*.—Newton, in his *Principia*, lib. 3; who first assigned their proper orbits, and by calculations compared the observations of the great comet of 1680 with his theory.—Dr. Halley, in his *Synopsis Cometica*, in the *Philos. Trans.* No. 218, &c; who computed the elements and orbits of 24 comets, and who first ventured to predict the return of one in 1759, which happened accordingly.—De Lalande, *Théorie des Comètes*, 1759; also, in his *Astronomie*, vol. 3.—Clairaut, *Théorie du mouvement des Comètes*, 1760.—D'Alembert, *Opuscules Mathématiques*, vol. 2, pa. 97.—M. Albert Euler, 1762.—Séjour, *Essai sur les Comètes*, 1775.—Besides Boscovich, De la Grange, De la Place, Frisi, Lexel, Barker, Hancocks, Cole, with many others.—And M. Pringé's *Cométographie*, in 2 vols. 4to, 1784; in which is contained the most ample list of such comets as have been well observed, and their elements computed, to the number of 67. And accounts of a very few more that have been observed since that time, may be seen in the Mem. de l'Acad. and in the *Philos. Trans.* A very ingenious and ample work on comets is also published by Sir Henry Englefield, entitled, *On the determinations of the Orbits of Comets*.

The whole list of comets that have been noticed, on record, amount to upwards of 500, but the following is a complete list of all that have been properly observed, and their elements computed, the mean distance of the earth from the sun being supposed 100,000.

TABLE OF THE ELEMENTS OF COMETS.

M. Facio has suggested, that some of the comets have their nodes so very near the annual orbit of the earth, that if the earth should happen to be found in that part next the node at the time of a comet's passing by; as the apparent motion of the comet will be immensely swift, so its parallax will become very sensible; and its proportion to that of the sun will be given: whence, such transits of comets will afford the best means of determining the distance between the earth and sun.

The comet of 1472, for instance, had a parallax above 20 times greater than the sun's; and if that of 1618 had come down in the beginning of March, to its descending node, it would have been much nearer the earth, and its parallax much more notable. But hitherto none has threatened the earth with a nearer appulse than that of 1680: for Dr. Halley finds, by calculation, that Nov. 11th, at 1 h. 6 min. afternoon, that comet was not more than one semidiameter of the earth to the northward of the earth's path; at which time had the earth been in that part of its orbit, the comet would have had a parallax equal to that of the moon.—What might have been the consequence of so near an appulse, a contact, or lastly, a shock of these bodies? Mr. Whiston says, a deluge!

To determine the Place and Course of a Comet.—Observe the distance of the comet from two fixed stars, whose longitudes and latitudes are known: then with the distances thus found, calculate the place of the comet by spherical trigonometry.

Longomontanus shows an easy method of finding and tracing out the places of a comet mechanically, which is, to find two stars in the same line with the comet, by stretching a thread before the eye over all the three; then do the same by two other stars and the comet: this done, take a celestial globe, or a planisphere, and draw a line upon it first through the former two stars, and then through the latter two; so shall the intersection of the two lines be the place of the comet at that time. If this be repeated from time to time, and all the points of intersection connected, it will show the path of the comet in the heavens.

The last comet which has been observed, was that of 1807. It was distinctly seen by the naked eye for many weeks in September and October. Its elements are as recorded above; to which it may be added that its diameter, according to Dr. Herschel, is 538 miles.

The following observations on this comet have also been published by M. Burckhardt, of the Institute, on Sept. 22, 1807. "The comet approached nearest the sun on the 12th of September, at 10 o'clock in the evening; it was then distant 39 millions of leagues from the sun, and 54 from the

earth. Since that time the distance of the comet from the sun has increased, but its distance from the earth will diminish till the middle of October, when its least distance will exceed 41 millions of leagues. It is not probable that the comet will become more visible, as it loses somewhat more of its light by receding from the sun, than it gains by approaching nearer the earth. In general, the orbit of this comet is such, that it can never approach very near the earth. The body of the comet appears to be separated from the luminous matter, which surrounds it in the shape of a parabola. This phenomenon, which has not been perceived in other comets, has been ascertained by the observations of all the astronomers in Paris, and without doubt will not escape the notice of other astronomers. It does not follow, however, that the body of the comet is wholly separated from the luminous appearance, as the space that seems empty may be filled up by particles less luminous than the rest."

COMETARIUM, a machine adapted to give a representation of the revolution of a comet about the sun. It is so contrived as, by elliptical wheels, to show the unequal motion of a comet in every part of its orbit. The comet is represented by a small brass ball, carried by a radius vector, or wire, in an elliptical groove about the sun in one of its foci; and the years of its period are shown by an index moving with an equable motion over a graduated silvered circle. See a particular description, with a figure of it, in Ferguson's Astron. 8vo. pa. 400.

COMMANDINE (FREDERICK), a celebrated mathematician and linguist, was born at Urbino in Italy, in 1509; and died in 1575, at 66 years of age. He was famous for his learning and knowledge in the sciences. To a great depth, and just taste in the mathematics, he joined a critical skill in the Greek language, a happy conjunction that well qualified him for translating and expounding the writings of the Greek mathematicians. And accordingly, with a most laudable zeal and industry, he translated and published several of their works, to which no former writer had done that good office. On which account, Francis Moria, duke of Urbino, who was very conversant in those sciences, proved a very affectionate patron to him. He is greatly applauded by Bianchanus, and other writers; and he justly deserved their encomiums.

Of his own works he published the following:

1. Commentarius in Planisphaerium Ptolomaei: 1558, in 4to.
 2. De Centro Gravitatis Solid. Bonon. 1565, in 4to.
 3. Horologiorum Descriptio: Rom. 1562, in 4to.
- He translated and illustrated with notes, the following

works, most of them beautifully printed in 4to, by the celebrated printer Aldus:

1. Archimedis Circuli Dimensio; de Litteris Spiralibus; Quadratura Parabolae; de Conoidibus et Sphaeroidibus; de Arenæ Numero: 1558.

2. Ptolemai Planisphaerium; et Planisph. Jordani: 1558.

3. Ptolemai Analemma: 1562.

4. Archimedis de his qua vehuntur in aqua: 1565.

5. Apollonii Pergæi Conicorum libri quatuor, una cum Pappi Alexandrinæ Lemmatibus, et Commentariis Eutocii Ascalonitæ, &c: 1566.

6. Machometes Bagdadinus de Superficierum Divisionibus: 1570.

7. Elementa Euclidis: 1572.

8. Aristarchus de Magnitudinibus et Distantiis Solis et Lunæ: 1572.

9. Heronis Alexandrinæ Spiritualium liber: 1583.

10. Pappi Alexandrinæ Collectiones Mathem. 1588.

COMMANDING Ground, in Fortification, an eminence or rising ground, overlooking any post or strong place.—This is of three sorts; 1st, A Front Commanding Ground, or a height opposite to the face of the post, which batters upon its front: 2dly, A Reverse Commanding Ground, or an eminence that can play upon the rear or back of the post: 3dly, An Enfilade Commanding Ground, or an eminence in flank which can, with its shot, scour the whole length of a straight line.

COMMENSURABLE Quantities, or *Magnitudes*, are such as have some common aliquot part, or which may be measured or divided, without a remainder, by one and the same measure or divisor, called their common measure. Thus, a foot and a yard are commensurable, because there is a third quantity that will measure each, viz, an inch; which is 12 times contained in the foot, and 36 times in the yard.—Commensurables are to each other, as one rational whole number is to another; but incommensurables are not so: and therefore the ratio of commensurables is rational, but that of incommensurables, irrational; hence also the exponent of the ratio of commensurables is a rational number.

COMMENSURABLE Numbers, whether integers, or fractions, or surds, are such as have some other number, which will measure or divide them exactly, or without a remainder. Thus, 6 and 8 are commensurable, because 2 measures or divides them both. And $\frac{2}{3}$ and $\frac{4}{3}$, or $\frac{8}{12}$ and $\frac{9}{12}$ are commensurable fractions, because the fraction $\frac{1}{6}$ or $\frac{1}{12}$, &c, will measure them both; and in this sense, all fractions may be said to be commensurable. Also the surds $2\sqrt{2}$ and $3\sqrt{2}$ are commensurable, being measured by $\sqrt{2}$, or being to each other as 2 to 3.

COMMENSURABLE in Power. Euclid says, right lines are commensurable in power, when their squares are measured by one and the same space or superficies.

COMMON, is applied to, an angle, line, measure, or the like, that belongs to two or more figures or other things. As a common angle, a common side, a common base, a common measure, &c.

COMMON MEASURE, or divisor, is that which measures two or more numbers without a remainder. So of 8 and 12, a common measure is 2, and so is 4.

The greatest COMMON Measure is the greatest number that can measure two other numbers. So of 8 and 12, the greatest common measure is 4.

To find the greatest common measure of two numbers. Di-

vide the greater term by the less; then divide the divisor by the remainder, if there be any; and so on continually, always dividing the last divisor by the last remainder, till nothing remains; then is the last divisor the greatest common measure sought.

Thus, to find the greatest common measure of 816 and 1488.

$$\begin{array}{r} 816 \\ \hline 672) 816 (1 \\ \hline 672 \\ \hline 144) 672 (4 \\ \hline 576 \\ \hline 96) 576 (1 \\ \hline 96 \end{array}$$

$$\begin{array}{r} 96 \\ \hline 96) 96 (1 \\ \hline 96 \end{array}$$

The common measure, $\frac{96}{48}$) 96 (2

Therefore 48 is the greatest common measure of 816 and 1488, thus:

$$\begin{array}{r} 48) 816 (17 \\ \hline 48 \\ \hline 336 \\ \hline 336 \\ \hline 48 \end{array} \quad \begin{array}{r} 48) 1488 (31 \\ \hline 144 \\ \hline 336 \\ \hline 336 \\ \hline 48 \end{array}$$

The common measure is useful in fractions, to reduce a fraction to its least terms, by dividing those that are given by their greatest common measure. So $\frac{816}{1488}$ reduces to $\frac{17}{31}$, by dividing 816 and 1488 both by their greatest common measure 48.

COMMUNICATION of Motion, that act of a moving body, by which it gives motion, or transfers its motion to another body. Father Mallebranche considers the communication of motion as something metaphysical; that is, as not necessarily arising from any physical principles, or any properties of bodies, but flowing from the immediate agency of God.

The communication of motion results from, and is an evidence of the impenetrability and inertia of matter, as such; unless we admit the hypothesis of the penetrability of matter, advanced by Boscovich and Michell, and ascribe to the power of repulsion those effects which have been usually ascribed to its solidity and actual resistance.

Newton shows that action and reaction are equal and opposite; so that one body striking or acting against another, and thence causing a change in its motion, does itself undergo the very same change in its own motion, the contrary way. And hence, a moving body striking directly another at rest, it loses just as much of its motion as it communicates to the other. For the laws and quantity of motion so communicated, either in elastic or non-elastic bodies, see **COLLISION**.

COMMUTATION, Angle of, is the distance between the sun's true place seen from the earth, and the place of a planet reduced to the ecliptic: which therefore is found by taking the difference between the sun's longitude and the heliocentric longitude of the planet.

COMPANY, Rule of, or *Rule of Fellowship*, in Arithmetic, is a rule by which are determined the true shares of profit or loss, due to the several partners, or associates, in any enterprise, or trade, in due proportion to the stock contributed by each, and the time it was employed. To do which properly, see the *Rule of Fellowship*.

COMPARTMENT, a design composed of several dif-

ferent figures, disposed with symmetry; to adorn a parterre, a cailing, pannel of joinery, or the like.

C O M P A R T I T I O N, the useful and graceful distribution of the whole ground-plot of an edifice, into rooms of office, and of reception, or entertainment.

C O M P A S S, or *Mariner's Compass*, is an instrument used at sea by mariners to direct and ascertain the course of their ships. It consists of a circular brass box, which contains a paper card with the 32 points of the compass, or winds, fixed on a magnetic needle that always turns to the north, excepting a small deviation, which is variable at different places, and at the same place at different times. See *VARIATION of the Compass*.

The needle with the card turns on an upright pin fixed in the centre of the box. To the middle of the needle is fixed a brass conical socket or cap, by which the card hanging on the pin turns freely round the centre.

The top of the box is covered with a glass, to prevent the wind from disturbing the motion of the card. The whole is inclosed in another box of wood, where it is suspended by gimbal, or brass hoops, to keep the card in a horizontal position during the various motions of the ship. The whole ought to be so placed in the ship, that the middle section of the box, parallel to its sides, may be parallel to the middle section of the ship along its keel.

The invention of the compass is ascribed by some writers to Flavio Gioia, or Flavio of Malphi, about the year 1302; and hence it is that the territory of Principato, the part of the kingdom of Naples where he was born, has a compass for its arms. He divided his compass only into 8 points. Others are of opinion that the invention is due to the Chinese; and Gilbert, in his book *De Magnete*, affirms that Marcus Paulus, a Venetian, making a journey to China, brought back the invention with him in 1260. What strengthens this conjecture is, that at first they used the compass, in the same manner as the Chinese still do, viz, letting it float on a small piece of cork, instead of suspending it on a pivot. It is also added, that their emperor Chiningus, a celebrated astrologer, had a knowledge of it 1120 years before Christ. The Chinese divide their compass only into 24 points. But Ludi Vertomanus affirms, that when he was in the East Indies, about the year 1500, he saw a pilot of a ship direct his course by a compass, fastened and framed as those now commonly used. And Barlow, in his book called *The Navigator's Supply*, anno 1597, informs us, that in a personal conference with two East Indians, they affirmed, that instead of our compass, they use a magnetical needle of 6 inches, and longer, upon a pin in a dish of white China earth, filled with water; in the bottom of which they have two cross lines for the 4 principal winds, the rest of the divisions being left to the skill of their pilots. Also in the same book he observes, that the Portuguese, in their first discovery of the East Indies, got a pilot of Mahinde, who brought them thence in 33 days, within sight of Calicut.

But Fauchette relates some verses of Guoyot de Provence, who lived in France about the year 1200, which seem to make mention of the compass under the name of Marinette, or *Mariner's Stone*; which shew it was used in France near 100 years before either the Maltese or Venetian one. The French even lay claim to the invention, from the *fleur de lis* with which most people distinguish the north point of the card. With as much reason Dr. Wallis ascribes it to the English, from its name *Compass*, by which

name most nations call it, and which he observes is used in many parts of England to signify a circle.

The mariner's compass long continued very rude and imperfect, but at length received great improvement from the invention and experiments of Dr. Knight, who discovered the useful practice of making artificial magnets; and the further emendations of Mr. Smeaton, and Mr. McCulloch, by which the needles are larger and stronger than formerly, and instead of swinging in gimbal, the compass is supported in its very centre upon a prop, and the centres of motion, gravity, and magnetism, are brought almost all to the same point.

After the discovery of that most useful property of the magnet, or loadstone, viz, its giving a polarity to hardened iron or steel, the compass was many years in use before it was known in anywise to deviate from the poles of the world. About the middle of the 16th century, so confident were some persons that the needle invariably pointed due north, that they treated with contempt the notion of the variation, which about that time began to be suspected. However, careful observations soon discovered that in England, and its neighbourhood, the needle pointed to the eastward of the true north line; and the quantity of this deviation being known, mariners became as well satisfied as if the compass had none; because the true course could readily be obtained by making allowance for the true variation.

From succeeding observations it was afterwards discovered, that the deviation of the needle from the north was not a constant quantity, but that it gradually diminished, and at last, namely, about the year 1657, it was found that the needle pointed due north at London, and has ever since been going to the westward, till now the variation is upwards of two points of the compass: indeed it was $22^{\circ} 41'$ about the middle of the year 1781, as appears by the *Philos. Trans.* pa. 225, for that year, and is probably now somewhat more, which it would be of consequence to know. So that in any one place it may be suspected the variation has a kind of libratory motion, traversing through the north, to unknown limits eastward and westward. But the settling of this point must be left to time and future experiments. Since the above was printed in the former edition of this work, the magnetic observations have been partially resumed by the Royal Society; in consequence, the variation of the needle was there found to be (in September 1811) $24^{\circ} 14'$ west, and the dip or inclination $70^{\circ} 32\frac{1}{2}'$. See *VARIATION*, also *INCLINATION*, and *DIP*. Also for a further description of different compasses and their uses, see that useful book, *Robertson's Navigation*, vol. 2, pa. 231.

T H E A Z I M U T H C O M P A S S differs from the common sea compass in this, that the circumference of the card, or box is divided into degrees; and there is fitted to the box an index with two sights, which are upright pieces of brass, placed diametrically opposite to each other, having a slit down the middle of them, through which the sun or star is to be viewed at the time of observation.

T H E U S E o f t h e A z i m u t h C o m p a s s, is to take the bearing of any celestial object, when it is in, or above the horizon, that from the magnetical azimuth or amplitude, the variation of the needle may be known. See *AZIMUTH*, and *AMPLITUDE*.

The figure of the compass card, with the names of the 32 points or winds, are as in fig. 5, plate 8; where other

compasses are also exhibited. See also a new one in the Supplement to Cavallo's Treatise on Magnetism.

As there are 32 whole points quite around the circle, which contains 360 degrees, therefore each point of the compass contains the 32d part of 360, that is $11\frac{1}{4}$ degrees, or $11^{\circ} 15'$; consequently the half point is $5^{\circ} 37' 30''$, and the quarter point $2^{\circ} 48' 45''$.

The points of the compass are otherwise called rhumbs; and the numbers of degrees, minutes, and seconds, made by every quarter point with the meridian, are exhibited in the following table:

A TABLE of Rhumbs, showing the Degrees, Minutes, and Seconds, that every Point and Quarter-point of the Compass makes with the Meridian.

COMPASS Dials, are small dials, fitted in boxes, for the pocket, to show the hour of the day by the direction of the needle that indicates how to place them right, by turning the dial about till the cock or stile stand directly over the needle. But these can never be very exact, because of the variation of the needle itself; unless that variation be allowed for, in making and placing the instrument.

COMPASSES, or Pair of Compasses, a mathematical instrument for describing circles, measuring and dividing lines or figures, &c.

The common compasses consist of two sharp-pointed branches or legs of iron, steel, brass, or other metal, joined together at the top by a rivet, about which they move as on a centre. Those compasses are of the best kind in which the pin or axle, on which the joint turns, is made of steel, and also half the joint itself, as the opposite metals wear more equally: the points should also be made of hard steel, well polished; and the joint should open and shut with a smooth, easy, and uniform motion. In some compasses, the points are both fixed; but in others, one is made to take out occasionally, and a drawing-pen,

or pencil, put in its place. There are in use compasses of various kinds and contrivances, adapted to the various purposes they are intended for; as,

COMPASSES of Three Legs, or Triangular Compasses; the construction of which is like that of the common compasses, with the addition of a third leg or point, which has a motion every way. Their use is to take three points at once, and so to form triangles, and lay down three positions of a map to be copied at once.

Beam COMPASSES consist of a long straight beam or bar, carrying two brass cursors; one of these being fixed at one end, the other sliding along the beam, with a screw to fasten it on occasionally. To the cursors may be screwed points of any kind, whether steel, pencils, or the like.. To the fixed cursor is sometimes applied an adjusting or micrometer screw, by which an extent is obtained to very great nicety. The beam compasses are used to draw large circles, to take great extents, or the like.

Bow COMPASSES, or Bows, are a small sort of compasses, that shut up in a hoop, which serves for a handle. Their use is to describe arcs or circumferences with a very small radius.

Caliber COMPASSES. See CALIBER.

Clockmakers COMPASSES, are jointed like the common compasses; with a quadrant or bow, like the spring compasses, only of different use, serving here to keep the instrument firm at any opening. They are made very strong, with the points of their legs of well-tempered steel, as being used to draw or cut lines in pasteboard, or copper, &c.

Cylindrical and Spherical COMPASSES, consist of four branches, joined in a centre, two of them being circular and two flat, a little bent at the ends. The use of them is to take the diameter, thickness, or caliber of round or cylindrical bodies; as cannons, balls, pipes, &c.

There are also spherical compasses, differing in nothing from the common ones, but that their legs are arched; serving to take the diameters of round bodies.

Another sort of compasses also has lately been invented for measuring the diameter of round bodies, as balls, &c, which consist of two flat pieces of metal set at right angles on a straight bar or beam of the same; the one piece being fixed, and the other sliding thereon, so far as just to receive the round body between them; and then its diameter, or distance between the two pieces, is shown by the divisions marked on the beam.

Elliptical COMPASSES, are used to draw ellipses or ovals of any kind. The instrument consists of a beam AB (Plate 8, fig. 6.) about a foot long, bearing three cursors; to one of which may be screwed points of any kind; and to the bottom of the other two are riveted two sliding dove-tails, adjusted in grooves made in the cross branches of the beam. The dove-tails having a motion every way, by turning about the long branch, they go backward and forward along the cross; so that when the beam has gone half-way round, one of these will have moved the whole length of one of the branches; and when the beam has gone quite round, the same dove-tail has gone back the whole length of the branch. The same is understood of the other dove-tail.

Note, the distance between the two sliding dove-tails, is the distance between the two foci of the ellipse; so that by changing that distance, the ellipse will be more circular

or slender. Under the ends of the branches of the cross, are placed four steel points to keep it fast.

The use of this compass is easy: by turning round the long branch, the pen, pencil, or other points will draw the ellipse required.

Its figure shows both its use and construction.

German COMPASSES have their legs a little bent outwards, near the top; so that when shut, the points only meet,

Hair COMPASSES are so contrived within side by a small adjusting screw to one of the legs, as to take an extent to a hair's breadth.

Proportional COMPASSES are those whose joint lies, not at the end of the legs, but between the points terminating each leg. These are either simple, or compound. In the former kind the centre, or place of the joint is fixed; so that one pair of these serves only for one proportion.

Compound Proportional COMPASSES have the joint or centre moveable. They consist of two parts or sides of brass, which lie upon each other so exactly as to appear but one when they are shut. These sides easily open, and move about the centre, which is itself moveable in a hollow canal cut through the greatest part of their length. To this centre on each side is fixed a sliding piece, of a small length, with a fine line drawn thereon serving as an index, to be set against other lines or divisions placed upon the compasses on both sides. These lines are, 1, A line of lines; 2, a line of superficies, areas, or planes, the numbers on which answer to the squares of those on the line of lines; 3, a line of solids, the numbers on which answer to the cubes of those on the line of lines; 4, a line of circles, or rather of polygons to be inscribed in circles. These lines are all unequally divided, the first three from 1 to 20, and the last from 6 to 20. The use of the first is to divide a line into any number of equal parts; by the 2d and 3d are found the sides of like planes or solids in any given proportion; and by the 4th, circles are divided into any number of equal parts, or any polygons inscribed in them. See Plate 8, fig. 7.

Spring COMPASSES, or *Dividers*, are made of hardened steel, with an arched head, which by its spring opens the legs; the opening being directed by a circular screw fastened to one of the legs, let through the other, and worked with a nut.

Trisecting COMPASSES, for the trisecting of angles mechanically, for which purpose they were invented by M. Tarragon. The instrument consists of two central rules, and an arch of a circle of 120 degrees, immovable, with its radius: the radius is fastened with one of the central rules, like the two legs of a sector, that the central rule may be carried through all the points of the circumference of the arch. The radius and rule should be as thin as possible; and the rule fastened to the radius should be hammered cold, to be more elastic; and the breadth of the other central rule must be triple the breadth of the radius: in this rule also is a groove, with a dove-tail fastened on it, for its motion; there must also be a hole in the centre of each rule.

Turn-up COMPASSES, a late contrivance to save the trouble of changing the points; the body is like the common compasses; and towards the bottom of the legs without-side, are added two other points, besides the usual ones; the one carrying a drawing-pen point, and the other a past-crayon; both being adjusted to turn up, to be used or not, as occasion may require.

COMPLEMENT in general, is what is wanting, or necessary, to complete some certain quantity or thing.

COMPLEMENT of an arch or angle, as of 90° or a quadrant, is what any given arch or angle wants of it; so the complement of 50° is 40° , and the complement of 100° is -10° , a negative quantity.—The complement to 180° is usually called the supplement, to distinguish it from the complement to 90° , properly so called.—The sine of the complement of an arc, is contracted into the word cosine; the tangent of the complement, into cotangent; &c.

Arithmetical COMPLEMENT, is what a number or logarithm wants of unity or 1 with some number of ciphers. It is best found, by beginning at the left-hand side, and subtracting every figure from 9, except the last, or right-hand figure, which must be subtracted from 10. So, the arithmetical comp. of the log. 9.5329714, by subtracting from 9's, &c., is 0.4670286.

The arithmetical complements are much used in operations by logarithms, to change subtractions into additions, which are more conveniently performed, especially when there are more than one of them in the operation.

COMPLEMENT, in Astronomy, is used for the distance of a star from the zenith; or the arc contained between the zenith and the place of a star which is above the horizon. It is the same as the complement of the altitude, or co-altitude, or the zenith distance.

COMPLEMENT of the Course, in Navigation, is the quantity which the course wants of 90° , or 8 points, viz, a quarter of the compass.

COMPLEMENT of the Curtain, in Fortification, is that part of the anterior side of the curtain, which makes the demigore.

COMPLEMENTS of the Line of Defence, is the remainder of that line, after the angle of the flank is taken away.

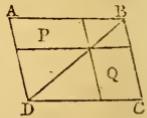

COMPLEMENTS of a Parallelogram, or in a Parallelogram, are the two lesser parallelograms, made by drawing two right lines parallel to each side of the given parallelogram, through the same point in the diagonal. So p and q are the complements in the parallelogram ABCD.

In every case, these complements are always equal, viz, the parallelogram $p = q$.

COMPLEMENT of Life, a term much used, in the doctrine of Life Annuities, by De Moivre, and, according to him, it denotes the number of years which a given life wants of 86, this being the age which he considered as the utmost probable extent of life. So 56 is the complement of 30, and 30 is the complement of 56.

That author supposed an equal annual decrement of life through all its stages, till the age of 86. Thus, if there be 56 persons living at 30 years of age, it is supposed that one will die every year, till they be all dead in 56 years. This hypothesis in some cases is near the truth, for the value of single lives. Demoivre had another hypothesis, that of life decreasing in geometrical progression, for calculating the value of joint lives; but more inaccurate than the former. See *Life ANNUITIES*; De Moivre's Treatise on Annuities, pa. 83; Simpson's *Life Annuities*; Price on *Reversionary Payments*, pa. 2; and Baily's *Life Annuities*.

COMPOSITE Number, is one that is compounded of,

or made up by the multiplication of two other numbers, greater than 1, or which can be measured by some other number greater than 1. As 12, which is composed, or compounded of 2 and 6, or 3 and 4, viz, by multiplying together 2 and 6, or 3 and 4, both products making the same number 12; which therefore is a composite number. Composites are opposed to prime numbers, or primes, which cannot be exactly measured by any other number except unity; or be produced by multiplying together two other factors.

COMPOSITE Numbers between themselves, are the same with commensurable numbers, or such as have a common measure or factor; as 15 and 12, which have the common term 3. The doctrine of Prime and Composite numbers is pretty fully treated in the 7th and 8th books of Euclid's Elements.

COMPOSITE Numbers, in musical calculations, are such as are composed by the multiplication of the prime integers 2, 3, 5. All primes larger than these, or composite numbers into which such enter, are not musical numbers, but are irrational, or surd, in a musical sense.

COMPOSITE Order, in Architecture, is the last of the five orders of columns; and is so called, because its capital is composed out of those of the other orders. Thus, it borrows a quarter-round from the Tuscan and Doric; a double row of leaves from the Corinthian; and volutes from the Ionic. Its cornice has single modillions, or dentils; and its column is 10 diameters in height. This order is also called the Roman order, and Italic order, as having been invented by the Romans, like as the other orders are denominated from the people among whom they had their rise.

COMPOSITION, is a species of reasoning by which we proceed from things that are known and given, step by step, till we arrive at such as were before unknown or required; viz, proceeding upon principles self-evident, on definitions, postulates, and axioms, with a previously demonstrated series of propositions, step by step, till it gives a clear knowledge of the thing to be known or demonstrated. Composition, otherwise called the synthetical method, is opposed to Resolution, or the analytical method, and is chiefly used by the ancients, Euclid, Apollonius, &c. See PAPPUS; also the term ANALYSIS.

COMPOSITION of forces, or motion, is the union or assemblage of several forces or motions that are oblique to one another, into an equivalent one in another direction.

1. When several forces or motions are united, that act in the same line of direction, the combined force or motion will be in the same line of direction also. But when oblique forces are united, the compounded force takes a new direction, different from both, and is either a right line or a curve, according to the nature of the forces compounded.

2. If two compounding motions be both equalable ones, whether equal to each other or not, the line of the compound motion will be a straight one. Thus, if the one equalable in the direction AB be sufficient to carry a body over the space AB in any time, and the other equalable motion sufficient to pass over AC in the same time; then by the compound motion, or both acting on the body together, it would in the same time pass over the diagonal AD of the parallelogram $ABDC$. For because the motions are uniform,

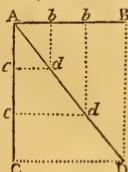

VOL. I.

any spaces Ab , Ac passed over in the same time, are proportional to the velocities, or to AB and AC ; and consequently all the points A , d , d , D , of the path are in the same right line.

3. And though the compounding motions be not equalable, but variable, either accelerated or retarded, provided they do but vary in a similar manner, the compounded motion will still be in a straight line. Thus, suppose for instance, that the motions both vary in such a manner, as that the spaces passed over in the same time, whether they be equal to each other or not, are both as the same power n of the time; then $AB^n : AC^n :: AB^m : AC^m$, and hence $AB : AC :: AB^m : AC^m$, and therefore, as before, ADD is still a right line.

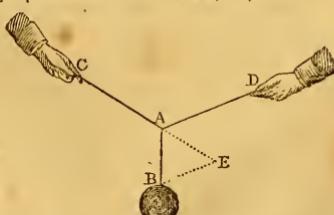

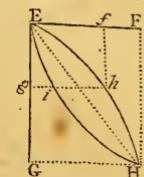

4. But if the compounding motions be not similar to each other, as when the one is equalable and the other variable, or when they are varied in a dissimilar manner, then the compounded motion is in some curve line: so, if the motion in the one direction EF be in a less proportion, with respect to the time, than that in the direction EG is, then the path will be a curve line EhH convex towards EF ; but if the motion in EF be in a greater proportion than that in EG , then the path of the compound motion will be a curve eHh concave towards EF : that is, in general, the curvilinear path is convex towards that direction in which the motion is in the less proportion to the time. Hence, for a particular instance, if the motion in the direction EF be a motion of projection, which is an equalable motion, and the motion in the direction EG that arising from gravity, which is a uniformly accelerated motion, or in proportion to the squares of the times; then is $EG : EH^2 :: EG : GH^2$, and EG as gh^2 , that is $EG : EG :: GH^2 : gh^2$, which is the property of the parabola; and therefore the path EhH of any body projected, is the common parabola.

5. If there be three forces united, or acting against the same point A at the same time, viz, the force or weight B in the direction AB , and the forces or tensions in the directions AC , AD ; and if these three forces mutually balance each other so as to keep the common point A in equilibrio, then are these forces directly proportional to the respective sides of a triangle, formed by drawing lines parallel to the directions of these forces; or indeed perpendicular to those directions, or making any one and the same angle with them. So that, if BE be drawn parallel, for instance, to AD , and meet CA produced in E , forming the triangle ABE , then are the three forces in the directions AB , AC , AD , respectively proportional to the sides AB , AE , BE .

And this theorem, with its corollaries, Dr. Keil observes, is the foundation of all the new mechanics of M. Varignon;

2 Z

by help of which may the force of the muscles be computed, and most of the mechanic theorems in Borelli, De Motu Animalium, may immediately be deduced. And hence also may any number of forces be compounded together into one only. See *COLLISION*, *Composition of Forces*, &c.

COMPOSITION of Numbers and Quantities. See **COMBINATION**.

COMPOSITION of Proportion, according to the 15th definition of the 5th book of Euclid's Elements, is when, of 4 proportionals, the sum of the 1st and 2d is to the 2d, as the sum of the 3d and 4th is to the 4th:

* as if it be $a : b :: c : d$,
then by composition $a + b : b :: c + d : d$.

Or, in numbers, if $2 : 4 :: 9 : 18$,
then by composition $6 : 4 :: 27 : 18$.

COMPOSITION of Ratios, is the adding of ratios together; which is performed by multiplying together their corresponding terms, viz. the antecedents together, and the consequents together, for the antecedent and consequent of the compounded ratio; like as the addition of logarithms is the same thing as the multiplication of their corresponding numbers. Or, if the terms of the ratios be placed fraction-wise, then the addition or composition of the ratios is performed by multiplying the fractions together. Thus, the ratio of $a : b$, or of $2 : 4$, added to the ratio of $c : d$, or of $6 : 8$, makes the ratio of $ac : bd$, or of $12 : 32$; and so the ratio of ac to bd is said to be compounded of the ratios of a to b , and c to d . So likewise, if it were required to compound together the three ratios, viz. of a to b , c to d , and e to f ; then $\frac{a}{b} \times \frac{c}{d} \times \frac{e}{f} = \frac{ace}{bdf}$ are the terms of the compound ratio; or the ratio of ace to bdf is compounded or made up of the ratios of a to b , c to d , and e to f .

Hence, if the consequent of each ratio be the same as the antecedent of the preceding ratio, then is the ratio of the first term to the last, compounded, or made up of all the other ratios, viz. the ratio of a to e , equal to the sum of all the ratios of a to b , of b to c , of c to d , and of d to e ; for $\frac{a}{b} \times \frac{b}{c} \times \frac{c}{d} \times \frac{d}{e} = \frac{a}{e}$ the terms or exponents of the compounded ratio.

Hence also, in a series of continual proportionals, the ratio of the first term to the third is double of the ratio of the first to the second, and the ratio of the 1st to the 4th is triple of it, and the ratio of the 1st to the 5th is quadruple of it, and so on; that is, the exponents are double, triple, quadruple, &c., of the first exponent: as in the series $1, a, a^2, a^3, a^4, \&c.$; where the ratio 1 to a^2 is double, of 1 to a^3 triple, &c., of the ratio of 1 to a ; or the exponent of $a^2, a^3, a^4, \&c.$, double, triple, quadruple, &c., of a .

COMPOUND INTEREST, called also *Interest upon Interest*, is that which is reckoned not only upon the principal, but on the interest itself forborn, which thus becomes a sort of secondary principal.

If r be the amount of 1 pound for 1 year, that is the sum of the principal and interest together for one year; then is r^2 the amount for 2 years, and r^3 the amount for 3 years, and in general, r^t the amount for t years; that is r^t is the sum or total amount of all the principals and interests together of 1*l* for the whole time or number of years t ; con-

sequently, if p be any other principal sum, forborn for t years, then its amount in that time at compound interest, is $p = pr^t$.

The Rule therefore in words is this: to one pound add its interest for one year, or half year, or for the first time at which the interest is reckoned; raise the sum r to the power denoted by the time or number of terms; then this power multiplied by the principal, or first sum lent, will produce the whole amount.

For example, To find how much 50*l* will amount to in 5 years at 5 per cent. per annum, compound interest.—Here the interest of 1*l* for 1 year is .05, and therefore $r = 1.05$; hence the 5th power of it for 5 years, is $r^5 = 1.27628 \&c.$; multiply this by $p = 50$ gives the amount pr^t or 63.814*l* or 63*l* 16*s* 3*d* for the amount sought.

If the compound interest, or amount of any sum, be required for the parts of a year, it may be determined as follows:

1. When the time is any aliquot part of a year.

Rule. Find the amount of 1*l* for 1 year as before, and that root of it which is denoted by the aliquot part will be the amount of 1*l* for that time; which multiplied by the principal, will be the amount of the given sum required.

2. When the time is not an aliquot part of a year.

Rule. 1. Reduce the time into days, and the 365th root of the amount of 1*l* for 1 year, is the amount of the same sum for one day. 2. Raise this amount to that power whose index is equal to the number of days, and it will be the amount of 1*l* for the given time. 3. Multiply this amount by the principal, and it will be the amount of the given sum required.

Note. The easiest way of extracting the roots, especially high ones, is by logarithms, thus: Divide the logarithm of the rate, or amount of 1*l*, for a year, by the denominator of the given aliquot part, and the quotient will be the logarithm of the root sought.

But Compound Interest for any given number of whole years, is best computed by means of such a table as the following, being the amounts of 1*l* for any number of years, and at several rates of compound interest.

As an example of the use of this table, suppose it were required to find the amount of 250*l* for 35 years at 4 per cent. compound interest.

In the column of 4 per cent, and line of 35 years,
is - - - - - 3.94609,
which multiplied by the principal - - - - - 250
gives - - - - - 986.52250
or - - - - - 986 10s 5*d*, which is the amount sought.

Note. By a bare inspection of this table, it appears how many years are required for any sum of money to double itself, at any rate of compound interest; viz. by looking in the columns when the amount becomes the number 2. So it is found that at the several rates the respective times requisite for doubling any sum, are nearly thus; viz,

Rate	3	3½	4	4½	5	6
Years	23½	20½	17½	15½	14½	12

TABLE of the Amount of £1 at Compound Interest for many Years and several Rates of Interest.

$\frac{R}{P}$	at 3 per cent.	3½ per cent.	4 per cent.	4½ per cent.	5 per cent.	6 per cent.

COMPOUND Motion, that motion which is the effect of several conspiring powers or forces, viz, such forces as are not directly opposite to each other: as when the radius of a circle is considered as revolving about a centre, and at the same time a point moving along it; which produces a kind of aspiral for the path of the point. And hence it is easily perceived, that all curvilinear motion is compound, or the effect of two or more forces; though every compound motion is not curvilinear.

It is a popular theorem in Mechanics, that in uniform compound motions, the velocity produced by the conspiring powers or forces, is to that of either of the two compounding powers separately, as the diagonal of a parallelogram, according to the direction of whose sides they act separately, is to either of the sides. See **Composition of Motion**, and **Collision**.

COMPOUND Numbers, those composed of the multipli-

cation of two or more numbers: as 12, composed of 3 times 4. See **COMPOSITE**.

COMPOUND Pendulum, that which consists of several weights constantly keeping the same distance, both from each other, and from the centre about which they oscillate.

COMPOUND Quantities, in Algebra, are such as are connected together by the signs + or -. Thus, $a + b$, or $a - c + d$, or $aa - 2a$, are compound quantities. Compound quantities are distinguished into binomials, trinomials, quadrinomials, &c, according to the number of terms in them; viz, the binomial having two terms; the trinomial, three; the quadrinomial, 4; &c. Also, those that have more than two terms, are called by the general name of multinomials, as also polynomials.

COMPOUND Ratio, is that which is made by adding two or more ratios together; viz, by multiplying all their antecedents together for the antecedent, and all the consequents together for the consequent of the compound ratio. So 6 to 72 is a ratio compounded of the ratios 2 to 6, and 3 to 12; because $\frac{6}{72} = \frac{2}{6} \times \frac{3}{12}$: also ab to cd is a ratio compounded of the ratio of a to c , and b to d ; for $\frac{ab}{cd} = \frac{a}{c} \times \frac{b}{d}$. See **COMPOSITION of Ratios**.

COMPRESSION, the act of pressing, or squeezing something, so as to bring its parts nearer together, and make it occupy less space. Compression differs from condensation as the cause from the effect, compression being the action of any force on a body, without regarding its effects; whereas condensation denotes the state of a body that is actually reduced into a less bulk, and is an effect of compression, though it may be effected also by other means. Nevertheless, compression and condensation are often confounded.

Pumps, which the ancients imagined to act by suction, do in reality act by compression; the piston, in working in the narrow pipe, compresses the inclosed air, so as to enable it, by the force of its increased elasticity, to raise the valve, and make its escape; on which, the balance being destroyed, the pressure of the atmosphere on the stagnant surface, forces up the water in the pipe, thus evacuated of its air.

It was long thought that water was not compressible into less bulk: and it was believed, till lately, that after the air had been purged out of it, no art or violence was able to press it into less space. In an experiment made by the Academy del Cimento, water, when violently squeezed, made its way through the fine pores of a globe of gold, rather than yield to the compression.

But the ingenious Mr. Canton, attentively considering this experiment, found that it was not sufficiently accurate to justify the conclusion which had always been drawn from it; since the Florentine philosophers had no method of determining that the alteration of figure in their globe of gold, occasioned such a diminution of its internal capacity, as was exactly equal to the quantity of water forced into its pores. To bring this matter therefore to a more accurate and decisive trial, he procured a small glass tube of about two feet long, with a ball at one end, of an inch and a quarter in diameter. Having filled the ball and part of the tube with mercury, and brought it exactly to the heat of 50° of Fahrenheit's thermometer, he marked the place where the mercury stood in the tube,

which was about six inches and a half above the ball; he then raised the mercury by heat to the top of the tube, and there sealed the tube hermetically; then on reducing the mercury to the same degree of heat as before, it stood in the tube $\frac{2}{105}$ of an inch higher than the mark. The same experiment was repeated with water exhausted of air, instead of mercury, and the water stood in the tube $\frac{2}{105}$ of an inch above the mark. Since the weight of the atmosphere on the outside of the ball, without any counterbalance from within, will compress the ball, and equally raise both the mercury and water, it appears that the water expands $\frac{11}{105}$ of an inch more than the mercury by removing the weight of the atmosphere. Having thus determined that water is really compressible, he proceeded to estimate the degree of condensation corresponding to any given weight. For this purpose he prepared another ball, with a tube joined thereto; and finding that the mercury in $\frac{2}{105}$ of an inch of the tube was the hundred thousandth part of that contained in the ball, he divided the tube accordingly. He then filled the ball and part of the tube with water exhausted of air; and leaving the tube open, placed this apparatus under the receiver of an air-pump, and observed the degree of expansion of the water answering to any degree of rarefaction of the air; and again by putting it into the glass receiver of a condensing engine, he noted the degree of condensation of the water corresponding to any degree of condensation of the air. He thus found, by repeated trials, that, in a temperature of 50°, and when the mercury has been at its mean height in the barometer, the water expands one part in 21740; and is as much compressed by the weight of an additional atmosphere; or the compression of water by twice the weight of the atmosphere, is one part in 10870 of its whole bulk. Should it be objected, that the compressibility of the water was owing to any air which it might be supposed to contain, he answers, that more air would make it more compressible; he therefore let into the ball a bubble of air, and found that the water was not more compressed by the same weight than before.

In some further experiments of the same kind, Mr. Canton determined that water is more compressible in winter than in summer; but he observed the contrary in spirit of wine, and oil of olives. The following table was formed, when the barometer was at 29 inches and a half, and the thermometer at 50 degrees.

Compression of	Millionth pts.	Spec. grav.
Spirit of wine	66	846
Oil of olives	48	918
Rain water	46	1000
Sea water	40	1028
Mercury	3	13595

He infers that these fluids are not only compressible, but elastic; and that the compressions of them, by the same weight, are not in the inverse ratio of their densities, or specific gravities, as might be supposed. *Phil. Trans.*, vol. lili. 1762, art. 103; and vol. liv. 1764, art. 47.

The compression of the air, by its own weight, is surprisingly great: but the air may be still farther compressed by art. See *Elasticity of Air*. This immense compression and dilatation, Newton observes, cannot be accounted for in any other way, but by a repelling force, with which the particles of air are endued; by virtue of which, when at liberty, they mutually recede from each other.

He also further informs us, that this repelling power is stronger and more sensible in air, than in other bodies; because air is generated out of very fixed bodies, but not without great difficulty, and by the help of fermentation: now those particles always recede from each other with the greatest violence, and are compressed with the greatest difficulty, which, when contiguous, cohere the most strongly. See *AIR, ATTRACTION, COHESION, DILATATION, and REPULSION*.

COMPUTATION, the manner of accounting and estimating time, weights, measures, money, &c. See *CALCULATION*, which it is also used for.

CONCAVE, an appellation used in speaking of the inner surface of hollow bodies, more especially of spherical or circular ones.

CONCAVE glasses, lenses, and mirrors, have either one side or both sides concave.

The property of all concave lenses is, that the rays of light, in passing through them, are deflected, or made to recede from one another; as in convex lenses they are inflected towards each other; and that the more as the concavity or convexity has a smaller radius. Hence parallel rays, as those of the sun, by passing through a concave lens, become diverging; diverging rays are made to diverge more; and converging rays are made either to converge less, or to become parallel, or go out diverging. And hence it is, that objects viewed through concave lenses, appear diminished; and the more so, as they are portions of less spheres. See *LENS*.

Concave mirrors have the contrary effect to lenses: they reflect the rays which fall on them, so as to make them approach more to, or recede from each other, than before, according to the situation of the object; and that the more as the concavity is greater, or as the radius of concavity is less. Hence it is that concave mirrors magnify objects that are presented to them; and that in a greater proportion, as they are portions of smaller spheres. And hence also concave mirrors have the effect of burning glasses. See *MIRROR, and BURNING-GLASS*.

CONCAVITY, that side of a figure or body which is hollow.—An arch of a curve has its concavity turned all the same way, when the right lines that join any two of its points are all on the same side of the arch.

Archimedes, intending to include in his definition such lines as have rectilinear parts, says, a line has its concavity turned one way, when the right lines that join any two of its points, are either all on one side of it, or while some fall upon the line itself, none fall on the opposite side. *Archim. de Sphaer. et Cyl. Def. 2*; and *MacLaurin's Fluxions*, art. 180.

When two lines that have their concavity turned the same way, have the same extremes, and the one includes the other, or has its concavity towards it, the perimeter of that which includes, is greater than that which is included. *Archim. ib. ax. 2*.

CONCENTRIC, having the same centre. It is opposed to eccentric, or having different centres. The word is chiefly used in speaking of round bodies and figures, such as circular, and elliptic ones; but it may also be used for polygons that are drawn parallel to each other, from the same centre.—Nonius's method of graduating instruments consists in describing with the same quadrant 45 concentric arches, dividing the outermost into 90 equal parts, the next into 89, and so on.

CONCHOID, or **CONCHILES**, the name of a curve invented by Nicomedes. It was much used by the ancients in the construction of solid problems, as appears by what Pappus says.—It is thus constructed: AP and BD being two lines intersecting at right angles; from P draw a number of other lines $PFDE$, &c., on which take always $DE = DF = AB = BC$; so shall the curve line drawn through all the points E, E, E, A, E, E, F , is called the second conchoid; though in reality, they are both but parts of the same curve, having the same pole P , and four infinite legs, to which the line BD is a common asymptote.

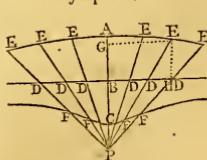

Fig. 1

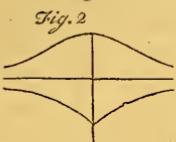

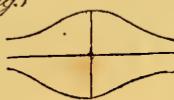

Fig. 2

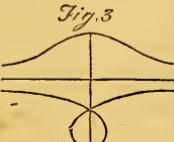

Fig. 3

The fixed point P is called the pole or centre of the conchoid. And the line BD is called the directrix.

To determine the equation of the curve: put $AB = BC = DE = DF = a$, $PB = b$, $BG = EH = x$, and $GE = BH = y$; then the equation to the first conchoid will be $x^2 \times (b+x)^2 + x^2y^2 = a^2 \times (b+x)^2$, or $x^4 + 2bx^3 + b^2x^2 + x^2y^2 = a^2b^2 + 2a^2bx + a^2x^2$; and, changing only the sign of x , as being negative in the other curve, the equation to the 2d conchoid will be $x^2 \times (b-x)^2 + x^2y^2 = a^2 \times (b-x)^2$ or $x^4 - 2bx^3 + b^2x^2 + x^2y^2 = a^2b^2 - 2a^2bx + a^2x^2$.

Of the whole conchoid, expressed by these two equations, or rather one equation only, with different signs, there are three cases or species; as first, when BC is less than BP , the conchoid will be as in fig. 1; when BC is equal to BP , the conchoid will be as in fig. 2; and when BC is greater than BP , the conchoid will be as in fig. 3.

Newton approves of the use of the conchoid for trisecting angles, or finding two mean proportionals, or for constructing other solid problems. Thus, in the Linear Construction of equations, towards the end of his Universal Arithmetic, he says, "The ancients at first endeavoured in vain at the trisection of an angle, and the finding of two mean proportionals by a right line and a circle. Afterwards they began to consider several other lines, as the conchoid, the cissoid, and the conic sections, and by some of these to solve these problems." Again, "Either therefore the trochoid is not to be admitted at all into geometry, or else, in the construction of problems, it is to be preferred to all lines of a more difficult description: and there is the same reason for other curves; for which reason we approve of the trisections of an angle by a conchoid, which Archimedes in his Lemmas, and Pappus in his Collections, have preferred to the inventions of all others in this case; because we ought either to exclude

all lines, besides the circle and right line, out of geometry, or admit them according to the simplicity of their descriptions, in which case the conchoid yields to none, except the circle." Lastly, "That is arithmetically more simple which is determined by the more simple equations, but that is geometrically more simple which is determined by the more simple drawing of lines; and in geometry, that ought to be reckoned best which is geometrically most simple: wherefore I ought not to be blamed, if, with that prince of mathematicians, Archimedes, and other ancients, I make use of the conchoid for the construction of solid problems."

CONCRETE Numbers are those that are applied to express or denote any particular subject; as 3 men, 2 pounds, &c. Whereas, if nothing be connected with a number, it is taken abstractedly or universally: thus, 4 signifies only an aggregate of 4 units, without any regard to a particular subject, whether men or pounds, or any thing else.

CONCURRING, or **CONGRUENT Figures**, in Geometry, are such as, being laid upon one another, do exactly correspond to, and cover one another, and consequently must be equal among themselves. Thus, triangles having two sides and the contained angle equal, each to each, are congruent or equal to each other in all respects.

CONDAMINE (CHARLES MARIE DE LA), a French mathematician, and chevalier of the order of St. Lazare. He was born at Paris in 1701; and began his career in the military service; but, soon yielding to his inclination for natural curiosities, he travelled over the East. Afterwards, in 1735, 1736, &c., he was employed, along with M. Godin, Bouguer, and other mathematicians, to measure the meridian in Peru, near Quito; from which he returned by the river Amazon, through vast dangers and difficulties, as may be seen in the account he published of the voyage, which was not finished under the course of ten years. After in some degree recovering his health he travelled through Italy and England, &c., and died in 1774. Condamine was admitted into the Academy of Sciences in 1730, the French Academy in 1760, and was also a member of several foreign academies. The published works of Condamine are,

1. Voyage dans l'Amérique Meridionale, 1745, 8vo.
2. Figure de la Terre, 1749, in 4to.
3. Voyage à l'Équateur, avec le Supplément, et l'Histoire des Pyramides de Quito, 1751 and 1752, 2 vols. 4to.
4. Three Memoirs on Inoculation, and Letters on the same subject.

Besides numerous scientific articles in most of the volumes of Memoirs of the Academy of Sciences, from the year 1731 to 1768 inclusively.

CONDENSATION, is the compressing or reducing a body into a less bulk or space; by which means it is rendered more dense and compact. Compression and Condensation (though sometimes used the one for the other) differ in this; viz., that the former denotes a diminution of bulk occasioned by the application of external force; whereas, the latter expresses the same effect when produced without that external application, as is the case with most bodies in cooling. But the word Condensation has been more commonly used for denoting the conversion of vapour into water, or of vapours in general into liquids.

Notwithstanding this definition, it is to be remarked, that in every case of condensation, or of the contraction of a body into a narrower space, the effect is produced by

the escape of something; and in bodies which appear to be the simplest in nature, the contraction which they undergo in cooling, is occasioned by the escape of the caloric, which the present state of philosophical knowledge reckons among the elementary substances. But the reverse of this is not always true; viz., bodies are not always contracted in their dimensions when the caloric escapes from them; and such has been found to be the case with water, with iron, and with some other substances in certain temperatures.

It is however evident that condensation in general consists in bringing the parts closer to each other, and increasing their contact, whatever may be their form or state of previous existence, or the means by which it is effected: in opposition to rarefaction, which renders the body lighter and looser, by setting the parts farther asunder, and diminishing their contact, and of consequence their cohesion.

Air condenses, either by cold, or by pressure, but much more by the latter; and most of all by chemical process. Water condenses also under the same circumstances of action; but it suddenly expands by congelation: indeed almost all matter, both solids and fluids, has the same property of condensation by those means. See COMPRESSION. So also vapour is condensed, or converted into water, by distillation, or naturally in the clouds. The way in which vapour commonly condenses, is by the escape of the caloric. On touching it, the vapour parts with this heat: and on doing so, it immediately loses the proper characteristics of vapour, and becomes water. But though this be the most common and usual way in which vapour in general is condensed, yet nature certainly proceeds after another manner; since we often observe the vapours most plentifully condensed when the weather is really warmer than at other times.—Most bodies are susceptible of three successive states of existence; namely, the solid, the liquid, and the elastic or vaporous; and all these are effected by the introduction of caloric. During every one of those states, a different degree of condensation is produced by the intermediate gradations of temperature, viz., such as are not quite sufficient to induce a different state of existence in the body concerned. Thus, a quantity of the vapour of water, which at the temperature of 242° (Fahrenheit's thermometer), and under the mean gravity of the atmosphere, occupies the space of 3600 cubic inches; if it be gradually cooled until the temperature becomes equal to about 212°, its bulk will be contracted so as to occupy the half of the space it did before, viz., about 1800 cubic inches. If the temperature be lowered below 212°, the vapour will be condensed into liquid water, which will occupy the space of not more than a single cubic inch. If the cooling be continued, the water will be contracted in its bulk, but not very regularly (that is, the decrements of bulk will not be exactly proportional to the decrements of heat) until the temperature descends to about 42°. Below that degree the water, instead of contracting its bulk, is expanded by further cooling; viz., by a further abstraction of caloric. This is a very remarkable property of water, on which some interesting phenomena of nature are depending. The water, though expanding below the temperature of 42°, still continues fluid, as far as about the temperature of 32°; but below this last-mentioned point, by further cooling it becomes a solid, namely, ice; and in this form water occupies a greater space than it did in a liquid state.

Since the enlargement of the bulk of water commences

at about the temperature of 42°, which is ten degrees above the point of melting ice, commonly called the freezing point, which is 32°, it is evident that the particles of water begin to arrange themselves in a particular order long before the freezing takes place. And, by following the analogy, it may be supposed that in every state of existence, the particles of bodies have, more or less, a tendency to arrange themselves in a certain order; to which tendency the irregularities in the condensations of bodies are probably to be attributed.

CONDENSER, a pneumatic engine, or syringe, by which an extraordinary quantity of air may be forced into a given space; so that frequently ten atmospheres, or ten times as much air as the space naturally contains, without the engine, may be thrown in by means of it, and its egress prevented by valves properly disposed.

The condenser is made either of metal or glass, and either in a cylindrical or globular form, into which the air is thrown with an injecting syringe. The receiver, or vessel containing the condensed air, should be made very strong, to bear the force of the air's elasticity thus increased; for which reason it is commonly made of brass. When glass is used, it will not bear so great a condensation of air; but then the experiment will be more entertaining, as the effect may be viewed of the condensed air upon any subject put therein.

CONDITION, EQUATIONS of, in the Integral Calculus, are certain equations of this form, $\frac{\dot{a}}{\dot{y}} = \frac{\dot{b}}{\dot{x}}$, useful in ascertaining whether a proposed fluxion will admit of finite integration, or a finite fluent. This method was given by M. Clairaut, in the Memoirs of the Academy of Sciences for the year 1740, and may be explained in this manner. When a given fluxional equation is very complex, it is often difficult to determine whether it be integrable or not; the object of this method is then to ascertain that point. In order to which, Clairaut demonstrates, that if there be a fluxional equation of the first order, expressed generally by these two terms $a\dot{x} + b\dot{y}$, where a denotes all the terms or quantities that multiply \dot{x} , and b all those that multiply \dot{y} , being fluxions of x and y ; and if in such equation, there be taken the fluxion of a , making y only variable; next in like manner the fluxion of b , making x only variable; then if that fluxion of a when divided by \dot{y} , give the same result as the fluxion of b when divided by \dot{x} , the proposed equation will be integrated. Suppose, for instance, the general proposed quantity be $ax^{m-1}y^n$: its fluxion is $amx^{m-1}y^n\dot{x} + any^{n-1}x^m\dot{y}$. Here then a is $amx^{m-1}y^n$, and b is $any^{n-1}x^m$. Now, by taking the fluxions of these two quantities again, making only y variable in A , and x only in B , striking out \dot{y} in the former, and \dot{x} from the latter, there results the same quantity $amnx^{m-1}y^{n-1}$. This rule is expressed more briefly by these kinds of symbols: if the fluxion of $a\dot{x} + b\dot{y}$ be integrable, then must $\frac{\dot{a}}{\dot{y}} = \frac{\dot{b}}{\dot{x}}$; that is, the fluxion of a , making only y variable, and dividing by \dot{y} , will be equal to the fluxion of b , making only x variable, and dividing by \dot{x} .

Clairaut shows, in like manner, that in a fluxional expression from three variables, x, y, z , thus expressed, $a\dot{x} + b\dot{y} + c\dot{z}$, in order that it may be integrable, these three following equations must be true, $\frac{\dot{a}}{\dot{y}} = \frac{\dot{b}}{\dot{x}}$, and $\frac{\dot{a}}{\dot{z}} = \frac{\dot{c}}{\dot{x}}$, and $\frac{\dot{b}}{\dot{z}} = \frac{\dot{c}}{\dot{y}}$; whence it is sufficiently suggested that if there

be a fluxional expression from four variables, it must be satisfied by six such equations, viz; as many as are the combinations of 4 things by 2 at a time; and so on for more complex cases. And this is what is meant by Equations of Condition.

For example, suppose the fluxional expression $\dot{x}\sqrt{y} + \frac{\dot{y}}{2\sqrt{y}} - a\dot{y}\sqrt{x} - \frac{ay\ddot{x}}{2x^2}$ be proposed, which is sufficiently complex not to be easily judged whether it be integrable or not. Here, taking all the terms that multiply \dot{x} , they give $\sqrt{y} - \frac{ay}{2x^2} = A$, and all the terms that multiply \dot{y} give $\frac{x}{2\sqrt{y}} - a\dot{y}\sqrt{x} = B$. Then taking the fluxion of A , making only y variable, and suppressing \dot{y} , gives $\frac{1}{2\sqrt{y}} - \frac{a}{2x^2}$; again, taking the fluxion of B , making only x variable, and dividing by \dot{x} , gives also $\frac{1}{2\sqrt{y}} - \frac{a}{2x^2}$, the same as the former; that is, $\frac{\dot{y}}{\sqrt{y}} = \frac{\dot{x}}{x}$, and consequently the proposed expression is quadrable.

Hence the integration is easy and evident, for it is only to integrate either $\dot{x}\sqrt{y}$ making y constant, or $\dot{y}\sqrt{x}$ making x ; that is either $\dot{x}\sqrt{y}/y$ or $\frac{\dot{y}}{2x^2}$ or $\frac{\dot{y}}{2\sqrt{y}} - a\dot{y}\sqrt{x}$, both of which give, by their integration, the same quantity $x\sqrt{y} - ay\sqrt{x}$, which is therefore the fluent of the proposed fluxion $\dot{x}\sqrt{y} + \frac{\dot{y}}{\sqrt{y}} - a\dot{y}\sqrt{x} - \frac{ay\ddot{x}}{2x^2}$.

CONDORCET (JOHN-ANTHONY NICHOLAS de CARRITAT, *Marquis of*), member of the Institute of Bologna, of the Academies of Turin, Berlin, Stockholm, Upsal, Philadelphia, Petersburg, Padua, &c, and secretary to the Academy of Sciences at Paris, was born at Ribemont in Picardie, the 17th of September 1743. His early attachment to the sciences, and progress in them, soon rendered him a conspicuous character in the commonwealth of letters. He was received as a member of the Academy of Sciences at 25 years of age, namely, in March 1769, as Adjunct-Mechanician; afterwards, he became Associate in 1770, Adjunct-Secretary in 1773, and sole Secretary soon after, which he enjoyed till his death, or till the dissolution of the Academy by the Convention.

Condorcet soon became an author, and that in the most sublime branches of mathematics. He published his *Essais d'Analyse* in several parts; the first part in 1765, at 22 years of age; the second, in 1767; and the third, in 1768. These works are chiefly on the Integral Calculus, or the finding of Fluxions, and make one volume 4to.

He published the Eloges of the Academicians or members of the Academy of Sciences, from the year 1666 till 1700, in several volumes. He wrote also similar Eloges of the Academicians who died during the time that he discharged the important office of Secretary to the Academy; as well as the very useful histories of the different branches of science commonly prefixed to the volumes of Memoirs, till the volume for the year 1783, when it is to be lamented that so useful a part of the plan of the Academy was discontinued.

His other memoirs contained in the volumes of the Academy, are the following.

1. Tract on the Integral Calculus; 1765.
2. On the problem of Three Bodies; 1767.
3. Observations on the Integral Calculus; 1767.
4. On the Nature of Infinite Series; on the Extent of

the Solutions which they give; and on a new method of Approximation for Differential Equations of all Orders; 1769.

5. On Equations for Finite Differences; 1770.
6. On Equations for Partial Differences; 1770.
7. On Differential Equations; 1770.
8. Additions to the foregoing Tracts; 1770.
9. On the Determination of Arbitrary Functions which enter the Integrals of Equations to Partial Differences; 1771.
10. Reflexions on the Methods of Approximation hitherto known for Differential Equations; 1771.
11. Theorem concerning Quadratures; 1771.
12. Inquiry concerning the Integral Calculus; 1772.
13. Calculation of Probabilities, part 1 and 2; 1781.
14. Continuation of the same, part 3; 1782.
15. Ditto, part 4; 1783.
16. Ditto, part 5; 1784.

Condorcet had the character of being a very worthy honest man, and a respectable author, though perhaps not a first-rate one, and produced an excellent set of Eloges of the deceased Academicians, during the time of his secretaryship. A late French political writer has observed of him, that he laboured to succeed to the literary throne of d'Alembert, but that he cannot be ranked among illustrious authors; that his works have neither animation nor depth, and that his style is dull and dry; that some bold attacks on religion and declamations against despotism have chiefly given a degree of fame to his writings.

On the breaking out of the troubles in France, our author took a decided part on the side of the people, and steadily maintained the cause he had espoused amid all the shocks and intrigues of contending parties; till, under the tyranny of Robespierre, he was driven from the convention, being one of those members proscribed on the 31st of May 1793, and he died March 28, 1794. The manner of his death is thus described by the public prints of that time. He was obliged to conceal himself with the greatest care for the purpose of avoiding the fate of Bristol and the other deputies who were executed. He did not however attempt to quit Paris, but concealed himself in the house of a female, who, though she knew him only by name, did not hesitate to risk her own life for the purpose of preserving that of Condorcet. In her house he remained till the month of March 1794, when it was rumoured that a domiciliary visit was to be made, which obliged him to leave Paris. Though he had neither passport nor civic card, he escaped through the barrier, and arrived at the plain of Mont Rouge, where he expected to find an asylum in the country-house of an intimate friend. Unfortunately this friend had set out for Paris, where he was to remain for three days.—During all this period, Condorcet wandered about the fields and in the woods, not daring to enter an inn on account of not having a civic card. Half dead with hunger, fatigue, and fear, and scarcely able to walk on account of a wound in his foot, he passed the night under a tree.

At length his friend returned, and received him with great cordiality; but as it was deemed imprudent that he should enter the house in the day-time, he returned to the woods till night. In this short interval between morning and night his caution forsook him, and he went to an inn at Clamars, where he ordered an omelette. His torn clothes, his dirty cap, his meagre and pale countenance, and the greediness with which he devoured the omelette, fixed the attention of the persons in the inn, among whom was a member of the revolutionary committee of Clamars,

mars. This man conceiving him to be Condorcet, who had effected his escape from the Bicetre, asked him whether he was going, and whether he had a passport. The confused manner in which he replied to these questions, induced the member to order him to be conveyed before the committee, who, after an examination, sent him to the district of Boury la Reine. He was there interrogated again; and the unsatisfactory answers which he gave, determined the directors of the district to send him to prison on the succeeding day.—During the night he was confined in a kind of dungeon. On the next morning, when his keeper entered with some bread and water for him, he found him stretched on the ground without any signs of life.

On inspecting the body, the immediate cause of his death could not be discovered, but it was conjectured that he had poisoned himself. Condorcet indeed always carried a dose of poison in his pocket; and he said to the friend who was to have received him into his house, that he had been often tempted to make use of it, but that the idea of a wife and daughter, whom he loved tenderly, restrained him. During the time that he was concealed at Paris, he wrote a history of the Progress of the Human Mind, in two volumes.

CONDUCTOR, in Electricity, a term first introduced in this science by Dr. Desaguliers, and used to denote those substances which are capable of receiving and transmitting electricity; in opposition to electrics, in which the matter or virtue of electricity may be excited and accumulated, or retained. The former are also called non-electrics, and the latter non-conductors. And all bodies are ranked under one or other of these two classes, though none of them are perfect electrics, nor perfect conductors, so as wholly to retain, or freely and without resistance to transmit the electric fluid.

To the class of conductors, belong all metals and semi-metals, ores, and all fluids (except air and oils), together with the substances containing them, the effluvia of flaming bodies, ice (unless very hard frozen), and snow, most saline and stony substances, charcoals, of which the best are those that have been exposed to the greatest heat, smoke, and the vapour of hot water.

It seems probable that the electric fluid passes through the substance, and not merely over the surfaces of metallic conductors; because, if a wire of any kind of metal be covered with some electric substance, as resin, sealing-wax, &c, and a jar be discharged through it, the charge will be conducted quite as well as without the electric coating.

Some philosophers have even alleged, that electricity will pervade a vacuum, and be transmitted through it almost as freely as through the substance of the best conductor: but Mr. Walsh found, that the electric spark or shock would no more pass through a perfect vacuum, than through a piece of solid glass. In other instances however, when the vacuum has been made with all possible care, the experiment has not succeeded.

It may also be observed, that many of the aforementioned substances are capable of being electrified, and that their conducting power may be destroyed and recovered by different processes: for example, green wood is a conductor; but baked, it becomes a non-conductor; again its conducting power is restored by charring it; and lastly it is destroyed by reducing this to ashes.

Again, many electric substances, as glass, resin, air, &c,

become conductors by being made very hot: however, air heated by glass must be excepted.

See, on this subject, Priestley's Hist. of Electricity, vol. 1; Franklin's Letters &c, pa. 96 and 262, edit. 1769; Cavallo's Complete Treat. of Electr. chap. 2; Henley's Exper. and Obser. in Electr. also Philos. Trans. vol. 67, p. 122; and elsewhere in the different volumes of the Transactions.

Prime CONDUCTOR, is an insulated conductor, so connected with the electrical machine, as to receive the electricity immediately from the excited electric. Mr. Grey first employed metallic conductors in this way, in 1734; and these were several pieces of metal suspended on silken strings, which he charged with electricity. M. Du Fay fastened to the end of an iron bar, which he used as his prime conductor, a bundle of linen threads, to which, he applied the excited tube; but these were afterwards changed for small wires suspended from a common gun-barrel, or other metallic rod.

In the present advanced state of the science, this part of the electrical apparatus has been considerably improved. The prime conductor is made of hollow brass, and usually of a cylindrical form. Care should be taken, that it be perfectly smooth and round, without points and sharp edges. The ends of the conductor are spherical; and it is necessary, that the part most remote from the electric should be made round and much larger than the rest, the better to prevent the electric matter from escaping, which it always endeavours most to do at the greatest distance from the electric: and the other end also should be furnished with several pointed wires or needles, either suspended from, or fixed to an open metallic ring, and pointing to the globe, or cylinder, or plate, to collect the electricity. It is best supported by pillars of solid glass, covered with sealing-wax or good varnish. Prime conductors of a large size are usually made of paste-board, covered with tin-foil or gilt paper; these being useful for throwing off a longer and denser spark than those of a smaller size: they should terminate in a smaller knob or obtuse edge, at which the sparks should be solicited. Mr. Nairne prepared a conductor 6 feet in length, and 1 foot in diameter, from which he drew electrical sparks at the distance of 16, 17, or 18 inches; and Dr. Van Marum still far exceeded this, with a conductor of 8 inches diameter, and upwards of 20 feet long, formed of different pieces, and applied to the large electrical machine in Teyler's Museum at Haerlem, the most powerful machine of the kind ever yet constructed. But the size of the conductor is always limited by that of the electric, there being a maximum which the size of the former should not exceed; for it may be so large, that the dissipation of the electricity from its surface may be greater than that which the electric is capable of supplying.

Dr. Priestley recommends a prime conductor of polished copper, in the form of a pear, supported by a pillar and a firm basis of baked wood: this receives its fire by a long arched wire of soft brass, which may be easily bent, and raised or lowered to the globe: it is terminated by an open ring, in which some sharp-pointed wires are suspended. In the body of this conductor are holes for the insertion of metalline rods. This, he observes, collects the fire perfectly well, and retains it equally every where. See Philosoph. Transact. vol. 64, art. 7; and Hist. Elect. vol. 2, § 2.

Mr. Henley has contrived a new kind of prime con-

or, which, from its use, is called the luminous conductor. It consists of a glass tube 18 inches long, and 2 inches diameter. The tube is furnished at both ends with brass caps and ferrules about 2 inches long, cemented and made air-tight, and terminated by brass balls. In one of these caps is drilled a small hole, which is covered by a strong valve, and serves for exhausting the tube of its air. Within the tube at each end there is a knotted wire, projecting to the distance of 2 inches and a half from the brass caps. To one of the balls is annexed a fine-pointed wire for receiving and collecting the electricity, and to the other a wire with a knob or ball for discharging it. The conductor, thus prepared, is supported on pillars of sealing-wax or glass. Besides the common purposes of a prime conductor to an electrical machine, this apparatus serves to exhibit and ascertain the direction of the electric matter in its passage through it. See a figure of this conductor in the Philos. Trans. with a description of experiments, &c., with it, vol. 64, pa. 403.

Conductors of Lightning, are pointed metallic rods, fixed to the upper parts of buildings, to secure them from strokes of lightning. These were invented and proposed by Dr. Franklin for this purpose, soon after the identity of electricity and lightning was ascertained; and they exhibit a very important and useful application of modern discoveries in this science. This ingenious philosopher, having found that pointed bodies are better fitted for receiving and throwing off the electric fire, than such as are terminated by blunt ends or flat surfaces, and that metals are the readiest and best conductors, soon discovered that lightning and electricity resembled each other in this and other distinguishing properties: he therefore recommended a pointed metalline rod, to be raised some feet above the highest part of a building, and to be continued down into the ground, or the nearest water. The lightning, should it ever come within a certain distance of this rod or wire, would be attracted by it, and pass through it, preferably to any other part of the building, and be conveyed into the earth or water, and there dissipated, without doing any damage to the building. Many facts have occurred to evince the utility of this simple and apparently trifling apparatus. And yet some electricians, of whom Mr. Wilson was the chief, have objected to the pointed termination of this conductor; preferring rather a blunt end: because, they pretend, a point invites the electricity from the clouds, and attracts it at a greater distance than a blunt conductor. Philos. Trans. vol. 54, pa. 234; vol. 63, pa. 49; and vol. 68, pa. 232.

This subject has indeed been very accurately examined and discussed; and pointed conductors are almost universally, and for the best reasons, recommended as the most proper and eligible. A sharp-pointed conductor, as it attracts the electric matter of a cloud at a greater distance than the other, draws it off gradually: and by conveying it away gently, and in a continued stream, prevents an accumulation and a stroke; whereas a conductor with a blunt termination receives the whole discharge of a cloud at once, and is much more likely to be exploded, whenever a cloud comes within a striking distance. To this may be added experience; for buildings guarded by either natural or artificial conductors terminating in a point, have very seldom been struck by lightning; but others, having flat or blunt terminations, have often been struck and damaged by it.

The best conductor for this purpose, is a rod of iron, VOL. I.

or rather of copper, as being a better conductor of electricity, and less liable to rust, about 3 quarters of an inch thick, which is either to be fastened to the walls of a building by wooden cramps, or supported by wooden posts, at the distance of a foot or two from the wall; though less may do: its upper end should terminate in a pyramidal form, with a sharp point and edges; and, when made of iron, gilt or painted near the top, or else pointed with copper; and be elevated 5 or 6 feet above the highest part of the building, or chimneys, to which it may be fastened. The lower end should be driven 5 or 6 feet into the ground, and directed from the foundations of the building, or continued till it communicates with the nearest water: and if this part be made of lead, it will be less apt to decay. When the conductor is formed of different pieces of metal, care should be taken that they are well joined: and it is farther recommended, that a communication be made from the conductor by plates of lead, 8 or 10 inches broad, with the lead on the ridges and gutters, and with the pipes that carry down the rain, which should be continued to the bottom of the building, and be made to communicate either with water or moist earth, or with the main pipe which supplies the house with water. If the building be large, two, three, or more conductors should be applied to different parts of it, in proportion to its extent. Philos. Trans. vol. 64, pa. 403.

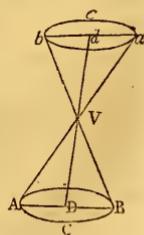

Chains have been used as conductors for preserving ships; but as the electric matter does not pass readily through the links composing them, copper wires, a little thicker than a goose-quill, have been preferred, and are now generally used. They should reach 2 or 3 feet above the highest mast, and be continued down in any convenient direction, so as always to touch the sea water. Philos. Trans. vol. 52, pa. 633. See also Franklin's Letters &c., 1769, pa. 65, 124, 479, &c.; and Cavallo's Electr. ch. 9.

For the Construction and management of Electrical Kites, and Conductors or Machines for drawing electricity from the clouds, see Priestley's Hist. of Electr. vol. 2, pa. 103, edit. 1775.

CONE, a kind of round pyramid, or a solid body having a circle for its base, and its sides formed by right lines drawn from the circumference of the base to a point at top, being the vertex or apex of the cone.

Euclid defines a cone to be a solid figure, whose base is a circle, and is produced by the entire revolution of a right-angled triangle about its perpendicular leg, called the axis of the cone. If this leg, or axis, be greater than the base of the triangle, or radius of the circular base of the cone, then the cone is acute-angled, that is, the angle at its vertex is an acute angle; but if the axis be less than the radius of the base, it is an obtuse-angled cone; and if they be equal, it is a right-angled cone.

But Euclid's definition only extends to a *right cone*, that is, to a cone whose axis is perpendicular or at right-angles to its base; and not to oblique ones, in which the axis is inclined to the same, the general definition, or description of which may be this: If a line VA continually pass through the point V , turning on that point as a joint, and the lower part of it be carried round the circumference ABC of a circle; then the space inclosed between that circle

and the path of the line, is a cone. The circle ABC is the base of the cone; v is its vertex; and the line vD , from the vertex to the centre of the base, is the axis of the cone. Also the other part of the revolving line, produced above v , will describe another cone $vabc$, called the opposite cone, and having the same common axis produced vD , and vertex v .

Properties of the Cone.—1. The area or surface of every right cone, exclusive of its base, is equal to a triangle whose base is the periphery, and its height the slant side of the cone. Or, the curve superficies of a right cone, is to the area of its circular base, as the slant side is to the radius of the base. And therefore, the same curve surface of the cone is equal to the sector of a circle whose radius is the slant side, and its arch equal to the circumference of the base of the cone.

2. Every cone, whether right or oblique, is equal to one-third part of a cylinder of equal base and altitude; and therefore the solid content is found by multiplying the base by the altitude, and taking $\frac{1}{3}$ of the product; and hence also all cones of the same or equal base and altitude, are equal.

3. Though the solidity of an oblique cone can be obtained in the same manner as that of a right one, it is otherwise with regard to the surface, since this cannot be reduced to the measure of a sector of a circle, because all the lines drawn from the vertex to the base are not equal. See a Memoir on this subject, by M. Euler, in the *Nouv. Mem. de Petersburg*, vol. 1. Dr. Barrow has demonstrated, in his *Lectiones Geometricæ*, that the solidity of a cone with an elliptic base, forming part of a right cone, is equal to the product of its surface by a third part of one of the perpendiculars drawn from the point in which the axis of the right cone intersects the ellipse; and that it is also equal to $\frac{1}{3}$ of the height of the cone multiplied by the elliptic base: consequently that the perpendicular is to the height of the cone, as the elliptic base is to the curve surface. For the curve surface of all the oblique parts of a cone, see my *Mensur.* pa. 174, &c.

4. To find the Curve Surface of the Frustum of a Cone. Multiply half the sum of the circumferences of the two ends, by the slant side, or distance between these circumferences.

5. For the Solidity of the Frustum of a Cone, add into one sum the areas of the two ends and the mean proportional between them, multiply that sum by the perpendicular height, and $\frac{1}{3}$ of the product will be the solidity. See also my *Mensur.* pa. 136, &c.

6. The Centre of Gravity of a cone is $\frac{4}{3}$ of the axis distant from the vertex.

Cones of the Higher Kinds, are those whose bases are circles of the higher kinds; and are generated, like the common cone, by conceiving a line turning on a point or vertex on high, and revolving round the circle of the higher kind.

Cone of Rays, in Optics, includes all the several rays which fall from any point of a radiant object, on the surface of a glass.

Double Cone, or Spindle, in Mechanics, is a solid formed of two equal cones joined at their bases. If this be laid on the lower part of two rulers, making an angle with each other, and elevated in a certain degree above the horizontal plane, the cones will roll up towards the superior ends, and appear to ascend, though in reality its centre of gravity descends perpendicularly lower.

CONFIGURATION, the exterior surface or shape that bounds bodies, and gives them their particular figure.

CONFUSED Vision. See VISION.

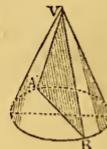

CONGELATION, or FREEZING, the act of fixing the fluidity of any liquid, by cold, or the application of cold bodies: in which it differs from coagulation, which is produced by other causes. See FREEZING, FROST, and ICE.

CONGRUITY, in Geometry, is applied to lines and figures, which exactly correspond when laid over each other; as having the same terms, or bounds. It is assumed, as an axiom, that those things are equal and similar, between which there is a congruity. Euclid, and most geometers after him, demonstrate great part of their elements from the principle of congruity: though Leibnitz and Wolfius substitute the notion of Similitude instead of that of congruity.

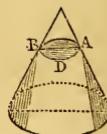

CONIC SECTIONS, are the figures made by cutting a cone by a plane.

2. According to the different positions of the cutting plane, there arise five different figures or sections, viz. a Triangle, a Circle, an Ellipse, a Parabola, and an Hyperbola: the last three of which only are peculiarly called conic sections.

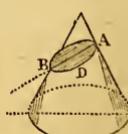

3. If the cutting plane pass through the vertex of the cone, and any part of the base, the section will evidently be a Triangle; as VAB .

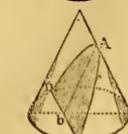

4. If the plane cut the cone parallel to the base, or make no angle with it, the section will be a Circle, as ABD .

5. The section DAB is an Ellipse, when the cone is cut obliquely through both sides, or when the plane is inclined to the base in a less angle than the side of the cone is.

6. The section is a Parabola, when the cone is cut by a plane parallel to the side, or when the cutting plane and the side of the cone make equal angles with the base.

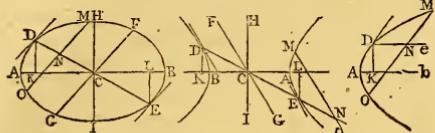

7. The section is an Hyperbola, when the cutting plane makes a greater angle with the base than the side of the cone does. And if the plane be continued to cut the opposite cone, this latter section is called the opposite hyperbola to the former; as DBC .

8. The Vertices of any section, are the points where the cutting plane meets the opposite sides of the cone, or the sides of the vertical triangular section; as A and B .—Hence, the ellipse and the opposite hyperbolas have each two vertices; but the parabola only one; unless we consider the other as at an infinite distance.

9. The Axis, or Transverse Diameter, of a conic section, is the line or distance AB between the vertices.—Hence the axis of a parabola is infinite in length.

Ellipse. Oppos. Hyperb.

10. The Centre c , is the middle point of the axis.—Hence the centre of a parabola is infinitely distant from the vertex. And of an ellipse, the axis and centre lie within the curve; but of an hyperbola, without.

11. A Diameter is any right line, as AB or DE , drawn through the centre, and terminated on each side by the curve: and the extremities of the diameter, or its intersections with the curve, are its Vertices.—Hence all the diameters of a parabola are parallel to the axis, and infinite in length; because drawn through the centre, a point at an infinite distance. And hence also every diameter of the ellipse and hyperbola has two vertices; but of the parabola, only one; unless we consider the other as at an infinite distance.

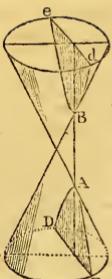

12. The Conjugate to any diameter, is the line drawn through the centre, and parallel to the tangent of the curve at the vertex of the diameter. So FG , parallel to the tangent at D , is the conjugate to DE ; and MN , parallel to the tangent at A , is the conjugate to AB .—Hence the conjugate MN of the axis AB , is perpendicular to the same; but the conjugates of other diameters are oblique to them.

13. An Ordinate to any diameter, is a line parallel to its conjugate, or to the tangent at its vertex, and terminated by the diameter and curve. So DK and EL are ordinates to the axis AB ; and MN and XO ordinates to the diameter DE .—Hence the ordinates of the axis are also perpendicular to it; but of other diameters, the ordinates are oblique to them.

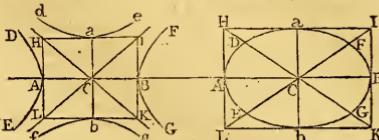

14. An Absciss is any part of a diameter, contained between its vertex and an ordinate to it; as AK or BK , and DN or EN .—Hence, in the ellipse and hyperbola, every ordinate has two abscisses; but in the parabola, only one; the other vertex of the diameter being infinitely distant.

15. The Parameter of any diameter, is a third proportional to that diameter and its conjugate, in the ellipse and hyperbola, or to any absciss and its ordinate in the parabola.

16. The Focus is the point in the axis where the ordinate is equal to half the parameter: as K and L , where DK or BL is equal to the semiparameter.—Hence, the ellipse and hyperbola have each two foci; but the parabola only

one.—The foci, or burning points, were so called, because all rays are united or reflected into one of them, which proceed from the other focus, and are reflected from the curve.

17. If dae , fbg , be two opposite hyperbolas, having abc for their first or transverse axis, and ab for their second or conjugate axis; and if dae , fbg be two other opposite hyperbolas, having the same axes, but in the contrary order, viz, ab their first axis, and abc their second; then these two latter curves dae , fbg , are called the Conjugate Hyperbolas to the former two, dae , fbg ; and each pair of opposite curves mutually conjugate to the other.

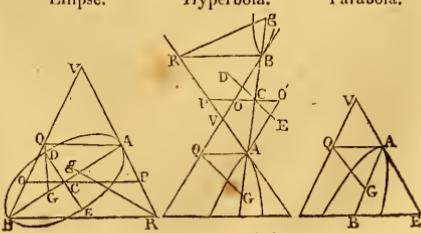

18. And if tangents be drawn to the four vertices of the curves, or extremities of the axis, forming the inscribed rectangle $HILK$; the diagonals HIC and IKL , of this rectangle, are called the Asymptotes of the curves.

19. Scholium. The rectangle, inscribed between the four conjugate hyperbolas, is similar to a rectangle circumscribed about an ellipse, by drawing tangents, in like manner, to the four extremities of the two axes; also the asymptotes or diagonals in the hyperbola, are analogous to those in the ellipse, cutting this curve in similar points, and making the pair of equal conjugate diameters. Moreover, the whole figure, formed by the four hyperbolas, is as it were, an ellipse turned inside out, cut open at the extremities D , E , F , G , of the said equal conjugate diameters, and those four points drawn out to an infinite distance, the curvature being turned the contrary way, but the axes, and the rectangle passing through their extremities, remaining fixed, or unaltered.

Further if there be placed or conjoined four cones, in such a manner, as to have all their vertices meet in a common point, also all their axes in the same plane, and their sides touching and coinciding through their whole length, in two lines crossing in the said common vertex point; then if these four cones be all cut by one plane, parallel to the common plane of their four axes, the section will exhibit a very beautiful appearance of four hyperbolic sections, of which each pair of opposite ones are equals, and each pair has also the resemblance of what are usually called the conjugates to the other pair; but are not really so, except only when the four cones are all equal; in which case the four hyperbolic sections are all equal also.

From the foregoing definitions are easily derived the following general corollaries to the sections.

Ellipse. Hyperbola. Parabola.

20. *Corol.* 1. In the ellipse, the semiconjugate axis, c_0 , or c_1 , is a mean proportional between c_0 and c_1 , the parts of the diameter $o_1 p$ of a circular section of the cone, drawn through the centre c of the ellipse, and parallel to the base of the cone. For $d e$ is a double ordinate in this circle, being perpendicular to $o_1 p$ as well as to $a b$.

21. In like manner, in the hyperbola, the length of the semiconjugate axis, c_0 or c_1 , is a mean proportional between c_0 and c_1 , drawn parallel to the base, and meeting the sides of the cone in o and p . Or, if a_0' be drawn parallel to the side v_n , and meet $v c$ produced in o' , making $c o' = c_0$; and on this diameter $o' p$ a circle be drawn parallel to the base: then the semiconjugate c_0 or c_1 will be an ordinate of this circle, being perpendicular to o' as well as to $a b$.

Or, in both figures, the whole conjugate axis $d e$ is a mean proportional between q_a and b_r , parallel to the base of the cone. See my Conic Sections, par. 6.

In the parabola, both the transverse and conjugate are infinite; for $a b$ and b_r are both infinite.

22. *Corol.* 2. In all the sections, $a g$ will be equal to the parameter of the axis, if $g q$ be drawn making the angle $a q g$ equal to the angle $b a r$. In like manner $b g$ will be equal to the same parameter, if $g b$ be drawn to make the angle $b a g$ = the angle $a b q$.

23. *Corol.* 3. Hence the upper hyperbolic section, or section of the opposite cone, is equal and similar to the lower one. For the two sections have the same transverse or first axis $a b$, and the same conjugate or second axis $d e$, which is the mean proportional between $a q$ and b_r ; and they have also equal parameters $a g$, $b g$. So that the two opposite sections make, as it were, but the two opposite ends of one entire section or hyperbola, the two being every where mutually equal and similar. Like the two halves of an ellipse, with their ends turned the contrary way.

24. *Corol.* 4. And hence, though both the transverse and conjugate axis in the parabola be infinite, yet the former is infinitely greater than the latter, or has an infinite ratio to it. For the transverse has the same ratio to the conjugate, as the conjugate has to the parameter, that is, as an infinite to a finite quantity, which is an infinite ratio.

The peculiar properties of each particular curve, will be best referred to the particular words ELLIPSE, HYPERBOLA, PARABOLA; and therefore it will only be proper here to notice a few of the properties that are common to all the conic sections.

Some other General Properties.

25. From the foregoing definitions, &c, it appears, that the conic sections are in themselves a system of regular curves, naturally allied to each other; and that one is changed into another perpetually, when it is either increased, or diminished, in infinitum. Thus, the curvature of a circle being ever so little increased or diminished, passes into an ellipse; and again, the centre of the ellipse going off infinitely, and the curvature being thereby diminished, is changed into a parabola; and lastly, the curvature of a parabola being ever so little changed, there ariseth the first of the hyperbolas; the innumerable species of which will all of them arise orderly by a gradual diminution of the curvature; till this quite vanishing, the last hyperbola ends in a right line. Hence it is manifest, that every regular curvature, like that of a circle, from the circle itself to a right line, is a conical curvature² and is

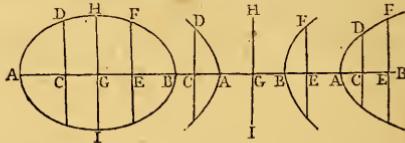

distinguished with its peculiar name, according to the divers degrees of that curvature.

26. That all diameters in a circle and ellipse intersect one another in the centre of the figure within the section: that in the parabola they are all parallel among themselves, and to the axis: but in the hyperbola, they intersect one another, without the figure, in the common centre of the opposite and conjugate sections.

27. In the circle, the latus rectum, or parameter, is double the distance from the vertex to the focus, which is also the centre. But in ellipses, the parameters are in all proportions to that distance, between the double and quadruple, according to their different species. While, in the parabola, the parameter is just quadruple that distance. And, lastly, in hyperbolas the parameters are in all proportions beyond the quadruple, according to their various kinds.

28. The first general property of the conic sections, with regard to the abscissas and ordinates of any diameter, is, that the rectangles of the abscissas are to each other, as the squares of their corresponding ordinates. Or, which is the same thing, that the square of any diameter is to the square of its conjugate, as the rectangle of two abscissas of that diameter, to the square of the ordinate which divides them. That is, in all the figures,

$$\text{the rect. } a c \cdot c b : \text{rect. } a e \cdot e b :: c d^2 : e f^2 :$$

But as in the parabola the infinites $c b$ and $e b$ are in a ratio of equality, for this curve the same property becomes $a c : a e :: c d^2 : e f^2$; that is, in the parabola, the abscissas are as the squares of their ordinates.

Or, when one of the ordinates is the semiconjugate $g n$, dividing the diameter equally in the centre, the same general property becomes,

$$a g \cdot g b \text{ or } a g^2 : a c \cdot c b :: g n^2 : c d^2 \cdot$$

$$\text{or } a b^2 : n^2 :: a c \cdot c b : c d^2.$$

29. Hence is derived the equation of the curves of the conic sections; thus, putting the diameter $a b = d$, its conjugate $n l = c$, absciss $a c = x$, and its ordinate $c d = y$; then is the other absciss $c b = d - x$ in the ellipse, $ord + x$ in the hyperbola, or d in the parabola; and hence the last analogy above, becomes $d^2 : c^2 :: x(d+x) : dx-x^2 : y^2$, or $d^2y^2 = c^2(dx+x^2)$ is the general equation for all the conic sections; and, in particular it is,

$$d^2y^2 = c^2(dx+x^2)$$
 in the ellipse,

$$d^2y^2 = c^2(dx+x^2)$$
 in the hyperbola, and

$$d^2y^2 = c^2dx$$
, or $dy^2 = c^2x$ in the parabola: Or the three equations may be otherwise expressed thus:

$$y^2 = \frac{c^2}{d^2}(dx-x^2)$$
 in the ellipse,

$$y^2 = \frac{c^2}{d^2}(dx+x^2)$$
 in the hyperbola, and

$$y^2 = \frac{c^2}{d^2}x$$
 or $= px$ in the parabola, where the parameter

$p = \frac{c^2}{d}$ the third proportional to the diameter and its conjugate, by the definition of it.

And from this one general proposition alone, which is

easily derived from the section in the solid cone itself, together with the definitions only, as laid down above, all the other properties of all the sections may easily be derived, without any further reference to the cone, and without mechanical descriptions of the curves in *plano*; as is done in my Treatise on Conic Sections, for the use of the Royal Mil. Acad.; in which also all the similar propositions in the ellipse and hyperbola are carried on word for word in them both.

The more ancient mathematicians, before the time of Apollonius Pergaeus, admitted only the right cone into their geometry, and they supposed the section of it to be made by a plane perpendicular to one of its sides; and as the vertical angle of a right cone may be either right, acute, or obtuse, the same method of cutting these several cones, *viz.* by a plane perpendicular to one side, produced all the three conic sections. The parabola was called the section of a right-angled cone; the ellipse, the section of the acute-angled cone; and the hyperbola, the section of the obtuse-angled cone. But Apollonius, who, on account of his writings on this subject, obtained the appellation of *Magnus Geometra*, the Great Geometrician, observed, that these three sections might be obtained in every cone, both oblique and right, and that they depended on the different inclinations of the plane of the section to the cone itself. Apollon. Con. Halley's edit. lib. 1, p. 9.

Instead of considering these curves as sections cut from the solid cone, which is the true genuine way of all the ancients, and of the most elegant writers among the moderns, Descartes and some others of the moderns have given arbitrary constructions of curves on a plane, from which constructions they have demonstrated the properties of these, and have afterwards proved that some principal property of them belongs to such curves or sections as are cut from a cone; and hence it is inferred by them that those curves, so described on a plane, are the same with the conic sections.

The doctrine of the conic sections is of great use in physical and geometrical astronomy, as well as in the physico-mathematical sciences. It has been much cultivated by both ancient and modern geometers, who have left many good treatises on the subject. The most ancient of these is that of Apollonius Pergaeus himself, containing 8 books, the first 4 of which have often been published; but Dr. Halley's edition has all the eight. Pappus, in his Collect. Mathem. lib. 7, informs us, that the first four of these were written by Euclid, though perfected by Apollonius, who added the other 4 to them. Among the moderns, the chief writers are Mydorge de Sectionibus Conicis; Gregory St. Vincent's Quadratura Circuli et Sectionum Coni; Lahire de Sectionibus Conicis; Trevigar Elem. Section. Con.; De Witt's Elementa Curvarum; Dr. Wallis's Conic Sections; De l'Hospital's Anal. Treat. of Conic Sections; Dr. Simson's Section. Con.; Milne's Elementa Section. Conicarum; Boscovich's excellent treatise; Muller's Conic Sections; Steel's Conic Sections; Emerson's Conic Sections; Dr. Hamilton's elegant treatise; my own treatise, above cited; and my friend Dr. Abram Robertson of Oxford has also published a curious work on this subject, containing not only a treatise on the science, but a history of the writings relating to it.

CONICS, that part of the higher geometry, or geometry of curves, which considers the cone, and the several curve lines arising from the sections of it.

CONJUGATE Axis, or Diameter, in the Conic Sections, is the axis, or a diameter parallel to a tangent to the curve at the vertex of another axis, or diameter, to which that is a conjugate. Indeed the two are mutually conjugates to each other, and each is parallel to the tangent at the vertex of the other.

CONJUGATE HYPERBOLAS, also called *Adjacent Hyperbolæ*, are such as have the same axes, but in the contrary order; the first or principal axis of the one being the 2d axis of the other, and the 2d axis of the former, the 1st axis of the latter. See art. 17 of CONIC SECTIONS.

CONJUNCTION, in Astronomy, is the meeting of the stars and planets in the same point or place in the heavens; and is either true or apparent.

True CONJUNCTION is when the line drawn through the centres of the two stars passes also through the centre of the earth. And **Apparent CONJUNCTION** is when that line does not pass through the earth's centre, but having only the same apparent longitude.

CONOID, is a figure resembling a cone, except that the slant sides from the base to the vertex are not straight lines as in the cone, but curved. It is generated by the revolution of a conic section about its axis; and it is therefore threefold, answering to the three sections of the cone, *viz.* the *Elliptical Conoid*, or spheroid, the *Hyperbolic Conoid*, and the *Parabolic Conoid*.

If a conoid be cut by a plane in any position, the section will be of the figure of some one of the conic sections; and all parallel sections, of the same conoid, are like and similar figures. When the section of the solid returns into itself, it is an ellipse; which is always the case in the sections of the spheroid, except when it is perpendicular to the axis; which position is also to be excepted in the other solids, the section being always a circle in that position. In the parabolic conoid, the section is always an ellipse, except when it is parallel to the axis, when it is a parabola. And in the hyperbolic conoid, the section is an ellipse, when its axis makes with the axis of the solid, an angle greater than that made by the said axe of the solid and the asymptote of the generating hyperbola; the section being an hyperbola in all other cases, but when those angles are equal, in which case it is a parabola.

But when the section is parallel to the fixed axis, it is of the same kind with, and similar to the generating plane itself; that is, the section parallel to the axis, in the spheroid, is an ellipse similar to the generating ellipse; in the parabolic conoid it is a parabola, similar to the generating one; and in the hyperbolic conoid, it is an hyperbola similar to the generating one.

The section through the axis, which is the generating plane, is, in the spheroid the greatest of the parallel sections, but in the hyperboloid it is the least, and in the paraboloid those parallel sections are all equal.

The analogy of the sections of the hyperboloid to those of the cone, are very remarkable, all the three conic sections being formed by cutting an hyperboloid in the same positions as the cone is cut. Thus, let an hyperbola and its asymptote revolve together about the transverse axis, the former describing an hyperboloid, and the latter a cone circumscribing it; then let it be supposed that they are both cut by one plane in any position; so shall the two sections be like, similar, and concentric figures; that is, if the plane cut both the sides of each, the sections will be concentric and similar ellipses; but if the cutting plane be parallel to the asymptote, or to the side of the cone, the

sections will be parabolas; and in all other positions, the sections will be similar and concentric hyperbolas.

And this analogy of the sections will not appear strange, when it is considered that a cone is a species of the hyperboloid; or a triangle a species of the hyperbola, the axes being infinitely small. See my Mensuration, prop. 1, part 3, sect 4, pa. 201; or my Tracts, vol. 2, pa. 137.

CONON (of SAMOS), a respectable mathematician and philosopher, who flourished about the 130th olympiad, being a contemporary and friend of Archimedes, to whom Conon communicated his writings, and sent him some problems, which Archimedes received with approbation, observing they ought to be published while Conon was living, for he comprehends them with ease, and can give a proper demonstration of them.

At another time he laments the loss of Conon, thus admiring his genius: "How many theorems in geometry," says he, "which at first seemed impossible, would in time have been brought to perfection! Alas! Conon, though he invented many, with which he enriched geometry, had not time to perfect them, but left many in the dark, being prevented by death." He had an uncommon skill in mathematics, joined to an extraordinary patience and application. This is farther confirmed by a letter sent to Archimedes by a friend of Conon's. "Having heard of Conon's death, with whose friendship I was honoured, and with whom you kept an intimate correspondence; as he was thoroughly versed in geometry, I greatly lament the loss of a sincere friend, and a person of surprising knowledge in mathematics. I then determined to send to you, as I had before done to him, a theorem in geometry, hitherto observed by no one."

Conon had some disputes with Nicoteles, who wrote against him, and treated him with too much contempt. Apollonius confesses it; though he acknowledges that Conon was not fortunate in his demonstrations.

Our author invented a kind of volute, or spiral, different from that of Dinostratus; but because Archimedes explained the properties of it more clearly, the name of the inventor was forgotten, and it was hence called Archimedes's volute or spiral.

CONSEQUENT, or Corollary, a consequence deduced from some foregoing principles.

CONSEQUENT, is the latter of the two terms of a ratio; or that to which the antecedent is referred and compared. Thus, in the ratio $a:b$, or a to b , the latter term b is the consequent, and a is the antecedent.

CONSISTENT Bodies, is a term much used by Mr. Boyle, for such as are usually called firm, or fixed bodies; in opposition to fluid ones.

CONSOLE, in Architecture, is an ornament cut upon the key of an arch, having a projecture or jetting, and occasionally serving to support small cornices, busts, and bases.

CONSONANCE, in Music, is commonly used in the same sense with concord, viz: for the union or agreement of two sounds produced at the same time, the one grave, the other acute, which is compounded together by such a proportion of each, as proves agreeable to the ear.

An unison is the first consonance, an eighth is the 2d, a fifth is the 3d; and then follow the fourth, with the third and sixths, major and minor.

CONSTANT Quantities are such as remain invariably the same, while others increase or decrease. Thus, the diameter of a circle is a constant quantity; for it remains

the same while the abscisses and ordinates, or the sines, tangents, &c, are variable. These are sometimes called given, or invariable, or permanent quantities; and in algebra it is now usual to represent them by the leading letters of the alphabet, $a, b, c, &c$; while the variable ones are denoted by the last letters, $x, y, z, &c$.

CONSTELLATIONS, certain imaginary figures of birds, beasts, fishes, and other animals in the heavens, within which are arranged certain stars. These assemblages are also sometimes called asterisms.

The ancients portioned out the firmament into several parts, or constellations; reducing a certain number of stars under the representation of certain images, to assist the imagination and memory, to conceive or retain their number, order, and disposition, or even to distinguish the virtues they attributed to them.

The division of the heavens into constellations is very ancient; being known to the most early authours, whether sacred or profane. In the Book of Job the names of some of them are mentioned; witness that sublime expostulation, "Canst thou restrain the sweet influence of the Pleiades, or loosen the bands of Orion?" And the same may be observed of the oldest among the heathen writers, Hesiod and Homer.

The ancients in their division took in only the visible firmament, or so much as came under their notice, as visible to the naked eye. The first or earliest of these, is contained in the catalogue of Ptolemy, given in the 7th book of his Almagest, prepared, as he assures us, from his own observations, compared with those of Hipparchus, and the other ancient astronomers. In this catalogue Ptolemy has formed 48 constellations. Of these, 12 are about the ecliptic, commonly called the 12 signs; 21 to the north of it; and 15 to the south. The northern constellations are, the Little Bear, the Great Bear, the Dragon, Cepheus, Bootes, the Northern Crown, Hercules, the Harp, the Swan, Cassiopeia, Perseus, Auriga, Ophiucus or Serpentary, the Serpent, the Arrow, the Eagle, the Dolphin, the Horse, Pegasus, Andromeda, and the Triangle.

The constellations about the ecliptic are Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius, Capricorn, Aquarius, and Pisces: or according to the English names, the Ram, the Bull, the Twins, the Crab, the Lion, the Virgin, the Balance, the Scorpion, the Archer, the Goat, the Water-bearer, and the Fishes.

The Southern constellations are, the Whale, Orion, the Eridanus, the Hare, the Great Dog, the Little Dog, the Ship, the Hydra, the Cup, the Raven, the Centaur, the Wolf, the Altar, the Southern Crown, and the Southern Fish.

The other stars not comprehended under these constellations, yet visible to the naked eye, the ancients called Informes, or Sporades, some of which the modern astronomers have since reduced into new figures, or constellations. But on the modern celestial globes, the constellations are made to include all the unformed stars. Ptolemy has set down the longitude and latitude of all these stars to about the year of Christ 137, amounting to the number of 1022, viz,

in the northern constellations	-	360
in the zodiacal constellations	-	346
in the southern constellations	-	316
in all of Ptolemy's catalogue	-	1022

Among the modern astronomers, Tycho Brahe is the

first who determined, with exactness, and in consequence of his own observations, the long. and lat. of the fixed stars, out of which he formed 45 constellations; of these, 43 were of the old ones described by Ptolemy, to which Tycho added the Coma Berenices, and Antinous; but he omits 5 of the old southern constellations, viz. the Centaur, the Wolf, the Altar, the Southern Crown, and Southern Fish; which he could not observe, because of the high northern latitude of Uranbourg.

After Tycho, Bayer gave the figures of 60 constellations, very exactly represented, and with tables annexed, having added to the 48 old ones of Ptolemy the following 12 about the south pole; viz. the Peacock, the Toucan, the Crane, the Phoenix, the Dorado, the Flying Fish, the Hydra, the Chameleon, the Bee, the Bird of Paradise, the Triangle, and the Indian. Besides accurately distinguishing the relative size and situation of every star, Bayer marks the stars in each constellation with the letters of the Greek and Roman alphabets, setting the first letter α to the first or principal star in each constellation, β to the 2d in order, γ to the 3d, and so on; a very useful method of noting and describing the stars, which has been used by all astronomers since, and who have farther enlarged this method, by adding the ordinal numbers 1, 2, 3, &c., to the other stars discovered since his time, when any constellation contains more than can be marked by the two alphabets. The number and order of the stars, as mentioned by Bayer, are,

of the 1st magnitude	-	-	17
of the 2d magnitude	-	-	63
of the 3d magnitude	-	-	196
of the 4th magnitude	-	-	415
of the 5th magnitude	-	-	348
of the 6th magnitude	-	-	341
of the unformed stars	-	-	326
in all			1706

After Bayer, a catalogue, with new constellations, was published by Schiller, in 1627, in a work entitled *Colun Stellatum Christianum*, the Christian Starry Heaven, in which he substitutes, very improperly, other figures of the constellations, and names, taken from the sacred scriptures, instead of the old ones.

In the year 1665, Riccioli published his *Astronomy Reformed*, containing a catalogue of the stars in 62 constellations, viz. the 60 of Bayer, with the Coma Berenices and Antinous of Tycho. He distributes the stars in all the constellations into four classes. In the first of these classes are contained those stars determined by his own observations, and those of Grimaldi. In the second are those stars which had been ascertained by Tycho Brahe and Kepler. In the third are the stars determined by Hipparchus and Ptolemy. And the 4th class consists of those of the southern hemisphere discovered by navigators, who have ascertained their places in a more or less accurate manner; in which he has marked the longitudes and latitudes for the year 1700, the period to which he has reduced all his observations. This catalogue was followed by a number of celestial schemes and maps of the heavens, published in 1673 by Pardies, who has represented very carefully all the constellations, with the stars they contain. After this, Vitalis published a catalogue of the fixed stars in his *Tables of the Primum Mobile*, in which their longitudes and latitudes, with the right ascensions and declinations are set down for the year 1675.

Some time after this, Royer published maps of the hea-

vens, reduced into 4 tables, with a catalogue of the fixed stars for the year 1700. To the stars marked by Bayer, he adds a number of stars not before seen, with others taken from the tables of Riccioli, and not mentioned by Bayer: he also formed, out of the unformed stars, eleven other constellations; five of which are to the north, and are called the Giraffe, the River Jordan, the River Tigris, the Sceptre, and the Flower-de-luce; with 6 on the south part, which are the Dove, the Unicorn, the Cross, the Great Cloud, the Little Cloud, and the Rhomboide. To this work Royer has joined the catalogue of the southern stars observed by Dr. Halley at the island of St. Helena.

Hevelius has also improved on the labours of those who went before him, and collected together several stars of the before unformed class into some new constellations. These are, the Unicorn, the Camelopardalis, described by Bartschius, the Sextant of Urania, the Dogs, the Little Lion, the Lynx, the Fox and Goose, the Sobieski's Crown, the Lizard, the Little Triangle, and the Cerberus; to which Gregory has added the Ring and the Armilla. Some of these new constellations however answer to those of Royer, as the Camelopardal to the Giraffe, the Dogs to the River Jordan, and the Fox to the River Tigris. The latitudes and longitudes are added for the year 1700.

Finally, Flamsteed has given a catalogue of the fixed stars, not only much more correct, but much larger than any of those that had appeared before his time. He has set down the longitude, latitude, right ascension, and polar distance of 2934 stars, as they were at the beginning of 1690, all determined from his own observations. He distinguishes all the stars into seven classes, or orders of magnitude, distinguishing those of Bayer by his letters, and marking their variation in right ascension, for showing their situation in the succeeding years. See the term CATALOGUE.

This catalogue was followed by an *Atlas Coelestis*, published at London in the year 1729, describing, in several schemes, the figures of the constellations seen in our hemisphere, with the exact position of the fixed stars, with respect to the circles of the sphere, as resulting from the last catalogue corrected by Flamsteed. And still later observations, made with farther improved telescopes, have greatly enlarged the number and accuracy of the stars; but the number of the constellations remains the same as above described, except that an attempt was afterwards made by Dr. Hill to add to the list 14 new ones, formed out of more of the clusters of unformed stars.

Beside the literal marks of the stars introduced by Bayer, it is usual also to distinguish them by that part of the constellation in which they are placed; and many of them again have their peculiar names; as Arcturus, between the knees of Bootes; Gemini, or Lucida, in the Corona Septentrionalis, or Northern Crown; Palilium, or Aldebaran, in the Bull's eye; Pleiades in his neck, and Hyades in his forehead; Castor and Pollux in the heads of Gemini; Capella, with the Hædi in the shoulder of Auriqa; Regulus, or Cor Leonis, the Lion's Heart; Spica Virginis in the hand, and Vindemiatrix in the shoulder of Virgo; Antares or Cor Scorpionis, the Scorpion's Heart; Fomalhaut, in the mouth of Piscis Australis, or Southern Fish; Regi, in the foot of Orion; Sirius, in the mouth of Canis Major, the Great Dog; Procyon, in the back of Canis Minor, the Little Dog; and the Pole Star, the last in the tail of Ursa Minor, the Little Bear.

The Greek and Roman poets, from the ancient theology,

give wild and romantic fables about the origin of the constellations, probably derived from the hieroglyphics of the Egyptians, and transmitted, with some alterations, from them to the Greeks, who probably obscured them greatly with their own fables. See Hyginus's *Poeticum Astron.*; Riccioli *Almagest.* lib. 6, cap. 3, 4, 5; Shelburne's Notes upon *Manilius*; Bailly's *Ancient Astronomy*; and Gebelin's *Monde Primitif*, vol. 4: from the whole of which it appears probable, that the invention of the signs of the zodiac, and probably of most of the other constellations of the sphere, is to be ascribed to some very ancient nation, inhabiting the northern temperate zone, probably what is now called Tartary, or the parts to the northward of Persia and China; and from thence transmitted through China, India, Babylon, Arabia, Egypt, Greece, &c.

It is a very probable conjecture, that the figures of the signs in the zodiac are descriptive of the seasons of the year, or months, in the sun's path: thus, the first sign Aries, denotes, that about the time when the sun enters that part of the ecliptic, the lambs begin to follow the sheep; that on the sun's approach to the 2d constellation, Taurus, the Bull, is about the time of the cows bringing forth their young. The third sign, now Gemini, was originally two kids, and signified the time of the goats bringing forth their young, which are usually two at a birth, while the former, the sheep and cow, commonly produce only one. The 4th sign, Cancer, the Crab, an animal that goes sideways and backwards, was placed at the northern solstice, the point where the sun begins to return back again from the north to the southward. The 5th sign, Leo, the Lion, as being a very furious animal, was thought to denote the heat and fury of the burning sun, when he has left Cancer, and entered the next sign Leo. The succeeding constellation, the 6th in order, received the sun at the time of the ripening of corn and the approach of harvest; which was aptly expressed by one of the female reapers, with an ear of corn in her hand; viz, Virgo, the maid. Libra, or the Balance, which is the following sign, evidently denotes the equality of days and nights, that takes place at that season: and Scorpio, the next in order, denotes the time of gathering in the fruits of the earth, which being generally an unhealthy season, is represented by this venomous animal, extending his long clavus, threatening the mischief that is likely to follow. The fall of the leaf was the season of the ancient hunting; for which reason the constellation Sagittarius represents a huntsman with his arrows and his club, the weapons of destruction for the creatures he pursues. The reason of the Goat's being chosen to mark the southern solstice, when the sun has attained his extreme limit in that quarter, and begins to return and mount again to the northward, is obvious enough; the character of that animal being, that it is mostly found climbing, and ascending some mountain, as it browses. There yet remain two of the signs of the zodiac to be considered with regard to their origin, viz, Aquarius and Pisces. As to the former, it is to be considered that the winter is a wet and uncomfortable season; this therefore was expressed by Aquarius, the figure of a man pouring out water from an urn. The last of the zodiacal constellations was Pisces, a couple of fishes, tied together, that had been caught: The lesson was, the severe season is over, your flocks do not yet yield their store; but the seas and rivers are open, and there you may take fish in abundance.

Through a vain and blind zeal, rather than from any

love for the science, some persons have been induced to alter either the figures of the constellations, or their names. Thus, venerable Bede, instead of the profane names and figures of the twelve zodiacal constellations, substituted those of the 12 apostles; which example was followed by Schiller, who completed the reformation, and gave Scripture names to all the constellations in the heavens. Thus, Aries, or the Ram, was changed into Peter; Taurus, or the Bull, into St. Andrew; Andromeda, into the Sepulchre of Christ; Lyra, into the Manger of Christ; Hercules, into the Magi coming from the East; the Great Dog, into David; and so on. And Weigel, professor of mathematics in the university of Jena, made a new order of constellations; changing the firmament into a Cœlum Heraldicum; and introducing the arms of all the princes in Europe, by way of constellations. Thus Ursa Major, the Great Bear, he transformed into the elephant of the kingdom of Denmark; the Swan, into the Ruta with swords of the House of Saxony; Ophiuchus, into the Cross of Cologne; the Triangle, into Compasses, which he calls the Symbol of Artificers; and the Pleiades into the Abacus Pythagoricus, which he calls that of merchants; &c.

But the more judicious among astronomers never approved of these innovations; as they only tend to introduce confusion into the science. The old constellations are therefore still retained; both because better could not be substituted, and also to keep up the greater correspondence and uniformity between the old astronomy and the new. See *CATALOGUE*.

CONSTRUCTION, in Geometry, the art or manner of drawing or describing figures, schemes, the lines of a problem, or such like.

CONSTRUCTION of Equations, in Algebra, is the finding the roots or unknown quantities of an equation, by geometrical construction of right lines or curves; or the reducing given equations into geometrical figures; which is effected by lines or curves according to the order or rank of the equation.

The roots of any equation may be determined, that is, the equation may be constructed, by the intersections of a straight line with another line or curve of the same dimensions as the equation to be constructed: for the roots of the equation are the ordinates of the curve at the points of intersection with the right line; and it is well known that a curve may be cut by a right line in as many points as its dimensions amount to. Thus, then, a simple equation will be constructed by the intersection of one right line with another; a quadratic equation, or an affected equation of the 2d rank, by the intersections of a right line with a circle, or any of the conic sections, which are all lines of the 2d order; and which may be cut, by the right line, in two points, thereby giving the two roots of the quadratic equation. A cubic equation may be constructed by the intersection of the right line with a line of the 3d order; and so on.

But if, instead of the right line, some other line of a higher order be used; then the 2d line, whose intersections with the former are to determine the roots of the equation, may be taken as many dimensions lower, as the former is taken higher. And, in general, an equation of any degree will be constructed by the intersections of two lines whose dimensions, multiplied together, produce the dimension of the given equation. Thus, the intersections of a circle with the conic sections, or of these with each other, will construct biquadratic equations, or those of

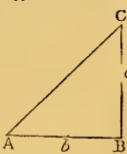

the 4th power, because $2 \times 2 = 4$; and the intersections of the circle or conic sections with a line of the 3d order, will construct equations of the 5th and 6th power; and so on.—For example,

To construct a Simple Equation. This is done by resolving the given simple equation into a proportion, or finding a third or fourth proportional, &c. Thus, 1. If the equation be $ax = bc$; then $a : b :: c : x = \frac{bc}{a}$, the fourth proportional to a, b, c .

2. If $ax = b^2$; then $a : b :: b : x = \frac{b^2}{a}$, a third proportional to a and b .

3. If $ax = b^2 - c^2$; then, since $b^2 - c^2 = (b + c)(b - c)$, $\times (b - c)$, it will be $a : b + c :: b - c : x = \frac{b + c \times b - c}{a}$, a fourth proportional to $a, b + c$ and $b - c$.

4. If $ax = b^2 + c^2$; then construct the right-angled triangle ABC, whose base is b , and perpendicular is c , so shall the square of the hypotenuse be $b^2 + c^2$, which call h^2 ; then the equation is $ax = h^2$, and $x = \frac{h^2}{a}$, a third proportional to a and h .

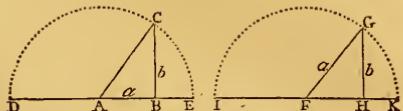

To construct a Quadratic Equation.

1. If it be a simple quadratic, it may be reduced to this form $x^2 = ab$; and hence $a : x :: x : b$, or $x = \sqrt{ab}$ a mean proportional between a and b .

Therefore upon a straight line take $AB = a$, and $BC = b$; then upon the diameter AC describe a semicircle, and raise the perpendicular BD to meet it in D ; so shall BD be = x the mean proportional sought between AB and BC , or between a and b .

2. If the quadratic be affected, let it first be $x^2 + 2ax = b^2$; then form the right-angled triangle ABC, whose base AB is a , and perpendicular BC is b ; and with the centre A and radius AC describe the semicircle CE ; so shall DB and BE be the two roots of the given quadratic equation $x^2 + 2ax = b^2$.

3. If the quadratic be $x^2 - 2ax = b^2$, then the construction will be the very same as of the preceding one $x^2 + 2ax = b^2$.

4. But if the form be $2ax - x^2 = b^2$; form a right-angled triangle whose hypotenuse FG is a , and perpendicular GH is b ; then with the radius FG and centre F describe a semicircle IG ; so shall IH and HK be the two roots of the given equation $2ax - x^2 = b^2$, or $x^2 - 2ax = -b^2$. See Maclaurin's Algebra, part 3, cap. 2, and Simpson's Algebra, pa. 267.

To construct Cubic and Biquadratic Equations.—These are constructed by the intersections of two conic sections; for the equation will rise to 4 dimensions, by which are determined the ordinates from the 4 points in which these conic sections may cut one another; and the conic sections may be assumed in such a manner, as to make this

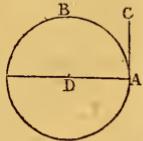

equation coincide with any proposed biquadratic: so that the ordinates from these 4 intersections will be equal to the roots of the proposed biquadratic. When one of the intersections of the conic section falls upon the axis, then one of the ordinates vanishes, and the equation, by which these ordinates are determined, will then be of 3 dimensions only, or a cubic; to which any proposed cubic equation may be accommodated. So that the three remaining ordinates will be the roots of that proposed cubic. The conic sections for this purpose should be such as are most easily described; the circle may be one, and the parabola is usually assumed for the other.

Viete, in his Canonica Recensione Effectorum Geometricarum, and Ghetaldus, in his Opus Posthumum de Resolutione et Compositione Mathematica, as also Descartes, in his Geometria, have shown how to construct simple and quadratic equations. Descartes has also shown how to construct cubic and biquadratic equations, by the intersection of a circle and a parabola: And the same has been done more generally by Baker, in his Clavis Geometrica, or Geometrical Key. But the genuine foundation of all these constructions was first laid and explained by Slusius in his Mesolabium, part 2. This doctrine is also pretty well handled by Lahire, in a small treatise, called La Construction des Equations Analytiques, annexed to his Conic Sections. Newton, at the end of his Algebra, has given the construction of cubic and biquadratic equations mechanically; as also by the conchoid and cissoid, as well as the conic sections. See also Dr. Halley's Construction of Cubic and Biquadratic Equations; Colson's, in the Philos. Trans.; the Marquis de l'Hospital's Traité Analytique des Sections Coniques; Maclaurin's Algebra, part 3, c. 3, &c.

CONTACT, the relative state of two things that touch each other, but without cutting or entering; or whose surfaces join to each other without any interstice.

The contact of curve lines or surfaces, with either straight or curved ones, is only in points; and yet these points have different proportions to one another, as is shown by Mr. Robartes, in the Philos. Trans. vol. 27, pa. 470; or my Abr. vol. 5, pa. 678. Because few or no surfaces are capable of touching in all points, and the cohesion of bodies is in proportion to their contact, those bodies will adhere fastest together, that are capable of the greatest contact.

Angle of Contact, is the opening between a curve line and a tangent to it, particularly the circle and its tangent; as the angle formed at A between BA and AC , at the point of contact A . It is demonstrated by Euclid, that the line CA standing perpendicular on the radius DA , touches the circle only in one point: and that no right line can be drawn between the tangent and the circle. Hence, the angle of contact is less than any rectilinear angle; and the angle of the semicircle between the radius DA and the arch AB , is greater than any rectilinear acute angle. This seeming paradox of Euclid has exercised the wits of mathematicians: it was the subject of a long controversy between Peletarius and Clavius; the former of whom maintained that the angle of contact is heterogeneous to a rectilinear one, as a line is to a surface; the latter maintained the contrary. Dr. Wallis has a formal treatise on the

angle of contact, and of the semicircle ; where, with other great mathematicians, he approves of the opinion of Peletarius.

CONTENT, a term often used for the measurement of bodies and surfaces, whether solid or superficial ; or the capacity of a vessel and the area of a space ; being the quantity either of matter or space included within certain bounds or limits.

CONTIGUITY, the relation of bodies touching one another.

CONTIGUOUS, a relative term, understood of things so disposed, that their surfaces touch each other.

CONTIGUOUS Angles, are such as have one leg or side common to each angle ; and are otherwise called adjacent angles ; in contradistinction to those made by continuing their legs through the point of contact, which are called opposite or vertical angles.

CONTINENT, a terra firma, main-land, or a large extent of country, not interrupted by seas : so called, in opposition to island, peninsula, &c.

Our earth is usually divided into two grand continents, the old and the new : the old continent comprehends Europe, Asia, and Africa ; the new continent comprehends North and South America. Since the discovery of New Holland and New South Wales, it is a doubt with many whether to call that vast country an island or a continent.

CONTINGENT Line, the same with tangent line in Dialling, being the intersection of the planes of the dial and equinoctial, and at right angles to the substilar line.

CONTINUAL, or **CONTINUED PROPORTIONALS**, are a series of three or more quantities compared together, so that the ratio is the same between every two adjacent terms, viz. between the 1st and 2d, the 2d and 3d, the 3d and 4th, &c. As 1, 2, 4, 8, 16, &c, where the terms continually increase in a double ratio ; or 12, 4, $\frac{4}{3}$, $\frac{1}{3}$, where the terms decrease in a triple ratio. A series of continual or continued proportionals, is otherwise called a Progression.

CONTINUED Fractions. See FRACTIONS.

CONTINUED Quantity, or **Body**, is that whose parts are joined and united together.

CONTINUED Proportion, is that in which the consequent of the first ratio is the same with the antecedent of the second ; as in these, $3 : 6 :: 6 : 12$. See **CONTINUAL Proportion**.

On the contrary, if the consequent of the first ratio be different from the antecedent of the second, the proportion is called **Discrete** : as $3 : 6 :: 4 : 8$.

CONTRACTION, in Arithmetic, is the shortening or contracting certain operations, as in Multiplication, Division, Extraction of the Square Root, &c : the method for which see under the respective heads.

CONTRA-HARMONICAL Proportion, that relation of three terms, in which the difference of the first and second is to the difference of the 2d and 3d, as the 3d is to the first. Thus, for instance, 3, 5, and 6, are numbers contra-harmonically proportional ; for $2 : 1 :: 6 : 3$.

CONTRA-MURE, in Fortification, is a little wall built before another partition wall, to strengthen it, so that it may receive no damage from the adjacent buildings.

CONTRATE-WHEEL, is that wheel in watches which is next to the crown, whose teeth and hoop lie contrary to those of the other wheels ; from whence comes its name.

CONTRAVALLATION, *Line of*, in Fortification, is a trench, guarded with a parapet ; being made by the be-

siegers, between them and the place besieged, to secure themselves on that side, and stop the sallies of the garrison. It is made beyond the reach of musket-shot from the town ; sometimes going quite around it, and sometimes not, as occasion may require. The besiegers lie between the lines of circumvallation and contravallation : but it is now seldom used.

CONVERGING Curves. See CURVE.

CONVERGING, or **CONVERGENT Lines**, in Geometry, are those that continually approximate, or whose distance becomes continually less and less the farther they are continued, till they meet : in opposition to divergent lines, whose distance becomes continually greater.

Lines that converge the one way, diverge the other.

CONVERGING Rays, in Optics, are such as incline towards one another in their passage, and in Dioptrics, are those rays which, in their passage out of one medium into another of a different density, are refracted towards one another ; so that, if far enough continued, they will meet in a point or focus.

CONVERGING Series, a series of terms or quantities, that always decrease the further they proceed, or which tend to a certain magnitude or limit : in opposition to diverging series, or such as become larger and larger continually. See SERIES.

CONVERSE. A proposition is said to be the converse of another, when, after drawing a conclusion from something first supposed, we return again, by making a supposition of what had before been concluded, and draw from thence as a conclusion what before was made the supposition. Thus, when it is supposed that the two sides of a triangle are equal, and thence demonstrate or conclude that the two angles opposite to those sides are equal also ; then the converse is to suppose that the two angles of a triangle are equal, and thence to prove or conclude that the sides opposite to those angles are also equal.

CONVERSION, or **CONVENTENDO**, is when there are four proportionals, and it is inferred, that the first is to its excess above the 2d, as the 3d to its excess above the 4th : according to Euclid, lib. 5, def. 17.

Thus, if it be $8 : 6 :: 4 : 3$, then convertendo, or by conversion, $8 : 2 :: 4 : 1$. Or if there be $a : b :: c : d$, then convertendo, or by conversion, $a : a-b :: c : c-d$.

CONVEX, round or curved and protuberant outwards, as the outside of a globular body.

CONVEX Lens, *Mirror*, &c. See LENS, MIRROR, &c.

CONVEXITY, the exterior or outward surface of a convex or round body.

COORDINATES, in the Higher Geometry, is the general term used, when the absciss and ordinates of a curve are considered connectedly, whether they are at right angles with each other or not ; and the nature of a curve is determined by the equation between its coordinates.

COPERNICAN, something relating to Copernicus. As the

COPERNICAN Sphere. See SPHERE.

COPERNICAN System, is that system of the world, in which it is supposed that the sun is at rest in the centre, and the earth and planets all moving around him in their own orbits. Here it is supposed, that the heavens and stars are at rest ; and the diurnal motion which they appear to have, from east to west, is imputed to the earth's diurnal motion from west to east.

This system was maintained by many of the ancients; particularly Elephantus, Seleucus, Aristarchus, Philolaus, Cleanthes Samius, Nicetas, Heracles Ponticus, Plato, and Pythagoras; from the last of whom it was anciently called the Pythagoric, or Pythagorean System. The same system was also held by Archimedes, in his book of the number of the Grains of Sand; but after him it became neglected, and even forgotten, for many ages; till about 300 years since, when Copernicus revived it; from whom it took the new name of the Copernican System. See the next article.

COPERNICUS (NICHOLAS), an eminent astronomer, was born at Thorn in Prussia, January 19, 1473. He was instructed in the Latin and Greek languages at home; and afterward sent to Cracow, where he studied philosophy, mathematics, and medicine: though his genius was naturally turned to mathematics, which he chiefly studied, and pursued through all its various branches.

He set out for Italy at 23 years of age; stopping at Bologna, that he might converse with the celebrated astronomer of that place, Dominic Maria, whom he assisted for some time in making his observations. From hence he passed to Rome, where he was presently considered as not inferior to the famous Regiomontanus. Here he soon acquired so great a reputation, that he was chosen professor of mathematics, which he taught there for a long time with the greatest applause; and here also he made some astronomical observations about the year 1500.

Afterward, returning to his own country, he began to apply his fund of observations and mathematical knowledge, to correcting the system of astronomy which then prevailed. He set about collecting all the books that had been written by philosophers and astronomers, and to examine all the various hypotheses they had invented for the solution of the celestial phenomena; to try if a more symmetrical order and constitution of the parts of the world could not be discovered, and a more just and exquisite harmony in its motions established, than what the astronomers of those times so generally admitted. But of all their hypotheses, none pleased him so well as the Pythagorean, which made the sun to be the centre of the system, and supposed the earth to move both round the sun, and also round its own axis. He thought he discerned much beautiful order and proportion in this; and that all the embarrassment and perplexity, from epicycles and eccentricities, which attended the Ptolemaic hypotheses, would here be entirely removed.

He began to consider this system, and to write upon it, when he was about 35 years of age. He carefully contemplated the phenomena, made mathematical calculations, examined the observations of the ancients, and made new ones of his own; till, after more than 20 years chiefly spent in this manner, he brought his scheme to perfection, establishing that system of the world which goes by his name, and is now universally received by all philosophers.

This system however was at first considered as a most dangerous heresy, and his work had long been finished and perfected, before he could be prevailed on to give it to the world, notwithstanding being strongly urged to it by his friends. At length, yielding to their entreaties, it was printed, and he had but just received a perfect copy, when he died the 24th of May 1543, at 70 years of age; by which it is probable he was happily relieved from the violent fanatical persecutions of the church, which were

but too likely to follow the publication of his astronomical opinions; and which indeed was afterwards the fate of Galileo, for adopting and defending them. This work of Copernicus, first printed at Norimberg in folio, 1543, and of which there have been other editions since, is intituled *De Revolutionibus Orbium Cælestium*, being a large body of astronomy, in 6 books.

When Rheticus, the disciple of our author, returned out of Prussia, he brought with him a tract of Copernicus, on plane and spherical trigonometry, which he had printed at Norimberg, and which contained a table of sines. It was afterward printed at the end of the first book of the *Revolutions*. An edition of our author's great work was also published in 4to at Amsterdam in 1617, under the title of *Astronomia Instaurata*, illustrated with notes by Nicolaus Muler of Groningen.

COPERNICUS, the name of an astronomical instrument, invented by Whiston, to show the motion and phenomena of the planets, both primary and secondary. It is founded on the Copernican system, and therefore called by his name.

COPPER, is a malleable and ductile metal, of a pale-red colour, with a tinge of yellow. It is soluble with effervescence in nitrous acid, to which it gives a sky-blue colour: on the addition of liquid ammonia, a green precipitate is thrown down, which is resoluble in an excess of ammonia, forming a very rich purplish-blue fluid, and from this, if slightly supersaturated with muriatic acid, the copper is again precipitable in its metallic form, by a bar of clean iron. See Aikin's Chemical Dictionary, Article **COPPER**.

COR CAROLI, Charles's Heart, an extra-constellated star of the 2d magnitude in the northern hemisphere, between the Coma Berenices and Ursa Major; so called by Sir Charles Scarbrough, in honour of King Charles I.

COR HYDRAE, the Hydra's Heart, a star of the 2d magnitude, in the Heart of the constellation Hydra.

COR LEONIS, Lion's Heart, or Regulus, a star of the first magnitude in the constellation Leo.

COR SCORPII. See ANTARES.

CORBELLS, in Fortification, are little baskets about a foot and a half high, 8 inches broad at the bottom, and 12 at the top; which being filled with earth, are set against one another on the parapet, or elsewhere, leaving certain port-holes, from whence to fire under cover upon the enemy.

CORBEL, in Architecture, the representation of a basket, sometimes seen on the heads of caryatides.

CORBEL, or **CORBIL**, is also used, in Building, for a short piece of timber placed in a wall, with its end projecting out 6 or 8 inches, as occasion serves, in the manner of a shouldering-piece.

CORBET, the same as **CORBEL**.

CORDON, in Fortification, a row of stones jutting out between the ramparts and the basis of the parapet, like the tore of a column. The cordon ranges round the whole fortress, and serves to join the rampart, which is a-slope, and the parapet, which is perpendicular, more agreeably together. In fortifications raised of earth, this space is filled up with pointed stakes instead of a cordon.

CORDS, in Music, are the sounds produced by an instrument or the voice.

CORRIDOR, or **CORRIDOR**, in Fortification, is the covert-way lying entirely round the whole compass of the

works of a place, between the outside of the moat and the palisades, being about 20 yards broad.

CORRIDOR is also used, in Architecture, for a gallery, or long aisle, around a building, leading to several chambers at a distance from each other, sometimes wholly inclosed, and sometimes open on one side.

CORINTHIAN Order, of Architecture, is the 4th in order, or the 5th and last according to Scamozzi and Le Clerc. This order was invented by an Athenian architect, and is the richest and most delicate of them all; its capital is adorned with rows of leaves, and of 8 volutas, which support the abacus. The height of its column is 10 diameters, and its cornice is supported by modillions.

CORNEA Tunica, the second coat of the eye; so called from its substance resembling the horn of a lantern. This is situated in the fore-part; and is surrounded by the sclerota. It has a greater convexity than the rest of the eye, and is a portion of a small sphere, or rather spheroid, and consolidates the whole eye.

CORNICE, CORNICHE, or CORNISH, the third and uppermost part of the entablature of a column, or the uppermost ornament of any wainscoting, &c.

COROLLARY, or CONSEQUENTIARY, a consequence drawn from some proposition or principles already advanced or demonstrated, without the aid of any other proposition: thus from this theorem, That a triangle which has two equal sides, has also two equal angles, this consequence may be drawn, That a triangle which hath the three sides equal, has also its three angles equal.—What is now called a corollary, was by the earlier geometers named a *Porism*.

CORONA, Crown or Crowning, in Architecture, the flat and most advanced part of the cornice; so called because it crowns the cornice and entablature: by the workmen it is called the drip, as serving by its projection to screen the rest of the building from the rain.

CORONA, in Optics, a luminous circle, usually coloured, which is seen round the sun, moon, or largest planets. See *HALO*.

CORONA Borealis, or Septentrionalis, the *Northern Crown* or *Garland*, a constellation of the northern hemisphere, being one of the 48 old ones. It contains 8 stars according to the catalogue of Ptolemy, Tycho, and Hevelius; but according to the Britannic Catalogue, 21.

CORONA Australis, or Meridionalis, the *Southern Crown*, a constellation of the southern hemisphere, whose stars in Ptolemy's catalogue are 13; in the British catalogue, 12.

CORPUSCLE, the diminutive of *corpus*, used to express the minute parts, or particles, that constitute natural bodies; meaning much the same as atoms. Newton shows a method of determining the sizes of the corpuscles of bodies, from their colours.

CORPUSCULAR Attraction, denotes that power by which the minute component particles of bodies are united, and adhere to each other. It may be distinguished into attraction of aggregation, viz, that power by which the homogeneous particles of bodies are united; and attraction of affinity or of composition, viz, that power by which the heterogeneous particles of bodies are united.

CORPUSCULAR Philosophy, that scheme or system of physics, in which the phenomena of bodies are accounted for, from the motion, rest, position, &c, of the corpuscles or atoms of which bodies consist.

The Corpuscular philosophy, which now flourishes un-

der the name of the mechanical philosophy, is very ancient. Leucippus and Democritus taught it in Greece; from them Epicurus received it, and improved it; and from him it was called the Epicurean Philosophy.

Leucippus, it is said, received it from one Mochus, a Phenician physiologist, before the time of the Trojan war, and the first who philosophized about atoms: which Mochus is, according to the opinion of some, the Moses of the Scriptures.

After Epicurus, the corpuscular philosophy gave way to the peripatetic, which became the popular system. Thus, instead of atoms, were introduced specific and substantial forms, qualities, sympathies, &c, which amused the world, till Gassendus, Charleton, Descartes, Boyle, Newton, and others, retrieved the corpuscularian hypothesis; which is now become the basis of the mechanical and experimental philosophy.

Boyle reduces the principles of the corpuscular philosophy to the 4 following heads.

1. That there is but one universal kind of matter, which is an extended, impenetrable, and divisible substance, common to all bodies, and capable of all forms.—On this head, Newton finely remarks thus: “All things considered, it appears probable to me, that God in the beginning created matter in solid, hard, impenetrable, moveable particles; of such sizes and figures, and with such other properties, as most conduced to the end for which he formed them: and that these primitive particles, being solids, are incomparably harder than any of the sensible porous bodies compounded of them; even so hard as never to wear, or break in pieces: no other power being able to divide what God made one in the first creation. While these corpuscles remain entire, they may compose bodies of one and the same nature and texture in all ages: but should they wear away, or break in pieces, the nature of things depending on them would be changed: water and earth, composed of old worn particles, of fragments of particles, would not be of the same nature and texture now, with water and earth composed of entire particles at the beginning. And therefore, that nature may be lasting, the changes of corporeal things are to be placed only in the various separations, and new associations, of these permanent corpuscles.”

2. That this matter, in order to form the vast variety of natural bodies, must have motion in some, or all its assignable parts; and that this motion was given to matter by God, the creator of all things; and has all manner of directions and tendencies.—“These corpuscles (says Newton) have not only a vis inertiae, accompanied with such passive laws of motion as naturally result from that force; but also are moved by certain active principles; such as that of gravity, and that which causes fermentation, and the cohesion of bodies.”

3. That matter must also be actually divided into parts; and each of these primitive particles, fragments, or atoms of matter, must have its proper magnitude, figure, and shape.

4. That these differently sized and shaped particles, have different orders, positions, situations, and postures, from whence all the variety of compound bodies arises.

CORRECTION of a Fluent. See *FLUENT*.

CORRIDOR. See *CORRIDOR*.

CORTES (MARTIN), a Spanish author on Navigation, who flourished in the middle of the 16th century. In 1551

was published at Seville, his book entitled, *Breve de la Sphera y de la Arte de Nauegar con nuevos Instrumentos y Reglas*; which he says he composed at Cadiz in 1545. In the dedication to the emperor, Cortes boasts that he was the first who had reduced navigation into a Compendium, enlarging much on what he had performed. He briefly and clearly exposed the errors of plane-charts, and seemed to reflect on what had been said against the variation of the compass by Medina, when he advised the mariner, rather to be guided by experience, than to mind subtle reasonings. Besides, he endeavoured to account for this variation, in imagining the needle to be influenced by a magnetic pole (which he called the Point Attractive) different from that of the world; a notion which has been farther prosecuted by others.—A translation of Cortes's book by Richard Eden, was, on the recommendation of that great navigator Steven Burrough, and the encouragement of the Society for making discoveries at sea, published at London in 1561.

CORVUS, the *Raven*, a southern constellation, fabled by the Greeks, as taken up to heaven by Apollo, to whom it tattled that the beautiful maid Coronis, the daughter of Phlegoës, and mother of Esculapius by Apollo, played the deity false with Ischys, under a tree upon which the animal happened to be perched. The stars in this constellation, in Ptolemy's and Tycho's catalogues, are 7; but in the Britannic catalogue, 9.

COSECANT, COSINE, COTANGENT, COVERSED SINE, are the secant, sine, tangent, and versed sine of the complement of an arch or angle; *Co* being, in this case, a contraction of the word complement, and was first introduced by Gunter.

COSMICAL ASPECT, among astrologers, is the aspect of a planet with respect to the earth.

COSMICAL Rising, or Setting, is said of a star when it rises or sets at the same time when the sun rises.

But, according to Kepler, to rise or set cosmically, is only simply to rise or set, that is, to ascend above, or descend below, the horizon; as much as to say, to rise or set to the world.

COSMOGONY, the science of the formation of the universe; as distinguished from cosmography, which is the science of the parts of the universe, supposing it formed, and in the state as we behold it; and from cosmology, which reasons on the actual and permanent state of the world as it now is; whereas cosmogony reasons on the variable state of the world at the time of its formation.

COSMOGRAPHY, the description of the world; or the art that teaches the construction, figure, disposition, and relation of all the parts of the world, with the manner of representing them on a plane. It consists chiefly of two parts; *viz.*, *Astronomy*, which shows the structure of the heavens, with the disposition of the stars; and *Geography*, which shows those of the earth.

COSMOLOGY, the science of the world in general.

COSS, Rule of, meant the same as Algebra, by which name it was for some time called, when first introduced into Europe through the Italians, who named it *Regola de cosa*, the Rule of the thing; the unknown quantity, or that which was required in any question, being called cosa, the thing; the terms whence we have Coss, and Cossic numbers, &c.

COSTARD (GEORGE), was born at Shrewsbury 1710, and educated at Wadham-college, Oxford, of which he became a fellow and a tutor; he died at his vicarage at

Wickendenham, Jan. 10, 1782, in the 72d year of his age. Mr. Costard was a man of great learning; deeply read in divinity and astronomy; well versed in the Greek, and a perfect master of the Hebrew and other oriental languages.—His private character was amiable, and his correspondence with the literati was extensive both at home and abroad. He had a great veneration for the Greeks and their literature; and was generally skilled in the learning of most of the ancient nations. Besides various publications on divinity, &c., he was author of the *History of Astronomy*, 4to, 1767, with its application to geography, history, and chronology. His communications to the Royal Society, which are chiefly on astronomical subjects, are contained in vols. 43, 44, 48 and 68 of the *Philosophical Transactions*.

COTES (ROGER), a very eminent mathematician, philosopher, and astronomer, was born July 10, 1682, at Burbach in Leicestershire, where his father Robert was rector. He was first placed at Leicester school; where, at 12 years of age, he discovered a strong inclination to the mathematics. This being observed by his uncle, the Rev. Mr. John Smith, he gave him all the encouragement he could; and prevailed on his father to send him for some time to his house in Lincolnshire, that he might assist him in those studies; and here he laid the foundation of that deep and extensive knowledge in that science, for which he was afterwards so deservedly famous. He was hence removed to St. Paul's school, London, where he made a great progress in classical learning; and yet he found so much leisure as to support a constant correspondence with his uncle, not only in mathematics, but also in metaphysics, philosophy, and divinity. His next remove was to Trinity-college, Cambridge, where he took his degrees, and became fellow.

Jan. 1706, he was appointed professor of astronomy and experimental philosophy, on the foundation of Dr. Thomas Plume, archdeacon of Rochester; being the first that enjoyed that office, to which he was unanimously chosen, on account of his high reputation and merits. He entered into orders in 1713; and the same year, at the desire of Dr. Bentley, he published at Cambridge the second edition of Newton's *Mathematica Principia*; inserting all the improvements which the author had made to that time. To this edition he prefixed an excellent preface, in which he pointed out the true method of philosophizing, showing the foundation on which the Newtonian philosophy was raised, and refuting the objections of the Cartesians and all other philosophers against it.

The publication of this edition of Newton's *Principia* added greatly to his reputation; nor was the high opinion the public now conceived of him in the least diminished, but rather much increased, by several productions of his own, which afterward appeared. He gave in the *Philos. Transactions*, two papers, *viz.*, 1, *Logometria*, in vol. 29; and a *Description of the great fiery meteor that was seen March 6, 1716*, in vol. 31.

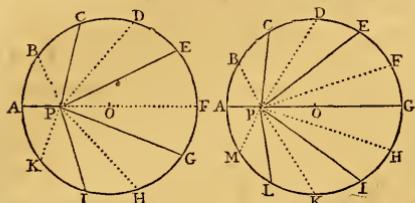

This extraordinary genius in the mathematics died, to the great regret of the university, and all the lovers of the sciences, June 5, 1716, in the very prime of his life, being not quite 34 years of age.

Mr. Cotes left behind him some very ingenious, and indeed admirable tracts, part of which, with the *Logometria* above mentioned, were published, in 1722, by Dr. Robert Smith, his cousin and successor in his professorship, afterwards master of Trinity-college, under the title of Har-

monia Mensurarum, which contains a number of very ingenious and learned works: See the Introduction to my Logarithms. He wrote also a Compendium of Arithmetic; on the Resolution of Equations; on Dioptrics; and on the Nature of Curves. Besides these pieces, he drew up, in the time of his lectures, a course of Hydrostatical and Pneumatical Lectures, in English, which were published also by Dr. Smith in 8vo, 1737, and are held in great estimation.

So high an opinion had Sir Isaac Newton of our author's genius, that he used to say, "If Cotes had lived, we might have known something."

COTESIAN theorem, in Geometry, an appellation used for an elegant property of the circle discovered by Mr. Cotes. The theorem is this: If the factors of the binomial $a^c - x^c$ be required, the index c being an integer number. With the centre O , and radius $AO = a$, describe a circle,

and divide its circumference into as many equal parts as there are units in $2c$, at the points $A, B, C, D, \& c.$; then in the radius, produced if necessary, take $OP = x$, and from the point P , to all the points of division in the circumference, draw the lines $PA, PB, PC, \&c.$; so shall these lines taken alternately, be the factors sought; viz,

$$PB \times PD \times PF \times PC \&c = a^c + x^c, \text{ and}$$

$PA \times PC \times PE \&c = a^c - x^c$, viz, $a^c - x^c$ or $x^c - a^c$, according as the point P is within or without the circle. For instance, if $c = 5$, divide the circumf. into 10 equal parts, and the point P being within the circle, then will

$$OA^5 + OP^5 = BP \times DP \times FP \times HP \times KP, \\ \text{and } OA^5 - OP^5 = AP \times CP \times EP \times GP \times IP.$$

In like manner, if $c = 6$, having divided the circumference into 12 equal parts, then will

$$OA^6 + OP^6 = BP \times DP \times FP \times HP \times KP \times MP, \\ OA^6 - OP^6 = AP \times CP \times EP \times GP \times IP \times LP.$$

The demonstration of this theorem may be seen in Dr. Pemberton's Epist. de Cotesii inventis. See also Dr. Smith's Theorematum Logometrica and Trigonometrica, added to Cotes's Harm. Mens. pa. 114; De Moivre Miscel. Analyt. pa. 17; Waring's Letter to Dr. Powell, pa. 39, and Simpson's Essays, p. 113.

By means of this theorem, the acute and elegant author was enabled to make a farther progress in the inverse method of Fluxions, than had been done before. But in the application of his discovery there still remained a limitation, which was removed by Demoivre. Vide ut supra.

COVERT-WAY, in Fortification, a space of ground level with the adjoining country, on the outer edge of the ditch, ranging quite round all the works. This is otherwise called the Corridor, and has a parapet with its banquette and glacis, which form the height of the parapet. It is sometimes also called the Counterscarp, because it is on the edge of the scarp.—One of the greatest difficulties in a siege, is to make a lodgment on the covert-way; because

it is usual for the besieged to palisade it along the middle, and undermine it on all sides.

COVING, in Building, is when houses are built projecting over the ground plot, and the turned projection formed into an arch.

COVING Cornice, is one that has a large casemate or hollow in it.

COUNT-WHEEL, is a wheel in the striking part of a clock, moving round once in 12 or 24 hours. It sometimes called the locking-wheel, because it has usually 11 notches in it at unequal distances from one another, to make the clock strike.

COUNTER-APPROACHES, in Fortification, lines or trenches made by the besieged, where they come out to attack the lines of the besiegers in form.

COUNTER-BATTERY, a battery raised to play on another, to dismount the guns, &c.

COUNTER-BREAST-WORK, the same as *Fausse-Braye*.

COUNTER-FORTS, BUTTRESSES, OR SPURS, are pillars of masonry serving to prop or sustain walls, or terraces, subject to bulge, or be thrown down.

COUNTER-FUGUE, in Music, is when fugues proceed contrary to one another.

COUNTER-GUARD, in Fortification, a work commonly serving to cover a bastion. It is composed of two faces, forming a salient angle before the flanked angle of a bastion.

COUNTER-HARMONICAL. See *CONTRA-HARMONICAL*.

COUNTER-MINE, a subterraneous passage, made by the besieged, in search of the enemy's mine, to give air to it, to take away the powder; or by any other means to frustrate the effect of it.

COUNTER-PART, a term in Music, only denoting that one part is opposite to another: so, the bass and treble are counter-parts to each other.

COUNTER-POINT, in Music, the art of composing harmony; or disposing and concerting several parts so together, as that they may make an agreeable whole.

COUNTER-POISE, any thing serving to weigh against another; particularly a piece of metal, usually of brass or iron, making an appendage to the Roman statera, or steelyard. It is contrived to slide along the beam; and from the division at which it keeps the balance in equilibrio, the weight of the body is determined. It is sometimes called the Pear, on account of its figure; and Mass, by reason of its weight. Rope-dancers make use of a pole by way of counterpoise, to keep their bodies in equilibrio.

COUNTERSCARP, is that side of the ditch that is next the country; or properly the talus that supports the earth of the covert-way: though by this word is often understood the whole covert-way, with its parapet and glacis. And so it must be understood when it is said, The enemy lodged themselves on the counterscarp.

COUNTER-SWALLS-TAIL, is an outwork in Fortification, in form of a single tenaille, wider towards the place, or at the gorge, than at the head, or next the country.

COUNTER-TENOR, one of the mean or middle parts of music; so called, as being opposite to the tenor.

COURSE, in Navigation, the point of the compass, or horizon, which a ship steers on; or the angle which the rhumb-line on which it sails makes with the meridian; being sometimes reckoned in degrees, and sometimes in points of the compass.

When a ship sails either due north or south, she sails on a meridian, makes no departure, and her distance and dif-

ference of latitude are the same. When she sails due east or west, her course makes right-angles with the meridian, and she sails either upon the equator, or a parallel to it; in which case she makes no difference of latitude, but her distance and departure are the same. But when the ship sails between the cardinal points, on a course making always the same oblique angle with the meridians, her path is then the loxodromic curve, being a spiral cutting all the meridians in the same angle, and terminating in the pole.

Hence arises a kind of geographical, or nautical paradox; at least to those who have but a limited knowledge of those subjects; which is this. If we suppose two places having different latitudes and longitudes, and that a person leaves one of those places on a certain point of the compass, bearing directly towards the other; and having arrived there, leaves this last place upon the direct opposite point of the compass to that on which he first set out, it will be found on his pursuing this course, that he will never return again to the place whence he first departed; but will leave it more or less on the right or left, according to the relative situations of the two places.

The cause of this deviation from his original track is however easily explained: for in the first case, as the traveller is supposed to go directly from one place to the other, he does not continue, in any two successive instances, to pursue the same point of the compass; whereas on his return, he is considered as constantly observing the same point, and hence arises the deviation in question.

For the same reason, if a vessel depart from a port situated in north latitude, and constantly pursue the same north-easterly, or north-westerly course, it will continually approach towards the north pole in a spiral traced on the terrestrial surface, but it will never arrive there, however far the voyage may be pursued. And exactly the same thing will take place with respect to the south pole, if the course be directed towards the south-east, or south-west.

COURTAIN. See CURTIN.

CРАB, in Mechanics, an engine used for mounting guns on their carriages. See GIN.

CРАB, on ship-board, is a wooden pillar, having its lower end let down through the ship's decks, and resting on a socket, like the capstan: in its upper end are three or four holes, at different heights, through the middle of it, one above another, to receive long bars, against which men act by pushing or thrusting.—It is employed to wind-in the cable, and for other purposes requiring a great mechanical power.

The Crab with three claws is used to launch ships, and to heave them into the dock, or off the key.

CРАBTREE (W^m.), an ingenious English astronomer, who resided at Broughton near Manchester in Lancashire, in the early part of the 17th century. He was the friend of the congenial young astronomer Horrox, near Liverpool, with whom he carried on a learned astronomical correspondence for the several years 1636, 1637, 1638, 1639, 1640; by which means he was very instrumental in encouraging Mr. Horrox to prosecute his useful astronomical observations and writings. A collection of those of Mr. Crabtree, mostly for the same years as those above, was published by Dr. Wallis, along with the works of his friend Horrox, in one vol. 4to, 1672. A long and learned letter of his to Mr. Gascoigne (the inventor of the Micrometer), on the nature and appearances of the solar spots, in the Philos. Trans. vol. 27, and in my Abridg. vol. 5, pa. 626.

CRAIG (REV. JOHN), F.R.S, a respectable Scotch di-

vine and mathematician, who it seems settled some time at Cambridge, but was afterwards vicar of Gillingham, in Dorsetshire, whence he commonly addressed his letters to the Royal Society. In 1685 he had a dispute with John Bernoulli, on the quadrature of curve lines and curvilinear figures. He had also another difference with that great mathematician on an algebraic equation; but afterwards finding himself wrong, he candidly acknowledged it in the Philosophical Transactions. He wrote several good pieces on mathematical subjects, partly published separately, and several published in the Philos. Trans. as also the translation of them from the Latin in my Abridgement, where a catalogue of them may be seen, in the index at the end of the 18th or last volume; being, 1. Quadratures of curves geometrically irrational.—2. Quadrature of the logarithmic curve.—3. On the curve of quickest descent.—4. On the solid of least resistance.—5. Method of determining the quadrature of figures.—6. Solution of Bernoulli's problem on curves.—7. On the length of curve lines.—8. Method of making logarithms.—9. On the head of a monstrous calf.

And his separate publications are, 1. Methodus figurarum quadraturas, &c, anno 1685, 4to.—2. De quadraturis et locis, &c, an. 1693, 4to.—3. De calculo fluentium, et de Optica analytica, &c, an. 1718, 4to.—4. Theologia Christianæ principia mathematica, 1699, and afterwards printed at Leipsic, with a learned preface. The object of this curious tract, is to apply mathematical calculation to the credibility of the Gospel history; and on this principle he maintains that the Christian religion must end, according to the doctrine of chances, anno dom. 3150, at which time Christ will make his second appearance. This work was answered by the abbé Hauteville, in a piece entitled, The Christian religion proved by facts.

CRAMER (GABRIEL), an eminent Swiss mathematician, was born at Geneva in 1704, and died 1752. He was made professor of mathematics at 19 years of age, and was author of several good works; as, his Theory of Curve Lines, 1750, 4to; he simplified the art of reducing the equations of a problem to the smallest number possible. To him the world owes the useful labour of collecting and publishing the works of James and John Bernoulli. He possessed a fund of knowledge in physics and the belles lettres, and rendered himself famous throughout Europe by his progress and skill in mathematics.

CRANE, a machine used in building, and in commerce, for raising large stones and other weights.

Perrault, in his notes on Vitruvius, makes the crane the same with the corvus, or raven, of the ancients.

The modern crane consists of several members or pieces, the principal of which is a strong upright beam, or arbor, firmly fixed in the ground, and sustained by eight arms, coming from the extremities of four pieces of wood laid across, through the middle of which the foot of the beam passes. About the middle of the arbor the arms meet, and are mortised into it; its top ends in an iron pivot, on which is borne a transverse piece, advancing out to a good distance like a crane's neck; whence the name. The middle and extremities of this are again sustained by arms from the middle of the arbor: and over it passes a rope, or chain, to one end of which the weight is fixed; the other is wound about the spindle of a wheel, which, turned, draws the rope, and that heaves up the weight; to be afterwards applied to any side or quarter, by the mobility of the transverse piece on the pivot.

Several improvements of this useful machine are mentioned in Desaguliers's Exper. Philos. pa. 178 & seq. particularly how to prevent the inconveniences arising from sudden jerks, as well as to increase its force by using a double axis in peritrochio, and two handles.

The Crane is of two kinds; in the first kind, called the rat-tailed crane, the whole machine, with the load, turns upon a strong axis; in the second kind, the gibbet alone moves on its axis. See Desaguliers, as above, for a particular account of the different cranes, and of the gradual improvements they have received. See also the Supplement to Ferguson's Lectures, pa. 3, &c.; or Philos. Trans. vol. 54, pa. 24, for a description of a new and safe crane, with four different powers adapted to different weights.

CRANE is the name of a southern constellation. See **GRUS**.

CRAKE is also a popular name for a syphon.

CRANK, a contrivance in machines, in manner of an elbow, only of a square form; projecting out from an axis, or spindle; and serving, by its rotation, to raise and fall the pistons of engines for raising water, or the like.

CRATER, the Cup, a constellation in the southern hemisphere; whose stars, in Ptolemy's catalogue, are 7; in Tycho's, 8; in Hevelius's, 10; and in the Britannic catalogue, 31.

CREEK, a part of a haven, where any thing is landed from the sea. It is also said to be a shore or bank on which the water beats, running in a small channel from any part of the sea.

CREPUSCULUM, *Twilight*; the time from the first dawn or appearance of the morning, to the rising of the sun; and again, between the setting of the sun, and the last remains of day.

The Crepusculum, or twilight, it is supposed, usually begins and ends when the sun is about 18 degrees below the horizon; for then the stars of the 6th magnitude disappear in the morning, and appear in the evening. It is of longer duration in the solstices than in the equinoxes, but it is longer in an oblique sphere, than in a right one; because, in those cases the sun, by the obliquity of his path, is longer in ascending through 18 degrees of altitude.

Twilight is occasioned by the sun's rays refracted in our atmosphere, and reflected from the particles of it to the eye. For let A be the place of an observer on the earth ADL, AB the sensible horizon, meeting in B the circle CBA bounding that part of the atmosphere which is capable of refracting and reflecting light to the eye. It is plain that when the sun is under this horizon, no direct rays can come to the eye at A: but the sun being in the refracted line CG, the particle c will be illuminated by the direct rays of the sun; and that particle may reflect those rays to A, where they enter the eye of the spectator. And thus the sun's light illuminating an innumerable multitude of particles, may be all reflected to the spectator at A.—From B draw BD touching the circle ADL in D; and let the sun be in the line AM at S: Then the ray SA will be reflected into BA, and will enter the eye, because the angle of incidence DBA is equal to the angle of reflection ABE: And this will be the first ray that reaches the eye in the morning, when the

dawning begins; or the last that falls upon the eye at night, when the twilight ends: for when the sun goes lower down, the particles at B can be no longer illuminated.

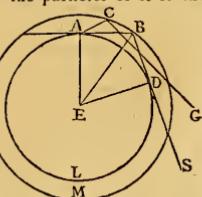

Kepler indeed assigns another cause of the crepusculum, viz; the luminous matter or atmosphere about the sun; which, arising near the horizon, in a circular figure, exhibits the crepusculum; in no wise, he thinks, owing to the refraction of the atmosphere.—The sun's luminous atmosphere indeed, though neither the sole nor principal cause of twilight, may lengthen its duration, by illuminating our air, when the sun is too low to reach it with his own light. Gregor. Astr. lib. 2, prop. 8.

The depression of the sun below the horizon, at the beginning of the morning, or end of the evening twilight, is determined in the same manner as the arch of vision; viz; by observing the moment when the air first begins to shine in the morning, or ceases to shine in the evening; then finding the sun's place for that moment, and thence the time till his rising in the horizon, or from his setting in it in the evening. It is now generally agreed that this depth is about 18 degrees upon an average.—Alhazen found it to be 19°; Tycho, 17°; Rothmann, 24°; Stevenson, 18°; Cassini, 15°; Riccioli, in the equinox in the morning 16°, in the evening 20° 30'; in the summer solstice in the morning 21° 25', in the winter solstice in the morning 17° 25'.

Nor is this difference among the determinations of astronomers to be wondered at; the cause of the crepusculum being inconstant: for, if the exhalations in the atmosphere be either more copious, or higher, than ordinary; the morning twilight will begin sooner, and the evening hold longer than ordinary: for the more copious the exhalations are, the more rays will they reflect, consequently the more will they shine; and the higher they are, the sooner will they be illuminated by the sun. On this account too, the evening twilight is longer than the morning, at the same time of the year in the same place. To this it may be added, that in a denser air the refraction is greater; and that not only the brightness of the atmosphere is variable, but also its height from the earth: and therefore the twilight is longer in hot weather than in cold, in summer than in winter, and also in hot countries than in cold, other circumstances being the same. But the chief differences are owing to the different situations of places on the earth, or to the difference of the sun's place in the heavens. Thus, the twilight is longest in a parallel sphere, and shortest in a right sphere, and longer to places in an oblique sphere, in proportion as they are nearer to one of the poles; a circumstance which affords relief to the inhabitants of the more northern countries, in their long winter nights. And the twilights are longest in all places of north latitude, when the sun is in the tropic of cancer; and to those in south latitude, when he is in the tropic of capricorn. The time of the shortest twilight is also different in different latitudes; in England, it is about the beginning of October and of March, when the sun is in the signs Δ and \times .

For the method of determining it by trigonometry, see Gregor. Astron. lib. 2, prob. 41. See also Robertson's Navigation, book 5, prob. 12.—Hence, from what has been said, it appears that when the difference between the sun's declination and the depth of the equator is less than 18°, so that the sun does not descend more than 18° below the horizon; the crepusculum will continue the whole night, as is the case in England from about the 22d of May to the 22d of July.

Given the latitude of the place, and the sun's declination;

to find the beginning of the morning, and end of the evening twilight.—In the oblique-angled spherical triangle ZPS , are given zp the colatitude, ps the co-declination, and $zs = 108^\circ$, being the sum of 90° the quadrant and 18° the depression at the extremity of the twilight. Then, by spherical trigonometry, calculate the angle zps the hour-angle from noon; which changed into time, at the rate of 15° for an hour, gives the time from noon at the beginning or end of twilight. See Robertson, ubi supra.

Of the Height of the sensible Atmosphere, as determined from the duration of twilight, see Keil's Astron. Lect. lect. 20, pa. 235, ed. 1721; or Long's Astron. vol. 1, pa. 260; where it is determined that the height at which the atmosphere is dense enough to reflect the rays of light, is about .42 miles.

CRESCENT, the new moon, which, as it begins to recede from the sun, shows a small rim of light, terminating in horns or points, which increase till it becomes full, and round in the opposition.

The term is sometimes also used for the same figure of the moon in her wane, or decrease, but improperly; both because the horns are then turned towards the west, and because the figure is on the decrease; the crescent properly signifying increase, from *cresco, I grow.*

CRONICAL. See ACRONICAL.

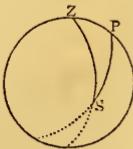

CRONOS, a name given to Saturn by some of the old astronomical writers.

CROSIER, four stars, in form of a cross; by the help of which, those that sail in the southern hemisphere find the antarctic pole.

CROSS, in Surveying, is an instrument consisting of a brass circle, divided into 4 equal parts, by two lines crossing each other in the centre. At each extremity of these lines is fixed a perpendicular sight, with small holes below each slit, for the better discovering of distant objects. The cross is mounted on a staff, or stand, to fix it in the ground, and is very useful for measuring small pieces of land, and taking offsets, &c.

Ex. Suppose it be required to survey the field ABCDE with the Cross. Measure along the diagonal line AC, and observe, with the Cross, when you are perpendicularly opposite to the corners, as at F, G, H, and from thence measure the perpendiculars FE, GB, HD. When you think you are nearly opposite a corner, set up the cross, with one of the bars or cross lines in the direction AC; then look through the sights of the other cross bar for the corner, as B; if it be seen through them, the cross is fixed in the right place; if not, take it up and move it backward or forward in the line AC, till the point B be seen through those sights; and then you have the true place of the perpendicular.

Invention of the Cross, Inventio Crucis, an ancient feast, which is still retained in our calendar, and solemnized on the 3d of May, in memory of the finding of the true cross of Christ, it is said, deep in the ground, on Mount Calvary, by St. Helena, the mother of Constantine; where she erected a church for the preservation of part of it: the

rest being brought to Rome, and deposited in the church of the Holy Cross of Jerusalem.

EVALUATION OF THE CROSS, an ancient feast, held on the 14th of September, in memory of this, that Heraclitus restored to Mount Calvary the true cross, in 642, which had been carried off, 14 years before, by Cosroes king of Persia, on his taking Jerusalem from the emperor Phocas. This feast is still retained in our calendar, on Sept. 14, under the name of Holy Rood, or Holy Cross.

CROSS-MULTIPLICATION, a method used chiefly by artificers in multiplying feet and inches by feet and inches, or the like;	9f. 10inc.
	6 8
	$\frac{59}{6}$ 0
	$\frac{59}{6}$ 6
	8
	65 6 8

CROSS-STAFF, or Fore-Staff, was a nautical instrument of box, or pear-tree, consisting of a square staff, of about 3 feet long, having each of its faces divided like a line of tangents, and having 4 cross pieces of unequal lengths to fit on to the staff, the halves of these being as the radii to the tangent lines on the faces of the staff.—The instrument was used in taking the altitudes of the celestial bodies at sea. It seems to have been pretty ancient, and was described by John Werner of Nuremberg, in his Annotations on the 1st book of Ptolemy's Geography, printed in 1514, recommending it for observing the distance between the moon and some star, for the purpose of determining his longitude. See FORE-STAFF.

CROUSAZ (JOHN PETER DE), a learned philosopher and mathematician, was born at Lausanne in Switzerland, April 13, 1663; where he died in 1748, at 85 years of age. Having made great progress in mathematics and the philosophy of Descartes, he travelled into Geneva, Holland, and France. He was successively professor in several universities; and at length was chosen governor to Prince Frederick of Hesse-Cassel, nephew to the king of Sweden.

Crousaz was author of many works, in various branches; belles-lettres, logic, philosophy, divinity, &c., &c.; but the most esteemed of them are, 1. His Logic; the best edition of which is that of 1741, in 6 vols. 8vo.—2. A Treatise on Beauty.—3. A Treatise on Education, 2 vols. 12mo.—4. A Treatise on the Human Understanding.—5. Several Treatises on Philosophy and Mathematics; as a Treatise on Motion, &c., with several papers inserted in the Memoirs of the French Academy of Sciences.

CROW, in Mechanics, an iron lever, made with a sharp point at one end, and two claws at the other; being used in heaving and purchasing great weights, &c.

CROWN, in Astronomy, a name given to two constellations, the southern and the northern.

CROWN, in Geometry, a plane ring included between two parallel or concentric peripheries of unequal circles.

The area of this is obtained, by multiplying its breadth by the length of a middle periphery, which is an arithmetical mean between the two peripheries that bound it; or by multiplying half the sum of the circumferences by half the difference of the diameters; or lastly, by multiplying the sum of the diameters by the difference of the diameters, and this last product by .7854. See my Mensuration, pa. 110, 4th edit.

CROWN-POST, is a post in some buildings standing upright in the middle, between two principal rafters; and from which proceed struts or braces to the middle of each

rafter. It is otherwise called a King-post, or King's-piece, or Joggle-piece.

Crown-Wheel, of a Watch, is the upper wheel next the balance, or that which drives the balance.

Crown-Work, in Fortification, is an out-work running into the field; designed to keep off the enemy, gain some hill, or advantageous post, and cover the other works of the place. It consists of two demi-bastions at the extremities, and an entire bastion in the middle, with curtains.

Crowned Horn-work, is a horn-work with a crown-work before it.

CRYSTALLINE Humour, is a thick compact humour of the eye, in form of a flattish convex lens, placed in the middle of the eye, and serving to make that refraction of the rays of light which is necessary to have them meet in the retina, and form an image there, by which vision may be performed.

CRYSTALLINE Heavens, in the Old Astronomy, two orbs imagined between the primum mobile and the firmament, in the Ptolemaic system, which supposed the heavens solid, and only susceptible of a single motion.

King Alphonsus of Arragon, it is said, introduced the Crystallines, to explain what was called the motion of trepidation, or titubation.—The first Crystalline, according to Regiomontanus, &c, serves to account for the slow motion of the fixed stars; by which they advance a degree in about 70 years, according to the order of the signs, or from west to east; which occasions a precession of the equinox. The 2d serves to account for the motion of libration, or trepidation; by which the celestial sphere librates from one pole towards the other, causing a difference in the sun's greatest declination.

CTESIBIUS, or **CTESEBES**, a mathematician of Alexandria, who was contemporary with Ptolemy king of Egypt, in the 165th olympiad, about 120 years before Christ. He was possessed of a very great strength of imagination, which placed him at once in a situation much above that which his birth otherwise entitled him to expect, being the son of a barber in that city. His memory is particularly cherished as the inventor of the pump. He also invented an hydraulic organ, though the circumstances that led to the discovery were purely accidental. On lowering a mirror in his father's shop, he observed that the counterpoise, which was included in a cylinder, produced a sound, by driving the air before it; and on examining the phenomenon more strictly, he conceived the idea of making an instrument, in which sounds should be produced by means of the action of water driving the air before it, which invention was afterwards carried into effect by the emperor Nero. Ctesibius was the inventor likewise of the clepsydra, or water-clock, by means of water falling upon a wheel, or a train of wheels, which were turned by it. The wheels communicated their motion to a small wooden image, which, by being gradually raised, pointed with an index to the proper hours, that were engraved on a column near the machine. This invention, it is highly probable, led to that of hour-glasses, or sand-glasses, for measuring time, which seems an imitation of the clepsydra. Ctesibius was also author of a treatise, " Geodesia, or the Art of dividing and measuring Bodies," which is said to be preserved in the library of the Vatican.

CTESIBIUS' Pump. See **PUMP**.

CUBATURE, or **CUBATION**, of a solid, is the measur-

ing the space contained in it, or finding the solid content of it, or finding a cube equal to it.

The cubature regards the content of a body, as the quadrature does the superficies or area of a figure.

CUBE, a regular solid body, inclosed by six equal sides or faces, which are squares.—A die is a small cube. It is also called a hexaedron, because of its six sides, and is the 2d of the five Platonic or Regular bodies?

The cube is supposed to be generated by the motion of a square plane, along a line equal and perpendicular to one of its sides.

To describe a Rete, or Net, for forming a cube, or with which it may be covered. See **BODY (regular)**.

To determine the Surface and Solidity of a Cube.—Multiply one side by itself, which will give one square or face; then this multiplied by 6, the number of faces, will give the whole surface. Also multiply one side, twice by itself, that is, cube it, which will give the solid content.

Duplication of a Cube. See **DUPLICATION**.

CUBES, or **CUBIC Numbers**, are formed by multiplying any numbers twice by themselves. So the cubes of 1, 2, 3, 4, 5, 6, &c, are 1, 8, 27, 64, 125, 216, &c.

The third differences of the cubes of the natural numbers are all equal to each other, being the constant number 6. For, let m^3 , n^3 , p^3 , be any three adjacent cubes in the natural series as above, that is, whose roots m , n , p , have the common difference 1; then because

$$n = m + 1, \text{ therefore, } n^3 = m^3 + 3m^2 + 3m + 1,$$

$$p = n + 1, \text{ therefore, } p^3 = n^3 + 3n^2 + 3n + 1; \text{ so that}$$

the difference between the 1st and 2d, and between the 2d and 3d cubes, are

$$n^3 - m^3 = 3m^2 + 3m + 1, \} \text{ the 1st differences;}$$

$$p^3 - n^3 = 3n^2 + 3n + 1, \} \text{ and the dif. of these differences, is}$$

$$3(n^2 - m^2) + 3(n - m) = 3(n + m) \cdot (n - m) + 3(n - m), \text{ or since } n - m = 1, \text{ it becomes } 3(n + m) + 3 = 3(n + m + 1) = 6(m + 1), \text{ the 2d difference.}$$

In like manner the next 2d diff. is $6(n + 1)$; hence the dif. of these two 2d diff. is $6(n - m) = 6$, which is therefore the constant 3d difference of all the series of cubes. And hence the series of cubes will be formed by addition only, viz, adding always the 3d dif. 6 to find the column or series of 2d diff., then these added always for the 1st diff., and lastly these always added for the cubes themselves, as below:

3d Difs.	2d Difs.	1st Difs.	Cubes.
6	6	1	0
6	12	7	1
6	18	19	8
6	24	37	27
6	30	61	64
6	36	91	125
6	42	127	216
6	48	169	343

Peletarius, among various speculations concerning square and cubic numbers, shows that the continual sums of the cubic numbers, whose roots are 1, 2, 3, &c, form the series of squares whose roots are 1, 3, 6, 10, 15, 21, &c.

$$\text{Thus, } 1 = 1 = 1^2,$$

$$1 + 8 = 9 = 3^2,$$

$$1 + 8 + 27 = 36 = 6^2,$$

$$1 + 8 + 27 + 64 = 100 = 10^2, \text{ &c.}$$

Or, in general, $1^3 + 2^3 + 3^3 + 4^3 + \dots + n^3 = (1 + 2 + 3 + \dots + n)^2$, whose root is $\frac{1}{2}n(n + 1)$.

It is also a pretty property, that any number, and the cube of it, being divided by 6, leave the same remainder; the series of remainders being 0, 1, 2, 3, 4, 5, continually repeated. Or that the differences between the numbers and their cubes, divided by 6, leave always 0 remaining; and the quotients, with their successive differences, form the several orders of figurate numbers. Thus,

Num.	Cubes.	Diffs.	Quot.	1 Diff.	2 Diff.
1	1	0	0	0	0
2	8	6	1	1	1
3	27	24	4	3	2
4	64	60	10	6	3
5	125	120	20	10	4
6	216	210	35	15	5
7	343	336	56	21	6

See a large table of cubes and squares, with their roots, &c., in the first volume of my Tracts, at the end.

The Cube of a Binomial, is equal to the cubes of the two parts or members, together with triple of the two parallelopipeds under each part and the square of the other; viz, $(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$. And hence the common method of extracting the cube root.

Cubic Equations, are those in which the unknown quantities rise to three dimensions; as $x^3 = a$, or $x^3 + ax^2 = b$, or $x^3 + ax^2 + bx = c$, &c.

All cubic equations may be reduced to this form, $x^3 + px = q$; viz, by taking away the 2d term, when there is one; which is done by substituting, in the given equation $x - \frac{1}{3}a$ for x .

All cubic equations have three roots; which are either all real, or else one only is real, and the other two imaginary; for all roots become imaginary by pairs.

But the nature of the roots, as to real and imaginary, is known partly from the sign of the co-efficient p , and partly from the relation between p and q : for the equation has always two imaginary roots when p is positive; it has also two imaginary roots when p is negative, provided $(\frac{p}{3})^3$ be less than $\frac{4q^3}{27}$, or $4p^3$ less than $27q^2$; otherwise the roots are all real; namely, whenever p is negative, and $4p^3$ either equal to, or greater than $27q^2$.

Every cubic equation of the above form, viz, wanting the 2d term, has both positive and negative roots, and the greatest root is always equal to the sum of the two less roots; viz, either one positive root equal to the sum of the two negative ones, or else one negative root equal to the sum of two smaller and positive ones. And the sign of the greatest, or single root, is positive or negative, according as q is positive or negative when it stands on the right-hand side of the equation, thus $x^3 + px = q$; and the two smaller roots have always the contrary sign to q .

So that, in general, the sign of p determines the nature of the roots, as to real and imaginary; and the sign of q determines the affection of the roots, as to positive and negative. See my Tract on Cubic Equations in the Philos. Trans. for 1780, and in my new Tracts, vol. 2, tract 28.

To find the Values of the Roots of Cubic Equations. Having reduced the equation to this form $x^3 + px = q$, its root may be found in various ways: the first of these, is that which is called Cardan's Rule, by whom it was first published, but invented by Ferreus and Tartalea. See AL-

GE BRA. The rule is this: Put $a = \frac{1}{3}p$, and $b = \frac{1}{2}q$; then by Cardan's method the root is $x = \sqrt[3]{[b + \sqrt{(b^2 + a^3)}] + \sqrt[3]{[b - \sqrt{(b^2 + a^3)}]}}$; or if there be $s = \sqrt[3]{[b + \sqrt{(b^2 + a^3)}]}$, and $d = \sqrt[3]{[b - \sqrt{(b^2 + a^3)}]}$, then $s + d = x$, the 1st or Cardan's root, also $-\frac{s+d}{2} + \frac{s-d}{2}\sqrt{-3}$ is the 2d root, and $-\frac{s+d}{2} - \frac{s-d}{2}\sqrt{-3}$ is the 3d root.

Now the first of these, or Cardan's root, is always a real root, though it is not always the greatest root, as it has been commonly mistaken for. And yet this rule always exhibits the root in the form of an imaginary quantity when the equation has no imaginary roots at all; but in the form of a real quantity when the equation has two imaginary roots. See the reason of this explained in my Tract above cited, art. 47. As to the other two roots, viz, $-\frac{s+d}{2} \pm \frac{s-d}{2}\sqrt{-3}$, though, in their general form they have an imaginary appearance; yet, by substituting certain particular numbers, they come out in a real form in all such cases as they ought to be so.

But, after the first root is found by Cardan's rule, the other two roots may be found, or exhibited, in several other different ways; some of which are as follow:

Let r denote the 1st, or Cardan's root,

and v and w the other two roots:

then is $v + w = -r$, and $vwr = q$;

and the resolution of these two equations will give the other two roots v and w , by a quadratic equation.

Or resolve the quadratic equation $x^2 + rx + r^2 + p = 0$, and its two roots will be those sought.

Or the same two roots will be

either $-\frac{1}{2}r + \frac{1}{2}\sqrt{(-p - \frac{3q}{r})}$ and $-\frac{1}{2}r - \frac{1}{2}\sqrt{(-p - \frac{3q}{r})}$,

or $-\frac{1}{2}r + \frac{1}{2}\sqrt{(r^2 - \frac{4q}{r})}$ and $-\frac{1}{2}r - \frac{1}{2}\sqrt{(r^2 - \frac{4q}{r})}$,

or $-\frac{1}{2}r + \frac{1}{2}\sqrt{(1 - \frac{4q}{q-pr})}$ and $-\frac{1}{2}r - \frac{1}{2}\sqrt{(1 - \frac{4q}{q-pr})}$.

Ex. 1. If the equation be $x^3 - 15x = 4$: here $p = -15$, $q = 4$, $a = -5$, $b = 2$; hence $\sqrt{(b^2 + a^3)} = \sqrt{(4 - 125)} = \sqrt{-121} = 11\sqrt{-1}$, $s = \sqrt[3]{(2 + \sqrt{-121})} = 2 + \sqrt{-1}$, and $d = \sqrt[3]{(2 - \sqrt{-121})} = 2 - \sqrt{-1}$: therefore $r = c + d = 4$, the 1st root; and

$-\frac{s+d}{2} \pm \frac{s-d}{2}\sqrt{-3} = -2 \mp \sqrt{3}$, the other two roots.

Ex. 2. If $x^3 - 6x = 4$: here $a = -2$, and $b = 2$; therefore $\sqrt{(b^2 + a^3)} = \sqrt{(4 - 8)} = \sqrt{-4} = 2\sqrt{-1}$, $s = \sqrt[3]{(2 + 2\sqrt{-1})} = -1 + \sqrt{-1}$, and $d = \sqrt[3]{(2 - 2\sqrt{-1})} = -1 - \sqrt{-1}$: hence then $r = s + d = -2$, the first root; and $1 \pm \sqrt{3}$ the other two roots.

Ex. 3. If $x^3 + 18x = 6$: here $a = 6$, and $b = 3$; then $\sqrt{(b^2 + a^3)} = \sqrt{(9 + 216)} = \sqrt{225} = 15$, $s = \sqrt[3]{(3 + 15)} = \sqrt[3]{18}$, and $d = \sqrt[3]{(3 - 15)} = \sqrt[3]{-12} = -\sqrt[3]{12}$: therefore $r = s + d = \sqrt[3]{18} - \sqrt[3]{12} = 331313$, the 1st root, and $-\frac{\sqrt[3]{18} - \sqrt[3]{12}}{\sqrt[3]{2}} \pm \frac{\sqrt[3]{18} + \sqrt[3]{12}}{\sqrt[3]{2}}\sqrt{-3}$ are the two other roots.

2. Another method for the roots of the equation $x^3 + px = q$, is by means of infinite series, as shown at art. 68, and seq. of my Tract above cited; whence it appears that the roots are exhibited in various forms of series as follow: viz,

$$2\sqrt[3]{b} \times (1 - \frac{2c^2}{3.6b^2} - \frac{2.5.8c^4}{3.6.9.12b^4} \text{ &c.})$$

for the 1st root, and

$$-\sqrt[3]{b} \times \left(1 - \frac{\frac{2t^2}{3}}{\frac{3}{2}bt^2} - \frac{\frac{2+5.8t^4}{3}}{\frac{3.6.9.12.15t^4}{3.6.9.12.15t^4}}\right) \text{ &c)$$

$\pm \sqrt[3]{\frac{-3}{b^2}} \times \left(\frac{1}{3} + \frac{2.5.8t^4}{3.6.9.12.15t^4}\right) \text{ &c}$

for the two other roots: where $a = \frac{1}{2}p$, $b = \frac{1}{2}q$, and $e = \sqrt{(b^2 + a^2)}$. And similar series, for the solution of cubic equations, were also employed by M. Leibnitz of Hanover, in the year 1677. Various other series for the same purpose may also be seen in my Tract, so often before cited.

3. A third method for the roots of cubic equations, is by angular sections, and the table of sines. It was first hinted by Bombelli, in his Algebra, that angles are trisected by the resolution of cubic equations. Afterwards Vieta gave the resolution of cubics, and the higher equations, by angular sections. Next, Albert Girard, in his Invention Nouvelle en l'Algèbre, shows how to resolve the irreducible case in cubics by a table of sines: and he also constructs the same, or finds the roots, by the intersection of the hyperbola and circle. Halley and DeMoivre also gave rules and examples of the same kind of resolutions by a table of sines. And, lastly, Mr. Anthony Thacker invented, and Mr. William Brown computed, a large set of similar tables, for resolving affected quadratic and cubic equations, with their application to the resolution of bi-quadratic ones. See IRREDUCIBLE Case. Also the resolution of these cases, by the tables of sines, tangents,

$$1st. \quad x^3 + px - q = 0 \quad \dots \quad x =$$

$$2d. \quad x^3 + px + p = 0 \quad \dots \quad x = \sqrt[3]{\left[-\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}\right]}$$

$$3d. \quad x^3 - px - q = 0 \quad \dots \quad x = \sqrt[3]{\left[\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]} + \sqrt[3]{\left[\frac{q}{2} - \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]}$$

$$4th. \quad x^3 - px + q = 0 \quad \dots \quad x = -\sqrt[3]{\left[\frac{q}{2} - \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]} - \sqrt[3]{\left[\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]}.$$

The roots of the first and second forms are negatives of each other; and those of the third and fourth are also negatives of each other. The first and second forms have only one root each. The third and fourth forms have also only one root each, when the quadratic surd $\sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}$ is possible; but have three roots each when that surd is impossible.

The roots of all the four forms may, in all cases, be easily computed as follows:

Forms 1st and 2d. Put $\frac{q}{2} \times \left(\frac{3}{p}\right)^{\frac{2}{3}} = \tan z$; and

$\sqrt[3]{\tan(45^\circ - \frac{z}{2})} = \tan u$. Then $x = \pm \sqrt{\frac{4p}{3}} \times \cot 2u$; where the upper sign belongs to the first form, and the lower sign to the second form.

Forms 3d and 4th. Put $\frac{q}{2} \times \left(\frac{p}{3}\right)^{\frac{2}{3}}$ if less than unity,

otherwise its reciprocal $\frac{q}{2} \times \left(\frac{3}{4}\right)^{\frac{2}{3}} = \cos z$. Then,

Case 1st. $\frac{2}{q} \times \left(\frac{p}{3}\right)^{\frac{2}{3}} < \text{unity}$. Put $\sqrt[3]{\tan(45^\circ - \frac{z}{2})}$

$= \tan u$. Then $x = \pm \sqrt{\frac{4p}{3}} \times \operatorname{cosec} 2u$; where the upper sign belongs to the third form, and the lower sign to the fourth form.

Case 2d. $\frac{2}{q} \times \left(\frac{p}{3}\right)^{\frac{2}{3}} > \text{unity}$. Then x has three values in

each form, viz, $x = \pm \sqrt{\frac{4p}{3}} \times \cos \frac{z}{3} = \mp \sqrt{\frac{4p}{3}} \times \cos$.

$(60^\circ - \frac{z}{3}) = \mp \sqrt{\frac{4p}{3}} \times \cos(60^\circ + \frac{z}{3})$; where the upper

and secants, in my Course of Mathematics, vol. 3, p. 181, 185, &c.

4. Again, the several methods of approach, or approximation, for the roots of all affected equations, which have been used in various ways by Stevin, Vieta, Newton, Halley, Raphson, and others.

To these may be added the method of Trial-and-error, or of Double Position, one of the easiest and best of any. Of this method, let there be taken the last example, viz, $x^3 + 18x = 6$, in which it is evident that x is very nearly equal to $\frac{1}{2}$, but a little less; take it therefore $x = .33$; then, $x^3 + 18x = 5.975937$, but should be 6, and therefore the error is .024063 in defect.

Again suppose $x = .34$; then $x^3 + 18x = 6.159304$, which is .159304 in excess.

Therefore $\frac{.34 \times .024063 + .33 \times .159304}{.024063 + .159304} = \frac{60752}{183367} = .3313$, the root as before very nearly.

The method of resolving all the cases of cubic equations by the tables of sines, tangents, and secants, are thus given by Dr. Maskelyne, p. 57, Taylor's Logarithms.

"The following method is adapted to a Cubic equation, wanting the second term; therefore, if the equation has the second term, it must be first taken away in the usual manner. There are four forms of cubic equations wanting the second term, whose roots, according to known rules equivalent to Cardan's are as follow :

$$\sqrt[3]{\left[\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}\right]} - \sqrt[3]{\left[-\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}\right]},$$

$$\sqrt[3]{\left[-\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}\right]} - \sqrt[3]{\left[\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} + \frac{p^3}{27}\right)}\right]},$$

$$\sqrt[3]{\left[\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]} + \sqrt[3]{\left[\frac{q}{2} - \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]},$$

$$\sqrt[3]{\left[\frac{q}{2} - \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]} - \sqrt[3]{\left[\frac{q}{2} + \sqrt{\left(\frac{q^2}{4} - \frac{p^3}{27}\right)}\right]}.$$

These belong to the third form, and the lower signs to the fourth form.

By Logarithms.

Forms 1st and 2d. $\log \frac{q}{2} + 10 - \frac{3}{2} \times \log \frac{p}{3} = \log \tan z$; and $\frac{\log \tan(45^\circ - \frac{z}{2}) + 20}{3} = \log \tan u$. Then $\log x = \frac{1}{2} \log \frac{4p}{3} + \log \cot 2u - 10$; and x will be affirmative in the first form, and negative in the second form.

Forms 3d and 4th. $\frac{3}{2} \times \log \frac{p}{3} + 10 - \log \frac{q}{2}$ being less than 10 (which is case first) or $\log \frac{q}{2} + 10 - \frac{3}{2} \times \log \frac{p}{3}$ being less than 10 (which is case 2d) $= \log \cos z$.

Case 1st. $\frac{\log \tan(45^\circ - \frac{z}{2}) + 20}{3} = \log \tan u$. Then \log

$x = \frac{1}{2} \log \frac{4p}{3} + 10 - \log \sin 2u$; and x will be affirmative in the third form, and negative in the 4th form.

Case 2d. Here x has three values.

1st. $\log \pm x = \frac{1}{2} \log \frac{4p}{3} + \log \cos \frac{z}{3} - 10$,

2d. $\log \mp x = \frac{1}{2} \log \frac{4p}{3} + \log \cos(60^\circ - \frac{z}{3})$,

3d. $\log \mp x = \frac{1}{2} \log \frac{4p}{3} + \log \cos(60^\circ + \frac{z}{3}) - 10$;

where the upper signs belong to the third form, and the lower signs to the fourth form; that is, the first value of x in the third form is positive, and its second and third

values negative; and the first value of x in the fourth form is negative, and its second and third values affirmative."

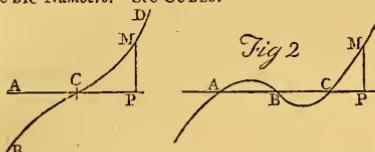

See also IRREDUCIBLE Case.

For the construction of cubic equations, see CONSTRUCTION.

CUBIC Foot, of any thing, is so much of it as is contained in a cube whose side is one foot.

CUBIC Hyperbola, is a figure expressed by the equation $xy^2 = a$, having two asymptotes, and consisting of two hyperbolas, lying in the adjoining angles of the asymptotes, and not in the opposite angles, like the Apollonian hyperbola; being otherwise called by Newton, in his *Emumeration Linearum Tertii Ordinis*, an hyperbolismus of a parabola; and is the 65th species of those lines according to him.

CUBIC Numbers. See CUBES.

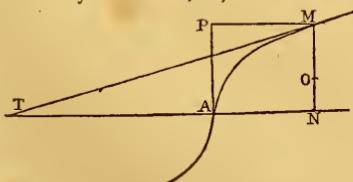

CUBIC Parabola, a curve, as BCD , of the 2d order, having two infinite legs CB , CD , tending contrary ways. And if the absciss, AP or x , touch the curve in c , the relation between the absciss and ordinate, viz., $AP = x$, and $PM = y$, is expressed by the equation $y = ax^3 + bx^2 + cx + d$; or when a coincides with c , by the equation $y = ax^3$, which is the simplest form of the equation of this curve.

If the right line AP (fig. 2) cut the cubical parabola in three points A , B , C ; and from any point P there be drawn the right line or ordinate PM , cutting the curve in one point M only: then will PM be always as the solid $AP \times BP \times CP$; which is an essential property of this curve.

And hence it is easy to construct a cubic equation, as $x^3 + a^2x = b^3$, by the intersection of this curve and a right line. See the Construction of a cubic equation by means of the cubic parabola and a right line, by Dr. Wallis, in his Algebra: As also the Construction of equations of 6 dimensions, by means of the cubic parabola and a circle, by Dr. Halley, in a lecture formerly read at Oxford.

The curve of this parabola cannot be rectified, not even by means of the conic sections. But a circle may be found equal to the Curve Surface, generated by the rotation of the curve AM about the tangent AP to the principal vertex A . Let MN be an ordinate, and MT a tangent at the point M ; and let PM be parallel to AN . Divide MN in the point O , so that MO be to ON as TM to MN . Then a mean proportional between $TM + ON$ and $\frac{1}{2}$ of AN will be the radius of a circle, whose area is equal to the superficies described by that rotation, viz, of AM about AP .

The Area of a Cubic Parabola is $\frac{1}{4}$ of its circumscribing parallelogram.

CUBIC Root, of any number, or quantity, is such a quantity as being cubed, or twice multiplied by itself, shall produce that which was given: So, the cubic root of 8 is 2, because 2^3 or $2 \times 2 \times 2$ is equal to 8.

The common method of extracting the cube root, founded on the property given above, viz., $(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$, is found in every book of common arithmetic, and is as old at least as Lucas de Burgo, where it is first met with in print. Other methods for the cube root may be seen under the article EXTRACTION OF ROOTS, particularly this one, viz., the cube root of n , or $\sqrt[3]{n} = \frac{n + a^3}{n - 2a^2} \times a$, very nearly, or $2a^3 + n : 2n + a^3 :: a : \sqrt[3]{n}$ the cube root of n nearly; where n is any number given whose cube root is sought, and a^3 is the nearest complete cube to n , whether greater or less.

For example, Suppose it were proposed to double the cube, or, which comes to the same thing, to extract the cube root of the number 2. Here the nearest cube is 1, whose cube root is 1 also, that is, $a^3 = 1$, and $a = 1$, also $n = 2$; therefore

$$2a^3 + n : 2n + a^3 :: a$$

$$4 : 5 :: 1 : \frac{1}{4} = 1.25 = \sqrt[3]{2} \text{ nearly.}$$

But, for a nearer value, assume now $a = \frac{4}{5}$, or $a^3 = \frac{64}{125}$; then is $2a^3 + n = \frac{2 \times 64}{125} + 2 = \frac{3 \times 64}{125} + 2$, and $2n + a^3 = 4 + \frac{64}{125} = \frac{512}{125}$; hence $378 : 381 :: \frac{4}{5} : \frac{64}{125}$ or $1.259921 = \sqrt[3]{2}$, or the cube root of 2, which is true in the last place of decimals—And this is the simplest and easiest method for the cube root of any number. See its investigation in my new Tracts, vol. 1, pa. 210.

Every number or quantity has three cubic roots, one that is real, and two imaginary: So, the cube root of 1 is either 1, or $\frac{1+\sqrt{-3}}{2}$, or $\frac{1-\sqrt{-3}}{2}$; and if r be the real root of any cube r^3 , the two imaginary cubic roots of it will be $\frac{1+\sqrt{-3}}{2}r$, and $\frac{1-\sqrt{-3}}{2}r$: for any one of these being cubed, gives the same cube r^3 .

CUBING of a Solid. See CUBATURE.

CUBO-CUBE, the 6th power.

CUBO-CUBO-CUBE, the 9th power.

CUBIT, a measure equal to the distance from the elbow of a man to the extremity of his fingers; and commonly estimated at half a yard, or 18 inches.

CULMINATION, the passage of a star or planet over the meridian, or that point of its orbit which it is in at its greatest altitude. Hence a star is said to culminate, when it passes the meridian.

To find the time of a Star's culminating. Estimate the time nearly; and find the right ascension, both of the sun and star, corrected for this estimated time; then the difference between these right ascensions, converted into solar time, at the rate of 15 degrees to the hour, gives the time of southing. See an example of this calculation every year in White's Ephemeris, pa. 45.

CULVERIN, was the name of a piece of ordnance; but is now disused.

CUNETTE. See CUVETTE.

CUNEUS. See WEDGE.

CUNITIA (MARIA), a lady of Silesia, who was famous for her extensive knowledge in many branches of learning, but more particularly in mathematics and astronomy, on which she wrote several ingenious treatises; particularly one entitled *Urania Propitia*, printed in 1650, in Latin and German, and dedicated to Ferdinand the 3d, emperor

of Germany. In this work are contained astronomical tables of great ease and accuracy, founded on Kepler's hypothesis. But notwithstanding her merit shines with such peculiar lustre as to reflect honour on her sex, history does not inform us of the time of her birth or death.

CURRENT, a stream or flux of water in any direction. The Setting of the current, is that point of the compass towards which the waters run; and the Drift of a current is the rate it runs an hour.

Currents in the sea, are either natural and general, as arising from the diurnal rotation of the earth on its axis, or the tides, &c; or accidental and particular, caused by the waters being driven against promontories, or into gulphs and straits; whence they are forced back, and thus disturb the natural flux of the sea.

The currents are so violent under the equator, where the motion of the earth is greatest, that they hurry vessels very speedily from Africa to America, but absolutely prevent their return the same way: so that ships are forced to run as far as the 40th or 45th degree of north latitude, to fall into the return of the current again, to bring them home to Europe. It is shown by Governor Pownal, that this current performs a continual circulation, setting out from the Guinea coast in Africa, for example, thence crossing straight over the Atlantic Ocean, and so setting into the Gulph of Mexico by the south side of it; then sweeping round by the bottom of the Gulph, it issues out by the north side of it, and thence takes a direction north-easterly along the coast of North America, till it arrive near Newfoundland, where it is turned by a whirling motion backward across the Atlantic again, upon the coasts of Europe, and thence southward to the coast of Africa, from which it commenced.

In the straits of Gibraltar, the currents set in by the south side, sweep along the coast of Africa to Egypt, by Palestine, and return by the northern side, or European coasts, and issue out again by the northern side of the straits. In St. George's Channel too they usually set eastward. The great violence and danger of the sea in the Straights of Magellan, is attributed to two contrary currents setting in, one from the south and the other from the north sea.

Currents are of some consideration in the art of navigation, as a ship is either accelerated or retarded by them in her course, according as the set is with or against the ship's motion. If the ship sail along the direction of a current, it is evident that the velocity of the current must be added to that of the vessel as observed by the log, because in this estimation the water is supposed to be at rest; but if her course be directly against the current, it must for the same reason be subtracted: and if she sail athwart it, her motion will be compounded with that of the current; and her velocity augmented or retarded, according to the angle of her direction with it; that is, she will proceed in the diagonal of the parallelogram formed according to the two lines of direction, and will describe or pass over that diagonal in the same time in which she would have described either of the sides, by the separate velocities.

For suppose $A E D C$ be a parallelogram, the diagonal of which is AD . Now if the wind alone would drive the ship from A to B , in the same time as the current alone would drive it from A to C : then, as the wind neither helps nor hinders the ship from coming towards the line CD , the

current will bring it there in the same time as if the wind did not act; and as the current neither helps nor hinders the ship from coming towards the line BD , the wind will bring it there in the same time as if the current did not act: therefore the ship must, at the end of that time, be found in both those lines, that is, in their meeting point: consequently the ship must have passed from A to D in the diagonal AD . See *Composition of Forces*.

See the Sailing in Currents largely exemplified in Robertson's Navigation, vol. 2, book 7, sect. 8.

CURRENTS, Under, are those currents which run at a certain depth below the surface of the water, and in a contrary direction. Dr. Smith, in the 14th vol. of the Philosophical Transactions, relates an experiment made in the Baltic Sound, which was communicated to him by an able seaman, who was present at the time it was made. Being at that place in one of his majesty's frigates, they went with their pinnace into the mid-stream, where they were carried away violently by the current: But having sunk a large basket by means of iron shot placed in it, and having at the same time a rope affixed to it, the motion of the boat, which was then drifting with the current, was checked; and by sinking the basket still lower and lower, the motion of the boat was more and more retarded, until it was finally driven in a contrary direction to that of the upper current, which last did not appear to extend to a greater depth than that of four or five fathoms; and as the upper current was stronger, the nearer it was to the surface; so the under current appeared to be more rapid, as the depth increased. Dr. Smith derives another argument in favour of an under current at the Straits, from the ossing between the north and south Foreland, where it runs tide and half tide; viz, it is either ebb or flood in that part of the Downs, three hours before it is so off at sea; a certain sign that, though the tide of flood runs above, the tide of ebb must run below, that is, close to the ground; and on the contrary, when it is ebb tide above, it will be flowing below.

CURRENT of Air. See *WIND*.

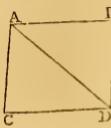

CURSOR, a small piece of brass &c, that slides; as, the piece in an equinoctial ring dial that slides to the day of the month; or the little ruler or label of brass sliding in a groove along the middle of another label, representing the horizon in the analemma; or the point that slides along the beam compass; &c.

CURTATE Distance, is the distance of a planet's place from the sun, reduced to the ecliptic; or, the interval between the sun and that point where a perpendicular, let fall from the planet, meets the ecliptic.

CURTATION, the interval between a planet's distance from the sun, and the curtate distance. From the foregoing article it is easy to find the curtate distance; whence the manner of constructing tables of curtation is obvious; the quantity of inclination, reduction, and curtation of a planet, depending on the argument of latitude. Kepler, in his Rodolphine Tables, reduces the tables of them all into one, under the title of *Tabulae Latitudinariae*.

CURTIN, CURTAIN, or COURTIINE, in Fortification, that part of a wall or rampart that joins two bastions, or lying between the flank of one and that of another.—The curtain is usually bordered with a parapet 5 feet high; behind which the soldiers stand to fire upon the cover-way, and into the moat.

CURVATURE of a Line, is its bending, or flexure; by which it becomes a curve, of any peculiar form and pro-

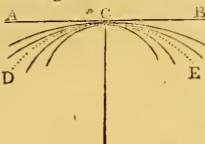

perties. Thus, the nature of the curvature of a circle is such, as that every point in the periphery is equally distant from a point within, called the centre; and so the curvature of the same circle is every where the same; but the curvature in all other curves is continually varying.—The curvature of a circle is so much the more, as its radius is less, being always reciprocally as the radius, for the curvature of a circle is its deviation from the tangent in a very small arc; and this deviation is equal to the versed sine of the arc, which is reciprocally as the radius. And, in like manner, the curvature of other curves is measured by the reciprocal of the radius of a circle having the same degree of curvature as itself, at some certain point.

Every curve recedes from its tangent by its curvature, the measure of which is the same as that of the angle of contact formed by the curve and tangent. Now the same tangent AB is common to an infinite number of circles, or other curves, all touching it and each other in the same point of contact C . So that any curve PCB may be touched by an infinite number of different circles at the same point C ; and some of these circles fall wholly within it, being more curved, or having a greater curvature than that curve; while others fall without it near the point of contact, or between the curve and tangent at that point, and being thus less deflected from the tangent than the curve is, they have a less degree of curvature there. Consequently there is one, of this infinite number of circles; which neither falls below it nor above it, but, being equally deflected from the tangent, coincides with it most intimately of all the circles; and the radius of this circle is called the Radius of Curvature of the curve; also the circle itself is called the Circle of Curvature, or the Osculatory circle of that curve, because it touches it so closely that no other circle can be drawn between it and the curve.

As a curve is separated from its tangent by its flexure or curvature, so it is separated from the osculatory circle by the increase or decrease of its curvature; and as its curvature is greater or less, according as it is more or less deflected from the tangent, so the variation of curvature is greater or less, according as it is more or less separated from the circle of curvature.

It appears however, from the demonstration of geometers, that circles may touch curve lines in such a manner, that there may be indefinite degrees of more or less intimate contact between the curve and its osculatory circle; and that a conic section may be described that shall have the same curvature with a given line at a given point, and the same variation of curvature, or a contact of the same kind with the circle of curvature.

If we conceive the tangent of any proposed curve to be a base, and that a new line or curve be described, whose ordinate, on the same base or absciss, is a 3d proportional to the ordinate and base of the first; this new curve will determine the chord of the circle of curvature, by its intersection with the ordinate at the point of contact; and it will also measure the variation of curvature, by means of the tangent of the angle in which it cuts that circle: the less this angle is, the closer is the contact of the curve and circle of curvature; and of this contact there may be indefinite degrees.

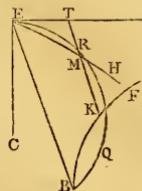

For example, let EMH be any curve, to which ET is a tangent at the point E ; then let there be always taken $MT : ET :: ET : TK$, and through all the points K draw the curve BKF ; then from the point of contact E draw EB parallel to the ordinate TK , meeting the last curve in B ; and finally, describe a circle ERQ through the point B and touching ET in E ; and it shall be the osculatory circle to the given curve EMH . And the contact of EM and ER is always the closer, the less the angle KBQ is. See Maclaurin's Fluxions, art. 366.

Hence it follows, that the contact of the curve EMH and its osculatory circle, is closest, when the curve BK touches the arch BQ in B , the angle BET being given; and it is farthest from this, or most open, when BK touches the right line BE in B .

Hence also there may be indefinite degrees of more and more intimate contact between a circle and a curve. The first degree is when the same right line touches them both in the same point; and a contact of this sort may take place between any circle and any arch of a curve. The 2d is when the curve EMH and circle ERB have the same curvature, and the tangents of the curve BKF and circle BQE intersect each other at B in any assignable angle. The contact of the curve EM and circle of curvature ER at E , is of the 3d degree, or order, and their osculation is of the 2d, when the curve BKF touches the circle BQE at n , but so as not to have the same curvature with it. The contact is of the 4th degree, or order, and their osculation of the 3d, when the curve BKF has the same curvature with the circle BQE at B , but so as that their contact is only of the 2d degree. And this gradation of more and more intimate contact, or of approximation towards coincidence, may be continued indefinitely, the contact of EM and ER at E being always of an order two degrees closer than that of BK and BQ at B . There is also an indefinite variety comprehended under each order: thus, when EM and ER have the same curvature, the angle formed by the tangents of BK and BQ admits of indefinite variety, and the contact of EM and ER is the closer the less that angle is. And when that angle is of the same magnitude, the contact of EM and ER is the closer, the greater the circle of curvature is. When BK and BQ touch at B , they may touch on the same or on different sides of their common tangent; and the angle of contact KBQ may admit of the same variety with the angle of contact MET ; but as there is seldom occasion for considering those higher degrees of more intimate contact of the curve EMH and circle of curvature ERB , Maclaurin calls the contact or osculation of the same kind, when, the chord EB and angle BET being given, the angle contained by the tangents of BK and BQ is of the same magnitude.

When the curvature of EMH increases from E towards H , and consequently corresponds to that of a circle gradually less and less, the arch EM falls within ER , the arch of the osculatory circle, and BK is within BQ . The contrary happens when the curvature of EM decreases from E towards H , and consequently corresponds to that of a circle which is gradually greater and greater, the arch EM falls without ER , and BK is without BQ . And according as the curvature of EM varies more or less, it is more or less unlike to the uniform curvature of a circle;

the arch of the curve EMH separates more or less from the arch of the osculatory circle ERB , and the angle contained by the tangents of BKF and BQE at B , is greater or less. Thus the quality of curvature, as it is called by Newton, depends on the angle contained by the tangents of BK and BQ at B ; and the measure of the inequality or variation of curvature, is as the tangent of this angle, the radius being given, and the angle BET being a right one.

The radii of curvature of similar arcs in similar figures, are in the same ratio as any homologous lines of these figures; and the variation of curvature is the same. See Maclaurin, art. 370.

When the proposed curve EMH is a conic section, the new line BKF is also a conic section; and it is a right line when EMH is a parabola, to the axis of which the ordinates TK are parallel. BKF is also a right line when EMH is an hyperbola, to one asymptote of which the ordinate TK is parallel.

When the ordinate EB , at the point of contact E , instead of meeting the new curve EK , is an asymptote to it, the curvature of EM is less than in any circle, or the radius of curvature vanishes; and in this case the curvature is said to be infinitely great. And of this kind is the curvature at the points of contrary flexure in lines of the 3d order.

When the curve BK passes through the point of contact E ; the curvature is greater than in any circle, or the radius of curvature vanishes; and in this case the curvature is said to be infinitely great. Of this kind is the curvature at the cusps of the lines of the 3d order.

As to the degree of curvature in lines of the 3d and higher orders, see Maclaurin, art. 379; also art. 380, when the proposed curve is mechanical.

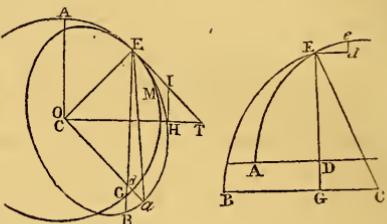

As curves which pass through the same point have the same tangent when the first fluxions of the ordinates are equal, so they have the same curvature when the 2d fluxions of the ordinate are likewise equal; and half the chord of the osculatory circle that is intercepted between the points where it intersects the ordinate, is a 3d proportional to the right lines that measure the 2d fluxion of the ordinate and first fluxion of the curve, the base being supposed to flow uniformly. When a ray revolving about a given point, and terminated by the curve, becomes perpendicular to it, the first fluxion of the radius vanishes; and if its 2d fluxion vanish at the same time, that point must be the centre of curvature. The same may be said, when the angular motion of the ray about that point is equal to the angular motion of the tangent of the curve; as the angular motion of the radius of a circle about its centre is always equal to the angular motion of the tangent of the circle. Hence the various properties of the circle may suggest several theorems for determining the centre of curvature.

See art. 396 of the said book, also the following, concerning the curvature of lines that are described by means of right lines revolving about given poles, or of angles that either revolve about such poles, or are carried along fixed lines.

It is to be observed that, as when a right line intersects an arc of a curve in two points, if by varying the position of that line the two intersections unite in one point, it then becomes the tangent of the arc; so when a circle touches a curve in one point, and intersects it in another, if, by varying the centre, this intersection join the point of contact, the circle has then the closest contact with the arc, and be-

comes the circle of curvature; but it still continues to intersect the curve at the same point where it touches it, that is, where the same right line is their common tangent, unless another intersection join that point at the same time. In general, the circle of curvature intersects the curve at the point of osculation, only when the number of the successive orders of fluxions of the radius of curvature, that vanish when this radius comes to the point of osculation, is an even number.

It has been supposed by some, that two points of contact, or four intersections of the curve and circle of curvature, must join to form an osculation. But Mr. James Bernoulli justly insisted, that the coalition of one point of contact and one intersection, or of three intersections, was sufficient. In which case, and in general, when an odd number of intersections only join each other, the point where they coincide continues to be an intersection of the curve and circle of curvature, as well as a point of their mutual contact and osculation. See Maclaurin's Flux. art. 493.

From these principles may be determined the circle of curvature at any point of a conic section. Thus, suppose $AEMHG$ be any conic section, to the point E of which the circle or radius of curvature is to be found. Let ET be a tangent at E , and draw EG and the tangent MH parallel to the chords of the circle of curvature; then take EB to EG as EI^2 to MH^2 ; or, when the section has a centre O , as in the ellipse and hyperbola, as the square of the semi-diameter oa parallel to ET , is to the square of the semi-diameter OA parallel to EB ; and a circle EB described on the chord EI that touches ET , will be the circle of curvature sought.

When BET is a right angle, or EB is the diameter of the circle of curvature, EG will be the axis of the conic section, and EB will be the parameter of this axis; also when the point e , where the conic section cuts EB , and the point B , are on the same side of E , then EMG will be an ellipse, and EG the greater or less axis, according as EG is greater or less than EB .

The propositions relating to the curvature of the conic sections, commonly given by authors, follow without much difficulty from this construction.

1. When the chord of curvature, thus found, passes through the centre of the conic section, it will then be equal to the parameter of the diameter that passes through the point of contact.

2. The square of the semi-diameter oa , is to the rectangle of half the transverse and half the conjugate axis, as the radius of curvature er is to oa . And therefore the cube of the semi-diameter oa , parallel to the tangent ET , is equal to the solid contained by the radius of curvature er , and the rectangle of the two semiaxes.

3. The perpendicular to either axis bisects the angle

made by the chord of curvature, and the common tangent of the conic section and circle of curvature.

4. The chord of the osculatory circle that passes through the focus, the diameter conjugate to that which passes through the point of contact, and the transverse axis of the figure, are in continued proportion.

5. When the section is an ellipse, if the circle of curvature at E meet oa in d , the square of ed will be equal to twice the square of oa . Hence $ed : oa :: \sqrt{2} : 1$. Which gives an easy method of determining the circle of curvature to any point E , when the semi-diameter oa is given in magnitude and position.

Several other properties of the circle of curvature, and methods of determining it, when the section is given; or vice versa, of determining the section when the circle of curvature is given; may be seen in MacLaurin's Flux. art. 375. See also the Appendix to MacLaurin's Algebra, sect. 1.

To determine the Radius and Circle of Curvature by the Method of Fluxions. Let AE be any curve, concave toward its axis AD ; draw an ordinate DE to the point E where the curvature is required to be found; and suppose EC perpendicular to the curve, and equal to the radius of the circle BEC of curvature sought; lastly, draw ED parallel to AD , and de parallel and indefinitely near to DE ; thereby making ed the fluxion or increment of the absciss AD , also de the fluxion of the ordinate DE , and ee that of the curve AE . Now put $x = AD$, $y = DE$, $z = AE$, and $r = CE$ the radius of curvature; then is $ed = \dot{x}$, $de = \dot{z}$, and $ee = \dot{z}$.

Now, by sim. tri. the 3 lines

-	ed	,	de	,	ee	
or	-	\dot{x}	,	\dot{y}	,	\dot{z}

are respectively as the three

-	GE	,	GC	,	CE	
therefore	-	GC	.	\dot{x}	=	GE ;

and the fluxion of this last equation is

$$GC \cdot \ddot{x} + GC \cdot \dot{x} = GE \cdot \ddot{y} + GE \cdot \dot{y},$$

or because $GC = -BG$, it is

$$GC \cdot \ddot{x} - BG \cdot \dot{x} = GE \cdot \ddot{y} + GE \cdot \dot{y}.$$

But, since the two curves AE and BE have the same curvature at the point E , their abscisses and ordinates have the same fluxions at that point, that is ed or \dot{x} is the fluxion both of AD and BG , and de or \dot{y} is the fluxion both of DE and GE . In the above equation therefore substitute \dot{x} for BG , and \dot{y} for GE , and it becomes

$$GC \cdot \ddot{x} - \dot{x}\dot{x} = GE \cdot \ddot{y} + \dot{y}\dot{y},$$

or

$$GC \cdot \ddot{x} - GE \cdot \dot{y} = \dot{x}^2 + \dot{y}^2 \text{ or } z^2.$$

Now mult. the three terms of this equation respectively by these three quantities, $\frac{\dot{y}}{GC}$, $\frac{\dot{x}}{GE}$, $\frac{z}{CE}$, which are equal, and it becomes $\dot{y}\dot{x} - \dot{x}\dot{y} = \frac{\dot{z}^2}{CE}$, or $\frac{\dot{z}^2}{r}$; and hence $r = \frac{\dot{z}^2}{\dot{y}\dot{x} - \dot{x}\dot{y}}$, which is the general value of the radius of curvature for all curves whatever, in terms of the fluxions of the absciss and ordinate.

Farther, as in any case either x or y may be supposed to flow equably, that is, either \dot{x} or \dot{y} constant quantities, or \dot{x} or $\dot{y} = 0$; nothing, by this supposition either of the terms in the denominator of the value of r may be made to vanish. So that when \dot{x} is constant, the value of r is $\frac{\dot{z}^2}{-\dot{x}\dot{y}}$, but is $\frac{\dot{z}^2}{\dot{y}\dot{x}}$ when \dot{y} is constant.

For example, suppose it were required to find the radius or circle of curvature to any point of a parabola, its vertex being A , and axis AD .—Now the equation of the curve is $ax = y^2$; hence $a\dot{x} = 2y\dot{y}$, and $a\ddot{x} = 2\ddot{y}$, supposing y constant; hence r or

$\frac{\dot{z}^2}{\dot{y}\dot{x}}$ or $\frac{(\dot{x}^2 + \dot{y}^2)^2}{\dot{y}\dot{x}}$ is $\frac{(a^2 + 4y^2)^2}{2a^2}$ or $\frac{(a + 4x)^2}{2a^2}$, the general value of the radius of curvature for any point E , the ordinate to which cuts off the absciss $AD = x$.

Hence, when x or the absciss is nothing, the last expression becomes barely $\frac{a^2}{2\sqrt{a}} = \frac{1}{2}a = r$, for the radius of curvature at the vertex of the parabola; that is, the diameter of the circle of curvature at the vertex of a parabola, is equal to a the parameter of the axis.

See CIRCLE of Curvature.

Variation of Curvature. See VARIATION.

Double CURVATURE, is used for the curvature of a line, which twists so that all the parts of it do not lie in the same plane. Such as the rhumb-line, or loxodromic curve.

CURVE, a line whose several parts proceed bowing, or tend different ways; in opposition to a straight line, all whose parts have the same course or direction.

The doctrine of curves, and of the figures and solids generated from them, constitute what is called the higher geometry.

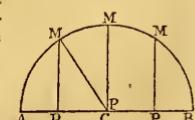

In a curve, the line AD , which bisects all the parallel lines MN , is called a Diameter; and the point A , where the diameter meets the curve, is called the Vertex: if AD bisect all the parallels at right angles, it is called the Axis. The parallel lines MN are called Ordinates or Applicates; and their halves, PM , or PN , Semi-ordinates. The portion of the diameter AP , between the vertex, or any other fixed point, and an ordinate, is called the Absciss: also the concourse of all the diameters, if they meet all in one point, is the Centre. This definition of the diameter, as bisecting the parallel ordinates, respects only the conic sections, or such curves as are cut only in two points by the ordinates; but in the lines of the 3d order, which may be cut in three points by the ordinates, then the diameter is that line which cuts the ordinates so, that the sum of the two parts that lie on one side of it, shall be equal to the part on the other side: and so on for curves of higher orders, the sum of the parts of the ordinates on one side of the diameter, being always equal to the sum of the parts on the other side of it.

Curve lines are distinguished into Algebraical or Geometrical, and Transcendental or Mechanical.

Algebraical or Geometrical CURVES, are those in which the relation of the absciss AD , to the ordinates PM , can be expressed by a common algebraic equation.

And Transcendental or Mechanical CURVES, are such as cannot be so defined or expressed by an algebraical equation. See TRANSCENDENTAL Curve.

Thus, suppose, for instance, the curve be the circle; and that the radius $AC = r$, the absciss $AP = x$, and the ordinate $PM = y$; then, because the nature of the circle is such, that the rectangle $AP \times PB$ is always $= PM^2$, therefore the equation is $x \cdot (2r - x) = y^2$, or $2rx - x^2 = y^2$, defining this curve, which is therefore an algebraical or geometrical line. Or, suppose $cx = x$; then is $cM^2 - cp^2 = PM^2$, that is $r^2 - x^2 = y^2$; which is another form of the equation of the curve.

The doctrine of curve lines in general, as expressed by algebraical equations, was first introduced by Descartes, who called algebraical curves geometrical ones; as admitting none else into the construction of problems, nor consequently into geometry. But Newton, and after him Leibnitz and Wolfius, are of another opinion; and think, that in the construction of a problem, one curve is not to be preferred to another for its being defined by a more simple equation, but for its being more easily described.

Algebraical or geometrical lines are best distinguished into orders according to the number of dimensions of the equation expressing the relation between its ordinates and abscissæ, or, which is the same thing, according to the number of points in which they may be cut by a right line. And curves of the same kind or order, are those whose equations rise to the same dimension. Hence, of the first order, there is the right line only; of the 2d order of lines, or the first order of curves, are the circle and conic sections, being 4 species only, viz, $dx - x^2 = y^2$ the circle, $\frac{c^2}{d^2} \cdot (dx - x^2) = y^2$ the ellipse, $\frac{c^2}{d^2} \cdot (dx + x^2) = y^2$ the hyperbola, and $dx = y^2$ the parabola; the lines of the 3d order, or curves of the 2d order, are expressed by an equation of the 3d degree, having three roots; and so on. Of these lines of the 3d order, Newton wrote an express treatise, under the title of *Enumeratio Linearum Tertii Ordinis*, showing their distinctive characters and properties, to the number of 72 different species of curves: but Mr. Stirling afterwards four more to that number; and Mr. Nic. Bernoulli and Mr. Stone added two more.

Curves of the 2d and other higher kinds. Newton observes, have parts and properties similar to those of the 1st kind: Thus, as the conic sections have diameters and axes; the lines bisected by these are ordinates; and the intersection of the curve and diameter, the vertex: so, in curves of the 2d kind, any two parallel right lines being drawn to meet the curve in 3 points; a right line cutting these parallels so, as that the sum of the two parts between the secant and the curve on one side, is equal to the 3d part terminated by the curve on the other side, will cut, in the same manner, all other right lines parallel to these, and that meet the curve in three points, that is, so as that the sum of the two parts on one side, will still be equal to the 3d part on the other side. These three parts therefore thus equal, may be called Ordinates, or Appellates; the cutting line, the Diameter; and where it cuts the ordinates at right angles, the Axis; the intersection of the diameter and the curve, the Vertex; and the concourse of two diameters, the Centre; also the concourse of all the diameters, the Common or General Centre.

Again, as an hyperbola of the first kind has two asymptotes; that of the 2d has 3; that of the 3d has 4; &c: and as the parts of any right line between the conic hyperbola and its two asymptotes, are equal on either side; so, in hyperbolas of the 2d kind, any right line cutting the curve and its three asymptotes in three points; the sum of the two parts of that right line, extended from any two asymptotes, the same way, to two points of the curve, will be equal to the 3d part extended from the 3d asymptote, the contrary way, to the 3d point of the curve.

Again, as in the conic sections that are not parabolical, the square of an ordinate, i.e. the rectangle of the ordinates drawn on the contrary sides of the diameter, is to the rectangle of the parts of the diameter terminated at the vertices of an ellipse or hyperbola, in the same proportion

as a given line called the latus rectum, is to that part of the diameter which lies between the vertices, and called the latus transversum; so, in curves of the 2d kind, not parabolical, the product under three ordinates, is to the product under the three parts of the diameter cut off at the ordinates and the three vertices of the figure, in a given ratio: in which, if there be taken three right lines situated at the three parts of the diameter between the vertices of the figure, each to each; then these three right lines may be called the Latera Recta of the figure; and the parts of the diameter between the vertices, the Latera Transversa.

And, as in a conic parabola, which has only one vertex to one and the same diameter, the rectangle under the ordinates is equal to the rectangle under the part of the diameter cut off at the ordinates and vertex, and a given right line called the latus rectum: so, in curves of the 2d kind, which have only two vertices to the same diameter, the product under three ordinates, is equal to the product under two parts of the diameter cut off at the ordinates and the two vertices, and a given right line, which may therefore be called the Latus Transversum.

Further, as in the conic sections, where two parallels, terminated on each side by a curve, are cut by two other parallels terminated on each side by a curve, the 1st by the 3d, and the 2d by the 4th; the rectangle of the parts of the 1st is to that of the 3d, as that of the 2d is to that of the 4th; so, when four such right lines occur in a curve of the 2d kind, each in three points; the product of the parts of the 1st, will be to that of the parts of the 3d, as that of the 2d to that of the 4th.

Lastly, the legs of curves, both of the 1st, 2d, and higher kinds, are either of the parabolic or hyperbolic kind: an hyperbolic leg being that which approaches infinitely towards some asymptote; and a parabolic one, that which has no asymptote.

These legs are best distinguished by their tangents; for, if the point of contact go off to an infinite distance, the tangent of the hyperbolic leg will coincide with the asymptote; and that of the parabolic leg, recede infinitely, and vanish. Therefore the asymptote of any leg is found, by seeking the tangent of that leg to a point infinitely distant; and the direction of an infinite leg is found, by seeking the position of a right line parallel to the tangent, where the point of contact is infinitely remote, for this line tends that way towards which the infinite leg is directed.

Reduction of Curves of the 2d kind.

Newton reduces all curves of the 2d kind to four cases of equations, expressing the relation between the ordinate and abscissæ, viz,

$$\text{in the 1st case, } xy^2 + ey = ax^3 + bx^2 + cx + d;$$

$$\text{in the 2d, } - \quad xy = ax^3 + bx^2 + cx + d;$$

$$\text{in the 3d, } - \quad y^2 = ax^3 + bx^2 + cx + d;$$

$$\text{in the 4th, } - \quad y = ax^3 + bx^2 + cx + d.$$

See Newton's *Enumeratio*, sect. 3; and Stirling's *Linear*, &c, p. 83.

Enumeration of the Curves of the 2d kind.

Under these four cases, the author brings a great number of different forms of curves, to which he gives different names. An hyperbola lying wholly within the angle of the asymptotes, like a conic hyperbola, he calls an Inscribed Hyperbola; that which cuts the asymptotes, and contains the parts cut off within its own periphery, a

Circumscribed Hyperbola; that which has one of its infinite legs inscribed and the other circumscribed, he calls Ambigenal; that whose legs tend towards each other, and are directed the same way, Converging; that where they tend contrary ways, Diverging; that where they are convex different ways, Cross-legged; that applied to its asymptote with a concave vertex, and diverging legs, Conchoidal; that which cuts its asymptote with contrary flexures, and is produced each way into contrary legs, Angueinous, or Snake-like; that which cuts its conjugate across, Cruciform; that which returning around cuts itself, Nodated; that whose parts concur in the angle of contact, and there terminate, Cuspidated; that whose conjugate is oval, and infinitely small, i. e. a point, Pointed; that which, from the impossibility of two roots, is without either oval, node, cusp, or point, Pure. And in the same manner he denominates a parabola Converging, Diverging, Cruciform, &c. Also when the number of hyperbolic legs exceeds that of the conic hyperbola, that is more than two, he calls the hyperbola Redundant.

Under those 4 cases the author enumerates 72 different curves: of these, 9 are redundant hyperbolae, without diameters, having three asymptotes including a triangle; the first consisting of three hyperbolae, one inscribed; another circumscribed, and the third ambigenal, with an oval; the 2d, nodated; the 3d, cuspidated; the 4th, pointed; the 5th and 6th, pure; the 7th and 8th, cruciform; the 9th or last, angueinous. There are 12 redundant hyperbolae, having only one diameter: the 1st, oval; the 2d, nodated; the 3d, cuspidated; the 4th, pointed; 5th, 6th, 7th, and 8th, pure; the 9th and 10th, cruciform; the 11th and 12th, conchoidal. And to this class Stirling adds 2 more. There are 2 redundant hyperbolae, with three diameters. There are 9 redundant hyperbolae, with three asymptotes converging to a common point; the 1st being formed of the 5th and 6th redundant parabolae, whose asymptotes include a triangle; the 2d formed of the 7th and 8th; the 3d and 4th, of the 9th; the 5th is formed of the 5th and 7th of the redundant hyperbolae, with one diameter; the 6th, of the 6th and 7th; the 7th, of the 8th and 9th; the 8th, of the 10th and 11th; the 9th, of the 12th and 13th: all which conversions are effected, by diminishing the triangle comprehended between the asymptotes, till it vanish into a point.

Six are defective parabolae, having no diameters: the 1st, oval; the 2d, nodated; the 3d, cuspidated; the 4th, pointed; the 5th, pure; &c.

Seven are defective hyperbolae, having diameters: the 1st and 2d, conchoidal, with an oval; the 3d, nodated; the 4th, cuspidated, which is the cissoid of the ancients; the 5th and 6th, pointed; the 7th, pure.

Seven are parabolic hyperbolae, having diameters: the 1st, oval; the 2d, nodated; the 3d, cuspidated; the 4th, pointed; the 5th, pure; the 6th, cruciform; the 7th, angueinous.

Four are parabolic hyperbolae; four are hyperbolisms of the hyperbola: three, hyperbolae of the ellipsis: two, hyperbolisms of the parabola.

Six are diverging parabolae; the 1st, a trident; the 2d, oval; the 3d, nodated; the 4th, pointed; the 5th, cuspidated (which is Neil's parabola, usually called the semicubical parabola); the 6th, pure.

Lastly, one, commonly called the cubical parabola.

Mr. Stirling and Mr. Stone have shown that this enu-

meration is imperfect, the former having added four new species of curves to the number, and the latter two, or rather these two were first noticed by Mr. Nic. Bernoulli. Also Mr. Murdoch and Mr. Geo. Sanderson have found some new species; though some persons dispute the reality of them. See the *Genesis Curvarum per Umbras*, and the *Ladies' Diary* 1788 and 1789, the prize question.

Organical Description of CURVES.—Sir Isaac Newton shows that curves may be generated by shadows. He says, if upon an infinite plane, illuminated from a lucid point, the shadows of figures be projected; the shadows of the conic sections will always be conic sections; those of the curves of the 2d kind, will always be curves of the 2d kind; those of the curves of the 3d kind, will always be curves of the 3d kind; and so on ad infinitum.

And, like as the projected shadow of a circle generates all the conic sections, so the 5 diverging parabolae, by their shadows, will generate and exhibit all the rest of the curves of the 2d kind: and thus some of the most simple curves of the other kinds may be found, which will form, by their shadows upon a plane, projected from a lucid point, all the other curves of the same kind. And in the French *Memoirs* may be seen a demonstration of this projection, with a specimen of a few of the curves of the 2d order, which may be generated by a plane cutting a solid formed from the motion of an infinite right line along a diverging parabola, having an oval, always passing through a given or fixed point above the plane of that parabola. The above method of Newton has also been pursued and illustrated with great elegance by Mr. Murdoch, in his treatise entitled *Newtoni Genesis Curvarum per Umbras, seu Perspectiva Universalis Elementa*.

Mr. Maclaurin, in his *Geometria Organica*, shows how to describe several of the species of curves of the 2d order, especially those having a double point, by the motion of right lines and angles: but a good commodious description by a continued motion of those curves which have no double point, is ranked by Newton among the most difficult problems. Newton gives also other methods of description, by lines or angles revolving above given poles; and Mr. Brackenridge has given a general method of describing curves, by the intersection of right lines moving about points in a given plane. See *Philos. Trans.* No. 437, or my *Abr.* vol. 8, pa. 5; and some particular cases are demonstrated in his *Exerc. Geometrica de Curvarum Descriptione*.

CURVES above the 2d Order. The number of species in the higher orders of curves increase amazingly, those of the 3d order only it is thought amounting to some thousands, all comprehended under the following ten particular equations,

$$\begin{aligned} \text{viz. } 1. \quad & + fx^2y^2 + gxy^3 + hxy^2 + iy^2 + hxy + ly, \\ \text{or } 2. \quad & + fxy^2 + gx^2y + hxy^2 + ixy + ky, \\ \text{or } 3. \quad & x^2y^2 + fy^3 + gxy^2 + hy^2 + kxy + iy, \\ \text{or } 4. \quad & xy^2 + fy^3 + gy^2 + hxy + iy, \\ \text{or } 5. \quad & y^3 + fxy^2 + gx^2y + hy, \\ \text{or } 6. \quad & y^3 + fxy^2 + gxy + hy, \\ & = ax^4 + bx^3 + cx^2 + dx + e; \\ \text{or } 7. \quad & y^4 + ex^3y + fxy^3 + gx^2y + hy^2 + ixy + ky, \\ \text{or } 8. \quad & x^3y + ey^3 + fxy^2 + gy^2 + hxy + iy, \\ \text{or } 9. \quad & xy^3 + ey^3 + fxy^2 + gxy + hy, \\ \text{or } 10. \quad & x^3y + ey^3 + fxy^2 + gxy + hy, \\ & = ax^3 + bx^2 + cx + d. \end{aligned}$$

Those who wish to see how far this doctrine has been

advanced, with regard to curves of the higher orders, as well as those of the 1st and 2d orders, may consult Mr. Maclaurin's *Geometria Organica*, and Brackenridge's *Exerc. Geom.*

All geometrical lines of the odd orders, viz, the 3d, 5th, 7th, &c, have at least one leg running on infinitely; because all equations of the odd dimensions have at least one real root. But vast numbers of the lines of the even orders are only ovals; among which there are several having very pretty figures, some being like single hearts, some double ones, some resembling fiddles, and others again single knots, double knots, &c.

Two geometrical lines of any order will cut each other in as many points as are denoted by the product of the two numbers expressing those orders.

The theory of curves forms a considerable branch of the mathematical sciences. Those who are curious of advancing beyond the knowledge of the circle and the conic sections, and to consider geometrical curves of a higher nature, and in a general view, will do well to study Cramer's *Introduction à l'Analyse des Lignes Courbes Algébriques*, which the learned and ingenious author composed for the use of beginners. There is an excellent posthumous piece too of Maclaurin's, printed as an Appendix to his *Algebra*, and entitled *De Linearum Geometricarum Proprietatibus Generalibus*. The same author, at a very early age, gave a remarkable specimen of his genius and knowledge in his *Geometria Organica*; and he carried these speculations farther afterwards, as may be seen in the theorems he has given in the *Philos. Trans.* See Abr. vol. 6. Other writings on this subject, besides the Treatises on the Conic Sections, are Archimedes de Spiralibus; Descartes *Geometria*; Dr. Barrow's *Lectiones Geometricæ*; Newton's *Enumeratio Linearum Tertii Ordinis*; Stirling's *Illustratio Tractatus Newtoni de Lineis Tertiæ Ordinis*; Maclaurin's *Geometria Organica*; Brackenridge's *Descriptio Linearum Curvarum*; M. de Gua's *Usages de l'Analyse de Descartes*; besides many other Tracts on Curves in the Memoirs of several Academies &c.

Use of Curves in the Construction of Equations. One great use of curves in Geometry is, by means of their intersections, to give the solution of problems. See CONSTRUCTION.

Suppose, ex. gr. it were required to construct the following equation of 9 dimensions, $x^9 + bx^7 + cx^5 + dx^3 + ex^4 + (m+f)x^3 + gx^2 + hx + k = 0$: assume the equation to a cubic parabola $x^3 = y$; then, by writing y for x^3 , the given equation will become $y^9 + bxy^7 + cy^5 + dx^2y + exy + my + fx^3 + gx^2 + hx + k = 0$; an equation to another curve of the 2d kind, where m or f may be assumed $= 0$ or any thing else: and by the descriptions and intersections of these curves will be given the roots of the equation to be constructed. It is sufficient to describe the cubic parabola once. When the equation to be constructed, by omitting the two last terms hx and k , is reduced to 7 dimensions; the other curve, by expunging m , will have the double point in the beginning of the absciss, and may be easily described as above: If it be reduced to 6 dimensions, by omitting the last three terms, $gx^2 + hx + k$; the other curve, by expunging f , will become a conic section. And if, by omitting the last three terms, the equation be reduced to three dimensions, we shall fall upon Wallis's construction by the cubic parabola and right line.

Rectification, Inflection, Quadrature, &c. of Curves. See the respective terms.

Curve of a Double Curvature, is a curve of which all its parts are not in the same plane.

A curve which can be traced upon a curve surface, and not upon a plane, is called a curve of double curvature. These kinds of curves may be considered as generated by the motion of a point upon a curve surface, provided the duration of its motion be not constantly in the same plane: for, except in the latter case, it is evident that the line so described is curved in two ways; that is, it partakes of the curvature of the surface, and of the continual and successive deflections of the describing point. Or, we may consider those curves as generated by the motion of a variable ordinate along any curve line regarded as an absciss.

Curves of double curvature may also be formed by two curve surfaces penetrating each other; as is the case when a sphere is penetrated by a right cylinder, if the axis of the latter do not pass through the centre of the former.

In the rectification of those curves, they may be considered as projected, first, upon some plane, whose position is known; by which means a plane curve will be obtained, which being considered as an absciss, the rectification of the original curve may be deduced from the usual methods employed for the rectification of plane curves.

Clairaut has published an ingenious treatise on curves of a double curvature. See his *Recherches sur les Courbes à Double Courbure*. Euler has also treated on this subject in the Appendix to his *Analysis Infinitorum*, vol. 2, pa. 323. As likewise Lacroix in his *Calcul Differential* &c, and other modern writers.

Family of Curves, is an assemblage of several curves of different kinds, all defined by the same equation of an indeterminate degree; but differently, according to the diversity of their kind. For example, Suppose an equation of an indeterminate degre-e, $a^{m-1}x = y^m$: if $m = 2$, then will $ax = y^2$; if $m = 3$, then will $a^2x = y^3$; if $m = 4$, then is $a^3x = y^4$, &c: all which curves are said to be of the same family or tribe.

The equations by which the families of curves are defined, are not to be confounded with the transcendental ones: for though with regard to the whole family, they be of an indeterminate degree, yet with respect to each several curve of the family, they are determinate; whereas transcendental equations are of an indefinite degree with respect to the same curve.

All algebraical curves therefore compose a certain family, consisting of innumerable others, each of which comprehends infinite kinds. For the equations by which curves are defined involve only products, either of powers of the abscisses and ordinates by constant coefficients; or of powers of the absciss by powers of the ordinates; or of constant, pure, and simple quantities, by one another. Moreover, every equation to a curve may have 0 for one member or side of it; for example $ax = y^2$, by transposition becomes $ax - y^2 = 0$. Therefore the equation for all algebraic curves will be

$$\left. \begin{array}{l} ay^m + bry^{m-1} + nx^2y^{m-2} + c - - - - - fy^m \\ \quad + fy^{m-1} + ky^{m-2} \\ \quad + gy^{m-2} \end{array} \right\} = 0.$$

Catacaustic, and Diacaustic Curves. See *CATACAUSTIC*, and *DIACAUSTIC*.

Exponential CURVE, is that which is defined by an exponential equation, as $ax^x = y$, &c.

CURVES by the Light, or *Courbes à la Lumière*, a name given to certain curves by M. Kurnwanowski, a Polish gentleman. He observed that any line, straight or curved, exposed to the action of a luminous point, received the light differently in its different parts, according to their distance from the light. These different effects of the light upon each point of the line, may be represented by the ordinates of some curve, which will vary precisely with these effects. Priestley's Hist. of Vision, pa. 752.

Logarithmic CURVE. See LOGARITHMIC Curve.

CURVE Reflectoire, so called because it is the appearance of the plane bottom of a basin covered with water, to an eye perpendicularly over it. In this position, the bottom of the basin will appear to rise upwards, from the centre outwards; but the curvature will be less and less, and at last the surface of the water will be an asymptote to it. M. Mairan, who first conceived this idea from the phenomena of light, found also several kinds of these curves; and he gives a geometrical deduction of their properties, showing their analogy to caustics by refraction. Mem. Ac. 1740; Priestley's Hist. of Vision, pa. 752.

Radical CURVES, a name given by some authors to curves of the spiral kind, whose ordinates, if they may be so called, do all terminate in the centre of the including circle, and appear like so many radii of that circle: whence the name.

Regular CURVES, are such as have their curvature turning regularly and continually the same way; in opposition to such as bend contrary ways, by having points of contrary flexure, which are called irregular curves.

Characteristic Triangle of a Curve, is the differential or elementary right-angled triangle whose three sides are, the fluxions of the absciss, ordinate, and curve; the fluxion of the curve being the hypotenuse. So, if pq be parallel to, and indefinitely near to the ordinate pq , and qr parallel to the absciss AP ; then qr is the fluxion of the absciss AP , and qr the fluxion of the ordinate pq , and qr the fluxion of the curve AQ ; hence the elementary triangle qqr is the characteristic triangle of the curve AQ ; and the three sides are $\dot{x}, \dot{y}, \dot{z}$; in which $\dot{x}^2 + \dot{y}^2 = \dot{z}^2$.

CURVILINEAR Angle, Figure, Superficies, &c., are such as are formed or bounded by curves; in opposition to rectilinear ones, which are formed by straight lines or planes.

CUSP, in Astronomy, is used to express the points or horns of the moon, or other luminary.

Cusp, in the Higher Geometry, is used for the point or corner formed by two parts of a curve meeting and terminating there. See CURVE.

CUSPIDATED Hyperbola, &c. See CURVE.

CUT-BASTION. See BASTION.

CUVETTE, or *CUNETTE*, in Fortification, is a kind of ditch within a ditch, being a pretty deep trench, about four fathoms broad, sunk and running along the middle of the great dry ditch, to hold water; serving both to keep off the enemy, and prevent him from mining.

CYCLE, a certain period or series of numbers proceeding orderly from first to last, then returning again to the first, and so circulating perpetually.

Cycles have chiefly arisen from the incommensurability of the periods of revolutions of the earth and celestial bo-

dies to one another. The apparent revolution of the sun about the earth has been arbitrarily divided into 24 hours, which is the basis or foundation of all our mensuration of time, whether days, years, &c. But neither the annual motion of the sun, nor that of the other heavenly bodies, can be measured exactly, and without any remainder, by hours, or their multiples. That of the sun, for example, is 365 days 5 hours 49 minutes nearly; that of the moon, 29 days 12 hours 44 minutes nearly.

Hence, in order to find equivalent expressions for these fractions in whole numbers, and yet in numbers which only express days and years, cycles have been invented; which, comprehending several revolutions of the same body, replace it, after a certain number of years, in the same points of the heaven whence it first departed; or, which is the same thing, in the same place of the civil calendar.

There are various cycles; as, the cycle of induction, the cycle of the moon, the cycle of the sun, &c.

CYCLE of Indiction, is a series of 15 years, returning constantly the same as the other cycles; and it commenced from the third year before Christ; whence it happens that if 3 be added to any given year of Christ, and the sum be divided by 15, what remains is the year of the induction. See INDICATION.

CYCLE of the Moon, or the *Lunar Cycle*, is a period of 19 years; in which time the new and full moons return to the same day of the Julian year. See CALIPPIC.

This cycle is also called the *Metonic period or cycle*, from its inventor Meton, the Athenian; and also the *Golden Number*, from its excellent use in the calendar: though, properly speaking, the golden number is rather the particular number which shows the year of the lunar cycle, which any given year is in. This cycle of the moon only holds true for $310\frac{7}{10}$ years: for, though the new moons do return to the same day after 19 years; yet not to the same time of the day, but near an hour and a half sooner; an error which in $310\frac{7}{10}$ years amounts to an entire day. Yet those employed in reforming the calendar made their calculations on a supposition that the lunations return precisely from 19 years to 19 years, for ever.

The use of this cycle, in the ancient calendar, is to show the new moon of each year, and the time of Easter. In the new one, it only serves to find the Epacts; which show, in either calendar, that the new moon falls 11 days too late.

As the Orientals began the use of this cycle at the time of the Council of Nice in 325, they assumed, that the first year of the cycle the paschal new moon fell on the 13th of March; on which account the lunar cycle 3 fell on the 1st of January in the third year.

The Occidentals, on the contrary, placed the number 1 to the 1st of January, which occasioned a considerable difference in the time of Easter. Hence, Dionysius Exiguus, on framing a new calendar, persuaded the Christians of the west to solve the difference, and come into the practice of the church of Alexandria.

To find the Year of the Lunar Cycle, is to find the golden number. See GOLDEN-NUMBER.

CYCLE of the Sun, or *Solar Cycle*, is a period or revolution of 28 years; beginning with 1, and ending with 28; which elapsed, the Dominical or Sunday-letters, and those that express the other feasts, &c, return into their former place, and proceed in the same order as before. The days of the month return again to the same days of the week; the sun's place to the same signs and degrees of the ecliptic on the same months and days, so as not to differ one-

degree in a hundred years; and the leap-years begin the same course with respect to the days of the week on which the days of the month fall.

This is called the cycle of the sun, or the solar cycle, not from any regard to the sun's course, which has no concern in it; but from Sunday, anciently called dies solis, the sun's day; as the dominical or sunday letter is chiefly sought for from this revolution.

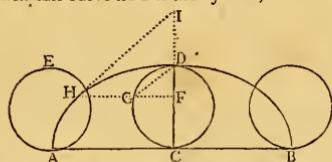

The reformation of the calendar under Pope Gregory the 13th, occasioned a considerable alteration of this cycle: In the Gregorian calendar, the solar cycle is not constant and perpetual; because every 4th secular year is common; whereas, in the Julian, it is bissextile. The epoch, or beginning of the solar cycle, both Julian and Gregorian, is the 9th year before Christ. And therefore,

To find the Cycle of the Sun for any given year: add 9 to the number given, and divide the sum by 28; the remainder will be the number of the cycle, and the quotient the number of revolutions since Christ. If there be no remainder, it will be the 28th or last year of the cycle.

CYCLE of the Sun, and Sunday Letters, from the Year 1800 to the Year 1900.

Great Pascal CYCLE, is another name for the Victorian or Dionysian Period. Which see.

CYCLOID, or TROCHOID, a mechanical or transcendental curve, which is thus generated: Suppose a wheel, or a circle, AE , to roll along a straight line AB , beginning at the point A , and ending at B , where it has completed just one revolution, thus measuring out a right line AB exactly equal to the circumference of the generating circle AE , while a nail or point A in the circumference of the wheel, or circle, traces out or describes a curvilinear path ADB ; then, this curve ADB is the cycloid, or trochoid.

Schooten, in his Commentary on Descartes, says that Descartes first conceived the notion of this elegant curve, and after him it was first published by Father Mersenne, in the year 1615. But Torricelli, in the Appendix de Dimensione Cycloidis, at the end of his treatise De Dimensione Parabolae, published 1644, says that this curve was considered and named a cycloid, by his predecessors, and particularly by Galileo about 45 years before, i.e. about 1599. And Dr. Wallis shows that it is of a much older standing, having been known to Bovilli about the year 1500, and even considered by Cardinal Cusanus much earlier, viz. before the year 1451. Philos. Trans. Abr. vol. 4, pa. 169. It would seem however that Torricelli's was the first regular treatise on the Cycloid; though several particular properties of it might be known prior to his work. He first showed, that the cycloidal space is equal to triple the generating circle, (though Pascal contends that Roberval showed this); also that the solid generated by the rotation of that space about its base, is to the cir-

cumscribing cylinder, as 5 to 8: about the tangent parallel to the base, as 7 to 8: about the tangent parallel to the axis, as 3 to 4: &c.

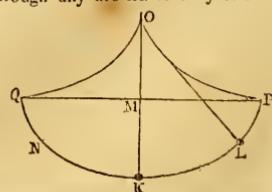

Honoratus Fabri, in his Synopsis Geom. has a short treatise on the cycloid, containing demonstrations of the above, and many other theorems concerning the centres of gravity of the cycloidal space, &c; which he says he found out before the year 1658.

From the preface to Dr. Wallis's treatise on the Cycloid we learn, that, in the year 1658, M. Pascal publicly proposed at Paris, under the name of Dettonville, the two following problems as a challenge, to be solved by the mathematicians of Europe, with a reward of 20 pistoles for the solution: viz., to find the area of any segment of the cycloid, cut off by a right line parallel to the base; also the content of the solid generated by the rotation of the same about the axis, and about the base of that segment. This challenger set the Doctor upon writing that treatise on the cycloid, which is a much better and more complete piece than had been given before upon this curve. He there gives the curve surfaces of the solids generated by the rotation of the cycloidal space about its axis, and about its base, with determinations of the centres of gravity, &c. He here likewise asserts that Sir Christopher Wren, in 1658, was the first who found a right line equal to the curve of the cycloid; and Mr. Huygens, in his Horolog. Oscillat. says that he himself was the first inventor of the segment of a cycloidal space, cut off by a right line parallel to the base at the distance of $\frac{1}{2}$ the axis of the curve from the centre, being equal to a rectilinear space, viz., to a regular hexagon inscribed in a generating circle; the demonstration of which may be seen in Wallis's treatise.

Several other authors have treated of the cycloid: as Pascal, in his treatise, under the name of Dettonville; Schooten in his Commentary on Descartes's Geometry, near the end of the 2d book; M. Reinau, in his Analyse Démontrée, tom. 2, pa. 595: also Newton, Leibnitz, Laloubere, Roberval, Descartes, Wren, Fabri, the Bernoulli's, Lahire, Cotes, Emerson, &c, &c.

Properties of the CYCLOID.—The circle AE , by whose revolution the cycloid is traced out, is called the Generating Circle; the line AB , which is equal to the circumference of the circle, is the Base of the cycloid; and the perpendicular AC on the middle of the base, is its Axis. The properties of the cycloid are among the most beautiful and useful of all curve lines: some of the most remarkable of which are as follow:

1. The circ. arc $DG = gn$ parallel to AB .
2. The semicircumf. $DGC =$ the semibase AC .
3. The arc $DH =$ double the chord DC .
4. The arc $DA =$ double the diameter DC .
5. The tang. II is parallel to the chord DC .
6. The space $ADBA =$ triple the circle AE .
7. The space $ADGCA =$ the same circle AE , &c.
8. A body falls through any arc KL of a cycloid reversed, in the same time, whether that arc be great or small; that is, from any point t , to the lowest point K , which is the vertex reversed; and that time is to the time of falling perpendi-

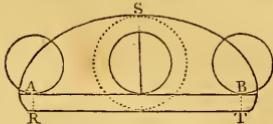

cularly through the axis MR , as the semicircumference of a circle is to its diameter, or as $3'1416$ to 2. And hence it follows that, if a pendulum be made to vibrate in the arc LKN of a cycloid, all the vibrations will be performed in the same time.

9. The evolute of a cycloid, is another equal cycloid. So that if two equal semicycloids OR , OQ , be joined at O , so that OR be equal to MK the diameter of the generating circle, and the string of a pendulum hung up at O , having its length equal to OK or to the curve OP ; then, by plying the string round the curve OP , to which it is equal, and the ball being let go, it will describe and vibrate in the other cycloid PKQ . We must not however conclude from this, that a body so vibrating will really perform all its vibrations in equal times, for this is only true in theory, that is, by supposing the string by which the vibrating body is suspended to be void of gravity. For in estimating the centre of oscillation of any body, regard must be had to this circumstance, and in the final expression the distance from the point of suspension is found to enter, together with the distance of the centre of oscillation of the string, and consequently this last centre of oscillation is constantly varying; which will prevent the body from performing all its vibrations in the same time: but the greater the weight of the body is, when compared with that of the string, the nearer will these times approach to an equality.

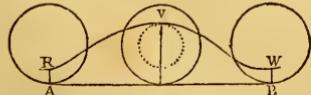

10. The cycloid is the curve of swiftest descent: or a heavy body will fall from one given point to another, through the arc of a cycloid passing by those two points, in a less time, than if it passed along any other curve, or even along a right line joining those two points.

John Bernoulli was the first who proposed to mathematicians this problem under the title of the *Brachystochronon*, that is, to find the curve of swiftest descent, or that curve, along which a heavy body would fall from one point to another, not in the same vertical line, in the least time. And solutions were given to it by his brother James Bernoulli, Leibnitz, Hôpital, and Newton. See Gregory's Mechanics, art. 277, vol. 1: also the Works of James and John Bernoulli, for many other curious properties concerning the descents in cycloids, &c.

CYCLOIDS are also either Curtate or Prolate.

CYCLOID, *Curtate*, or *contracted*, is the path described by some point without the circle, while the circumference rolls along a straight line; and a

CYCLOID, *Prolate*, or *Inflected*, is in like manner the path of some point taken within the generating circle.

Thus, if, while the circle rolls along the line AB , the point R be taken without the circle, it will describe or trace out the curtate or contracted cycloid rst ; but the point being taken within the circle, it will describe the prolate or inflected cycloid rww .

These two curves were both noticed by Torricelli and Schooten, and more fully treated of by Wallis, in his *Treatise on the Cycloid*, printed at Oxford in 1659; where he shows that these have properties similar to the first or primary cycloid; only the last of them is a curve having a point of inflection, and the other crossing itself, and forming a node.

By continuing the motion of the wheel, or circle, so as to describe a right line equal to the generating circumference several times repeated, there will be produced as many repetitions of the cycloids, which so united together will appear as in these figures following:

Curtate Cycloid.

Common Cycloid.

Inflected Cycloid.

CYCLOPÆDIA. See ENCYCLOPÆDIA.

CYGNUS, the *Swan*, a constellation of the northern hemisphere, being one of the 48 old ones, and fabled by the Greeks to be the swan, under the form of which Jupiter deceived Leda or Nemesis, from which embrace sprung the beauteous Helen. The stars in the constellation Cygnus, in Ptolemy's catalogue are 19, in Tycho's 18, in Hevelius's 47, and in the Britannic catalogue 81.

CYLINDER, a solid having two equal circular ends, and every plane section parallel to the ends a circle equal to them also.—The cylinder may be conceived to be thus generated:

Suppose two parallel circles AB , CD , and a right line carried continually round them, always parallel to itself; this line will describe the curve surface of a cylinder, $ARD'C'$, of which the two parallel circles AB and CD form the two ends. When the line or side is perpendicular to the ends, the cylinder is a right or perpendicular one; otherwise it is oblique.

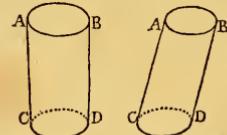

Or the right cylinder may be conceived to be generated by the rotation of a rectangle about one of its sides. The Axis of the cylinder is the line connecting the centres of its two parallel circular ends; and is equal to the altitude of the cylinder when this is a right one, but exceeds the altitude in the oblique cylinder, in the proportion of radius to the sine of the angle of its inclination to the base.

The convex surface of a cylinder is equal to the product of the axis and the circumference of its base.—The solidity of a cylinder is equal to the area of its base multiplied by its perpendicular altitude.

Cylinders of equal bases and altitudes, are equal.

Cylinders are to each other, as the product of their bases and altitudes. And equal cylinders have their bases reciprocally as their altitudes.

A cylinder is to its inscribed sphere, or spheroid, as 3 to 2: and to its inscribed cone as 3 to 1.

The oblique plane sections of a cylinder, are ellipses; but all the sections parallel to the ends, are circles.

For the surfaces and solidities of the unguis or oblique slices of a cylinder, see my Mensuration, p. 161, 4th edit.

CYLINDRICAL, pertaining to a cylinder.

CYLINDROID, a solid resembling the figure of a cylinder; but differing from it as having ellipses for its ends or bases, instead of circles in the cylinder.

In the cylindroid, the solidity and curve superficies are

found the same way as those of the cylinder; viz, by multiplying the circumference of the base by the length or axis, for the surface; and the area of the base by the altitude, for the solidity.

CYMATIUM, CINATIUM, or CIMA, in Architecture, a member, or moulding of the cornice, whose profile is waved; i. e. concave at top, and convex at bottom.

CYPHER, or nought. See CIPHER.

CYSSOID. See CISSOID.

D.

D A L

DADO, that part in the middle of the pedestal of a column &c, between its base and cornice.

DAILY, in Astronomy. See DIURNAL.

DALEMBERT, an eminent French mathematician and philosopher, and one of the brightest ornaments of the 18th century. He was perpetual secretary to the French Academy of Sciences, and a member of most of the philosophical academies and societies of Europe.

Dalembert was born at Paris, the 16th of November 1717. He derived the name of John le Rond from that of the church near which, after his birth, he was exposed as a foundling. But his father, informed of this circumstance, listening to the voice of nature and duty, took measures for the proper education of his child, and for his future subsistence in a state of ease and independence. His mother was a lady of rank, the celebrated Mademoiselle Tencin, sister to Cardinal Tencin, archbishop of Lyons.

He received his first education among the Jansenists, in the college of the four nations, where he gave early signs of genius and capacity. On quitting the college, finding himself alone, and unconnected in the world, he sought an asylum in the house of his nurse. He hoped that his fortune, though not ample, would enlarge the subsistence, and better the condition of her family, which was the only one that he could consider as his own. It was here therefore that he fixed his residence, resolving to apply himself entirely to the study of geometry.—And here he lived, during the space of 40 years, with the greatest simplicity, discovering the augmentation of his means only by increasing displays of his beneficence, concealing his growing reputation and celebrity from these honest people, and making their plain and uncouth manners the subject of good-natured pleasantry and philosophical observation. His good nurse perceived his ardent activity; heard him mentioned as the writer of many books; but never took it into her head that he was a great man, and rather beheld him with a kind of compassion. “ You will never,” said she to him one day, “ be any thing but a philosopher—and what is a philosopher?—a fool, who toils and plagues himself all his life, that people may talk of him when he is dead.”

In the year 1741 he was admitted a member of the Academy of Sciences; for which distinguished literary promotion, at so early an age (24), he had prepared the way by correcting the errors of a celebrated work (The Analyse Demontree de Reyneau), which was esteemed classical in France in the line of analytics. He after-

D A L

wards set himself to examine, with close attention and assiduity, what must be the motion and path of a body, which passes from one fluid into another denser fluid, in a direction oblique to the surface between the two fluids. Every one knows the phenomenon which happens in this case, and amuses children, under the denomination of ducks and drakes; but it was Dalembert who first explained it in a satisfactory and philosophical manner.

Two years after his election to a place in the Academy, he published his Treatise on Dynamics. The new principle developed in this treatise, consisted in establishing an equality, at each instant, between the changes that the motion of a body has undergone, and the forces or powers which have been employed to produce them: or, to express the same thing otherwise, in separating into two parts the action of the moving powers, and considering the one as producing alone the motion of the body, in the second instant, and the other as employed to destroy that which it had in the first. So early as the year 1744, Dalembert had applied this principle to the theory of the equilibrium, and the motion of fluids; and all the problems before resolved in physics, became in some measure its corollaries. The discovery of this new principle was followed by that of a new calculus, the first essays of which were published in a Discourse on the General Theory of the Winds, to which the prize-medal was adjudged by the Academy of Berlin in the year 1746, which proved a new and brilliant addition to the fame of Dalembert. This new calculus of Partial Differences he applied, the year following, to the problem of vibrating chords, the resolution of which, as well as the theory of the oscillations of the air and the propagation of sound, had been but imperfectly given by the mathematicians who preceded him; and these were his masters or his rivals.

In the year 1749 he furnished a method of applying his principle to the motion of any body of a given figure. He also resolved the problem of the precession of the equinoxes; determining its quantity, and explaining the phenomenon of the nutation of the terrestrial axis discovered by Dr. Bradley.

In 1752, Dalembert published a treatise on the Resistance of Fluids, to which he gave the modest title of an Essay; though it contains a multitude of original ideas and new observations. About the same time he published, in the Memoirs of the Academy of Berlin, Researches concerning the Integral Calculus, which is greatly indebted to him for the rapid progress it has since made.

Our author's eulogist ascribes to envy, detraction, &c,

all the opposition and censure that Dalembert met with on account of the celebrated Encyclopédie, or Dictionary of Arts and Sciences, in conjunction with Diderot. None surely will refuse the well-deserved tribute of applause to the eminent displays of genius, judgment, and true literary taste, with which Dalembert has enriched that great work. Among others, the Preliminary Discourse he has prefixed to it, concerning the rise, progress, connexions, and affinities of all the branches of human knowledge, is perhaps one of the most capital productions the philosophy of the age can boast of.

Some time after this, Dalembert published his Philosophical, Historical, and Philological Miscellanies. These were followed by the Memoirs of Christina queen of Sweden; in which he showed that he was acquainted with the natural rights of mankind, and was bold enough to assert them. His Essay on the Intercourse of Men of Letters with Persons high in Rank and Office, wounded the former to the quick, as it exposed to the eyes of the public the ignominy of those servile chains, which they feared to shake off, or were proud to wear. Dalembert gave elegant specimens of his literary abilities in his translations of some select pieces of Tacitus. But these occupations did not divert him from his mathematical studies: for about the same time he enriched the Encyclopédie with a multitude of excellent articles in that line, and composed his Researches on several Important Points of the System of the World, in which he carried to a higher degree of perfection the solution of the problem concerning the perturbations of the planets, that had several years before been presented to the Academy.

In 1759 he published his Éléments de Philosophie: a work much extolled, as remarkable for its precision and perspicuity. The resentment that was kindled (and the disputes that followed it) by the article Geneva, inserted in the Encyclopédie, are well known. Dalembert did not leave this field of controversy with flying colours. It was on this occasion that Frederick king of Prussia offered him an honourable asylum at his court, and the office of president of his Academy: but the king was not offended at Dalembert's refusal of these distinctions, though he cultivated an intimate friendship with him during the rest of his life. He had refused, some time before this, a proposal made by the empress of Russia to entrust him with the education of the Grand Duke;—a proposal accompanied with all the flattering offers that could tempt a man, ambitions of titles, or desirous of making an ample fortune: but the objects of his ambition were tranquillity and study.

In the year 1765, he published his Dissertation on the Destruction of the Jesuits. This piece drew upon him a swarm of adversaries, who only confirmed the merit of his work by their manner of attacking it. Besides the works already mentioned, he published 9 volumes of memoirs and treatises, under the title of Opuscules; in which he has resolved a multitude of problems relating to astronomy, mathematics, and natural philosophy; of which his panegyrist, Condorcet, gives a particular account, more especially of those which exhibit new subjects, or new methods of investigation. He published also Elements of Music; and rendered, at length, the system of Rameau intelligible: but he did not think the mathematical theory of the sonorous body sufficient to account for the rules of that art.

In the year 1772 he was chosen secretary to the French Vol. I.

Academy of Sciences. He formed, soon after this preference, the design of writing the lives of all the deceased academicians, from 1700 to 1772; and in the space of three years he executed this design, by composing 70 eulogies. Dalembert died on the 29th of October 1783, being nearly 66 years of age.

As it may be curious and useful to have in one view an entire list of Dalembert's writings, I shall here insert a catalogue of them, from Rozier's Nouvelle Table des Articles contenus dans les volumes de l'Academie Royale des Sciences de Paris, &c., as follows:

Traité de Dynamique, in 4to, Paris, 1743. The 2d ed. in 1758.—Traité de l'Équilibre et du Mouvement des Fluides. Paris, 1744; and the 2d edit. in 1770.

Reflexions sur la Cause Générale des Vents; which gained the prize at Berlin in 1746; and was printed at Paris in 1747, in 4to.—Recherches sur la Précession des Equinoxes, et sur la Nutation de l'Axe de la Terre dans le Système Newtonien. Paris, 1749, in 4to.—Essais d'une Nouvelle Théorie du Mouvement des Fluides. Paris, 1752, in 4to.—Recherches sur différents Points importans du Système du Monde. Paris, 1754 and 1756, 3 vols. in 4to.—Élemens de Philosophie, 1759.

Opuscules Mathématiques, ou Mémoires sur différents Sujets de Géométrie, de Mécaniques, d'Optiques, et d'Astronomie. Paris, 9 vol. in 4to; 1761 to 1773.

Élemens de Musique, théorique et pratique, suivant les Principes de M. Rameau, éclairés, développés, et simplifiés. 1 vol. in 8vo. à Lyon.—De la Destruction des Jésuites, 1765.—In the Memoirs of the Academy of Paris are the following pieces, by Dalembert: viz, Précis de Dynamique, 1743, Hist. 164.—Précis de l'Équilibre et du Mouvement des Fluides, 1744, Hist. 55.—Méthode générale pour déterminer les Orbites et les Mouvements de toutes les Planètes, en ayant égard à leur action mutuelle, 1745, p. 365.—Précis des Réflexions sur la Cause Générale des Vents, 1750, Hist. 41.—Précis des Recherches sur la Précession des Equinoxes, et sur la Nutation de l'Axe de la Terre dans le Système Newtonien, 1750, Hist. 134.—Essay d'une Nouvelle Théorie sur la Résistance des Fluides, 1752, Hist. 116.—Précis des Essais d'une Nouvelle Théorie de la Résistance des Fluides, 1753, Hist. 289.—Précis des Recherches sur les différents Points importans du Système du Monde, 1754, Hist. 125.—Recherches sur la Précession des Equinoxes, et sur la Nutation de l'Axe de la Terre, dans l'Hypothèse de la Dissimilitude des Méridiens, 1754, p. 413, Hist. 116.—Réponse à un Article du Mémoire de M. l'Abbé de la Caille, sur la Théorie du Soleil, 1757, p. 145, Hist. 118.—Addition à ce Mémoire, 1757, p. 567, Hist. 118.

Précis des Opuscules Mathématiques, 1761, Hist. 86.

Précis du troisième volume des Opuscules Mathématiques, 1764, Hist. 92.—Nouvelles Recherches sur les Verres Optiques, pour servir de suite à la théorie qui en a été donnée dans le volume 3^e des Opuscules Mathématiques. Premier Mémoire, 1764, p. 75, Hist. 175.—Nouvelles Recherches sur les Verres Optiques, pour servir de suite à la théorie qui en a été donnée dans le troisième volume des Opuscules Mathématiques. Second Mémoire, 1765, p. 53.—Observations sur les Lunettes Achromatiques, 1765, p. 53, Hist. 119.—Suite des Recherches sur les Verres Optiques. Troisième Mémoire, 1767, p. 43, Hist. 153.—Recherches sur le Calcul Intégral, 1767, p. 573.—Accident arrivé par l'Explosion d'une Meule d'Emouleur, 1768, Hist. 31.—Précis des Opuscules de Mathématiques,

4^e et 5^e volumes. Leur Analyse, 1768, Hist. 83.—Recherches sur les Mouvements de l'Axo d'une Planète quelconque dans l'hypothèse de la Dissimilitude des Méridiennes, 1768, p. 1, Hist. 95.—Suite des Recherches sur les Mouvements, &c., 1768, p. 332, Hist. 95.—Recherches sur le Calcul Intégral, 1769, p. 73.—Mémoire sur les Principes de la Mec. 1769, p. 278. And in the Memoirs of the Academy of Berlin, are the following pieces, by our author: viz., Recherches sur le Calcul Intégral, première partie, 1746.—Solution de quelques Problèmes d'Astronomie, 1747.—Recherches sur la courbe que forme une Corde Tendue, mise en Vibration, 1747.—Suite des recherches sur le Calcul Intégral, 1748.—Lettre à M. de Maupertuis, 1749.—Addition aux recherches sur la courbe que forme une Corde Tendue mise en Vibration, 1750.—Addition aux recherches sur le Calcul Intégral, 1750.—Lettre à M. le professeur Formey, 1755.—Extr. de differ. lettres à M. de la Grange, 1763.—Sur les Tautochrones, 1765.—Extr. de differ. lettres à M. de la Grange, 1769. Also in the Memoirs of Turin are, Differentes Lettres à M. de la Grange, en 1764 et 1765, tom. 3 of these Memoirs.—Recherches sur differens sujets de Math. t. 4.

DARCY (COUNT), an ingenious philosopher and mathematician, was born in Ireland in 1725; but his friends being attached to the Stuart family, he was sent to France, at 14 years of age, where he spent the rest of his life. Being put under the care of the celebrated Clairaut, he improved so rapidly in the mathematics, that at 17 years of age he gave a new solution of the problem concerning the curve of equal pressure in a resisting medium. This was followed the year after by a determination of the curve described by a heavy body, sliding by its own weight along a moveable plane, at the same time that the pressure of the body causes a horizontal motion in the plane. Darcy served in the war of 1744, and was taken prisoner by the English: and yet, during the course of the war he gave two memoirs to the Academy; the first of these contained a general principle in mechanics, that of the preservation of the rotatory motion; a principle which he again brought forward in 1750, by the name of the principle of the preservation of action.

In 1760, Darcy published "An Essay on Artillery, containing some curious experiments on the charges of gunpowder, &c., &c., and improvements on those of the ingenious Robins; which kind of experiments our author carried on occasionally to the end of his life."

In 1765, he published his Mémoir on the Duration of the Sensation of Sight, the most ingenious of his works: the result of these researches was, that a body may sometimes pass by our eyes without being seen, or marking its presence, otherwise than by weakening the brightness of the object it covers.

All Darcy's works bear the character which results from the union of genius and philosophy; but as he measured every thing on the largest scale, and required extreme accuracy in experiment, neither his time, fortune, nor avocations, allowed him to execute more than a very small part of what he projected. In his disposition, he was amiable, spirited, lively, and a lover of independence, a passion to which he nobly sacrificed, even in the midst of literary society.—He died of a cholera morbus in 1779, at 54 years of age.

Darcy was admitted a member of the French Academy in 1749, and was made pensioner-geometrician in 1770.

—His essays, printed in the Memoirs of the Academy of Sciences, are various and very ingenious, and are contained in the volumes for the years 1742, 1747, 1749, 1750, 1751, 1752, 1753, 1754, 1758, 1759, 1760, 1765, and in tom. 1 of the Savans Etrangers.

DARK Chamber. See CAMERA Obscura.

DARK Tent, a portable camera obscura, made somewhat like a desk, and fitted with optic glasses, to take prospects of landscapes, buildings, &c.

DATA, in Mathematics, denote certain things or quantities, supposed to be given or known, from which other quantities are discovered that were unknown, or sought. A problem or question usually consists of two parts, Data and Quæsita, Given and Sought. Euclid has an express and excellent treatise of Data; in which he uses the word for such spaces, lines, angles, &c, as are given; or to which others can be found equal.

Euclid's Data is the first in order of the books that have been written by the ancient geometers, to facilitate and promote the method of resolution or analysis. In general, a thing is said to be given, which is either actually exhibited, or that can be found, that is, which is either known by hypothesis, or that can be demonstrated to be known: and the propositions in the book of Euclid's Data show what things can be found or known, from those, that by hypothesis are already given: so that in the analysis or investigation of a problem, from those things that are laid down as given it is demonstrated, by the help of these propositions, that other things are given, and from these last that others are given, and so on, till it is demonstrated that that which was proposed to be found in the problem is given; and when this is done, the problem is solved; and its composition is made and derived from the compositions of the Data which were employed in the analysis. And thus the Data of Euclid are of the most general and necessary use in the solution of problems of every kind.

Marius, at the end of his Preface to the Data, is mistaken in asserting that Euclid has not used the synthetical, but the analytical method in delivering them: for, though in the analysis of a theorem, the thing to be demonstrated is assumed in the analysis; yet, in the demonstrations of the Data, the thing to be demonstrated, which is, that something is given, is never once assumed in the demonstration; from which it is manifest that every one of them is demonstrated synthetically: though indeed if a proposition of the Data be turned into a problem, the demonstration of the proposition becomes the analysis of the problem. See Simson's edition of Euclid's Data, which is esteemed the best.

DAVIS (CAPT. JOHN), a celebrated navigator, who flourished in the latter part of the 16th century. He gave name to the straits which he discovered; and great expectations were formed from his skill and long experience. In 1594 he published a small treatise, entitled, The Seaman's Secrets; a piece written with brevity, and was esteemed in its time, an 8th edition being printed in 1657; so that it seems to have supplanted Cortes'. Davis treats of plane sailing, calling it Horizontal; and gives the form for keeping a sea-reckoning. He shows also how to sail by the globe, and boasts of what he intended to do; much commanding great circle sailing, without describing it; as also what he calls Paradoxal, that is, by a projection on the plane of the equator with spiral rhombs, promising to publish a chart for that purpose. But above all he extols

the use of calculations in the cases of navigation, and states his intention to treat on that subject.

At the end of the book is given the figure of a staff of his contrivance, to make a back-observation, which it appears he was very vain of, and which seems to have been some time in use; but was afterwards supplanted by one of a more commodious form, called Davis's Quadrant, as if it were also of his invention, though perhaps only because a back-observation was made by both instruments, like as the quadrant itself was at first called Staff, and Back-staff.

DAVIS's Quadrant, the common sea quadrant, or back-staff. See BACK-STAFF. See also Robertson's Navigation, book 9, sect. 7.

DAY, a division of time arising from the appearance and disappearance of the sun.

DAY is either natural or artificial.

Artificial Day is that which is generally meant by the word Day, and is the time of its being light, or the time while the sun is above the horizon. Though sometimes the twilight is included in the term day-light; in opposition to night or darkness, being the time from the end of twilight to the beginning of day-light.

Natural Day is the portion of time in which the sun performs one revolution round the earth; or rather the time in which the earth makes a rotation on its axis. And this is either astronomical or civil.

Astronomical Day begins at noon, or when the sun's centre is on the meridian, and is counted 24 hours to the following noon.

Civil Day is the time allotted for day in civil purposes, and begins differently in different nations, but still including one whole rotation of the earth on its axis; beginning either at sun-rise, sun-set, noon, or midnight.

1st, At sun-rising, among the ancient Babylonians, Persians, Syrians, and most other eastern nations, with the present inhabitants of the Balearic islands, the Greeks, &c. 2dly, At sun-setting, among the ancient Athenians and Jews, with the Austrians, Bohemians, Marcomanni, Silesians, modern Italians, and Chinese. 3dly, At noon, with astronomers, and the ancient Umbri and Arabians. And 4thly, at midnight, among the ancient Egyptians and Romans, with the modern English, French, Dutch, Germans, Spaniards, and Portuguese.

The day is divided into hours; and a certain number of days makes a week, a month, or a year.

The different length of the natural day in different climates, has been matter of controversy, viz, whether the natural days be all equally long throughout the year; and if not, what their difference is? A professor of mathematics at Seville, in the Philos. Trans. vol. 10, pa. 425, asserts, from a continued series of observations for three years, that they are all equal. But Mr. Flamsteed, in the same Trans. pa. 429, refutes the opinion; and shows that a day, when the sun is in the equinoctial, is shorter than when he is in the tropics, by 40 seconds; and that 14 tropical days are longer than so many equinoctial ones, by 10 minutes. This inequality of the days depends upon two different principles: the one, the eccentricity of the earth's orbit; the other, the obliquity of the ecliptic with regard to the equator, which is the measure of time. As these two causes happen to be differently combined, the length of the day is varied. See *EQUATION OF TIME*.

DAY Sidereal, is the time in which any star appears to revolve from the meridian, to the meridian again, which

is $23^{\text{h}} 56' 4'' \frac{1}{10}$ of mean solar time; being the time in which the earth makes one complete revolution on its axis. See *SIDEREAL*.

DAY's-Work, in Navigation, denotes the reckoning or account of the ship's course, during 24 hours, or between noon and noon.

DEAD BEAT, a peculiar kind of scapement for clock and watch work, invented by Mr. Mudge for correcting the motion of pendulums &c. See *SCAPEMENT*.

DEAD RECKONING, in Navigation, the judgment or estimation which is made of the place where a ship is, without any observation of the heavenly bodies; being generally performed by keeping an account of her way by the log, in knowing the course she has been steered by the compass, and by combining and rectifying all the allowances for drift, lee-way, &c, according to the known trim of the ship. This reckoning however is always to be corrected, as often as any good observation can be obtained.

DECAGON, a plane geometrical figure of ten sides and ten angles. When all the sides and angles are equal, it is a regular decagon, and may be inscribed in a circle; otherwise, not.

If the radius of a circle, or the side of the inscribed hexagon, be divided in extreme and mean ratio, the greater segment will be the side of a decagon inscribed in the same circle. And therefore, as the side of the decagon is to the radius, so is the radius to the sum of the two. Whence, if the radius of the circle be r , the side of the inscribed decagon will be $(\sqrt{5} - 1) \times \frac{r}{2}$.

If the side of a regular decagon be 1, its area will be $\frac{1}{2}\sqrt{(5 + 2\sqrt{5})} = 7.6942088$; therefore as 1 is to 7.6942088, so is the square of the side of any regular decagon, to the area of the same: consequently, if s be the side of such a decagon, its area will be equal to $7.6942088 s^2$. See *REGULAR Figure*.

To inscribe a decagon in a circle geometrically. See my *Mensuration*, prob. 35, pa. 20, 4th edit.

DECEMBER, the last month of the year; in which the sun enters the tropic of Capricorn, making the winter solstice. In the time of Romulus, December was the 10th month; whence the name, viz, from decem, ten; for the Romans began their year in March, from which December is the 10th month. The month of December was under the protection of Vesta. Romulus assigned it 30 days; Numa reduced it to 29; which Julius Caesar increased to 31. At the latter part of this month they had the Juveniles Ludi, and the country-people kept the feast of the goddess Vacuna in the fields, having then gathered in their fruits, and sown their corn; whence it seems is derived our popular festival called Harvest-home.

DECHALES (CLAUD-FRANCIS-MILLIET), an excellent mathematician, mechanist, and astronomer, was born at Chambery, the capital of Savoy, in 1611. He chiefly excelled in a just knowledge of the mathematical and mechanical sciences: nor that he was bent upon new discoveries, or happy in making them; as his talent rather lay in explaining those sciences with ease and accuracy; which perhaps rendered him equally useful and deserving of esteem. Indeed it was generally allowed that he made the best use of the productions of other men, and that he drew the several parts of the mathematical sciences together with great judgment and perspicuity. His probity was not inferior to his learning; and these two qualities made him generally admired and beloved at Paris, where

for four years together he read public mathematical lectures in the college of Clermont.—From hence he removed to Marseilles, where he taught the art of navigation and the practical mathematical sciences.—He afterwards became professor of mathematics in the University of Turin, where he died March 28, 1678, at 67 years of age.

Among other works which do honour to his memory, are, 1. An edition of Euclid's Elements; in which he has omitted the less important propositions, and explained the uses of those he has retained.—2. A Discourse on Fortification; and another on Navigation.—3. These performances, with some others, were collected in 3 volumes folio, under the title of *Mundus Mathematicus*, being indeed a complete course of mathematics. And the same was afterward much enlarged, and published at Lyons, 1690, in 4 large volumes, folio.

DECIMALS, any thing proceeding by tens; as Decimal arithmetic, Decimal fractions, Decimal scales, &c.

DECIMAL Arithmetic, in a general sense, may be considered as the common arithmetical computation in use, in which the decimal scale of numbers is used, or in which the places of the figures change their value in a ten-fold proportion, being 10 times as much for every place more towards the left hand, or 10 times less for every place removed towards the right hand; the places being supposed indefinitely continued, both to the right and left. In this sense, the word includes both the arithmetic of integers, and decimal fractions. In a more restrained sense, however, it means only

DECIMAL Fractions, which are fractions whose denominator is always a 1 with some number of ciphers annexed, on the number of which depend the value of the fraction, but the numerator may be any number whatever; as $\frac{1}{10}$, $\frac{1}{100}$, $\frac{1}{1000}$, &c.

As the denominator of a decimal is always one of the numbers 10, 100, 1000, &c, the inconvenience of writing these denominators down may be avoided, by placing a proper distinction before the figures of the numerator only, to distinguish them from integers, for the value of each place of figures will be known in decimals, as well as in integers, by their distance from the 1st or unit's place of integers, having similar names at equal distances, as appears by the following scale of places, both in decimals and integers:

&c	8	8	8	8	8	8	8	.	8	8	8	8	8	8	&c
	millions								tenths						
		thousandths							hundredths						
			thousandths						thousandths						
				ten thousandths					ten thousandths						
					hundred thousandths					hundred thousandths					
						thousandths					thousandths				
							hundredths					hundredths			
								thousandths					thousandths		
									hundred thousandths					hundred thousandths	
										millionths					millionths

The mark of distinction for decimals, called the separatrix, has been various at different times, according to the fancy of different authors; sometimes a semiparenthesis, or a semicrotchet, or a perpendicular bar, or the same with a line drawn under the figures, or simply this line itself, &c.; but it is usual now to write either a comma or a full point near the bottom of the figures, in which I follow the practice of Sir I. Newton; a method which prevents the separatrix from being confounded with mere marks of punctuation, and which method is now used by the most correct mathematicians.

In setting down a decimal fraction without its denominator, the numerator must consist of as many places as there are ciphers in the denominator; and if it has not so many figures, the defect must be supplied by prefixing ciphers: thus $\frac{1}{10}$ is .1; and $\frac{1}{100}$ is .14; and $\frac{1}{1000}$ is .014; and $\frac{1}{10000}$ is .0003; &c.

As ciphers on the right-hand side of integers increase their value decimaly, or in a tenfold proportion, as 2, 20, 200, &c.; so, when set on the left-hand of decimal fractions, they decrease the value decimaly, or in a tenfold proportion, as .2, .02, .002, &c. But ciphers set on the other sides of these numbers, make no alteration in their value, neither of increase nor decrease, viz., on the left-hand of integers, or on the right-hand of decimals; so 2, or 02, or 002, &c., are all the same; as are also .2, or .20, or .200, &c.

Decimal fractions may be considered as having been introduced by Regiomontanus, about the year 1464, viz., when he transformed the tables of sines from a sexagesimal to a decimal scale. They were also used by Ramus, in his Arithmetic, written in 1550; and before his time by our countrymen Buckley and Recorde. But it was Stevinus, who first wrote an express treatise on decimals, viz., about the year 1582, in *La Practique d'Arithmetique*; since which time, this has commonly made a part in most treatises on arithmetic.

To reduce any *Vulgar fraction*, or parts of any thing, as suppose $\frac{3}{8}$, to a decimal fraction of the same value; add ciphers at pleasure to the numerator, and divide by the denominator: thus,

$$8) 3 \cdot 00$$

$$\cdot 375 = \frac{3}{8};$$

and therefore .375 or $\frac{375}{1000}$ is a decimal of the same value with the proposed vulgar fraction $\frac{3}{8}$.

Some vulgar fractions can never be reduced into decimals without defect; as $\frac{1}{3}$, which by division is .33333 &c infinitely. Such numbers are very properly called circulating decimals, and repetends, because of the continual return of the same figures. See REPETENDS and CIRCULATES.

The common arithmetical operations are performed the same way in decimals, as they are in integers; regard being had only to the particular notation, to distinguish the fractional from the integral part of a sum. Thus, in Addition and Subtraction of decimals, all figures of the same place or denomination are set directly under each other, the separatrix, or decimal points, forming a straight column. The operation of addition, or subtraction, is then performed the same as in integers. In Multiplication of decimals set down the numbers, and multiply them as in integers; and point off from the product as many places for decimals as there are decimals in both factors; prefixing ciphers if necessary. In Division, set down the numbers and divide also as in integers; making as many decimals in the quotient, as those in the dividend exceed those in the divisor. Examples are numerous and common in most books of arithmetic.

DECIMAL Scales, are any scales divided decimaly, or by tens.

DECLINATION, in Astronomy, is the distance of the sun, star, planet, &c., from the equinoctial, either northward or southward; being the same with latitude in geography, or distance from the equator.

Declination is either real or apparent, according as the real or apparent place of the point or object is considered.

The declination of any point s is an arch of the meridian SE , contained between the given point and the equinoctial $E\Omega$. The declination of a star &c, is found by knowing or observing the latitude of the place, i. e. the height of the pole, and then the meridian altitude of the star, &c; hence the difference between the co-latitude and the altitude of the star &c, is the declination, viz., the difference between \sin the co-latitude, and \sin the altitude, is \cos the declination. For example, Tycho found at Uranibourg the meridian altitude of Cauda Leonis, viz., $\sin = 50^{\circ} 59' 00''$ the co-latitude is $- - -$ $HE = 34^{\circ} 5' 45''$ remains the declin. north $- - -$ $ES = 16^{\circ} 53' 15''$

To find the Sun's Declination at any time; having given his place in the ecliptic; the rule is, as radius is to the sine of the sun's longitude, so is the sine of the greatest declination, or obliquity of the ecliptic, to his present declination sought.

In constructing tables of declination of the sun, planets, and stars, regard should be had to refraction, aberration, nutation, and parallax.

By comparing ancient observations with the modern, it appears that the declination of the fixed stars is variable; and that differently in different stars; for in some it increases, and in others decreases, and that in different quantities.

Circles of Declination, are great circles of the sphere passing through the poles of the world, on which the declination is measured; and consequently are the same as meridians in geography.

Parallax of Declination, is an arch of the circle of declination, by which the parallax in altitude increases or diminishes the declination of a star.

Parallels of Declination, are lesser circles parallel to the equinoctial. The tropic of Cancer is a parallel of declination at $23^{\circ} 28'$ distance from the equinoctial northward; and the tropic of Capricorn is the parallel of declination as far distant southward.

Refraction of the Declination, an arch of the circle of declination, by which the declination of a star is increased or diminished by means of the refraction.

Declination of the Compass, or Needle, is its deviation from the true meridian. See VARIATION.

Declination of a Vertical Plane, or Wall, in Dialling, is an arch of the horizon, comprehended either between the plane and the prime vertical; when it is counted from the east or west; or between the plane and the meridian, if it be reckoned from the north or south.

Declinator, or Declinatory, an instrument in dialling, by which the declination, inclination, and relevation of planes are determined.

Decliners, or Declining Dials, are those which cut obliquely, either the plane of the prime vertical, or the plane of the horizon.

The use of declining vertical dials is very frequent; because the erect walls of houses, on which dials are commonly drawn, mostly decline from the cardinal points. But incliners and recliners are very rare.

Declivity, a sloping or oblique descent.

Decrement, Equal, of Life. See COMPLEMENT of Life.

Decrments are the small parts by which a variable and decreasing quantity becomes less and less. The indefinitely small decrements are proportional to the fluxions,

which in this case are negative. See FLUXIONS: also INCREMENTS.

Decuple, a term of relation or proportion in arithmetic, implying a tenfold change or scale of variation, or one thing 10 times as much as another.

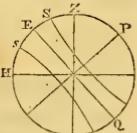

Decussation, a term in Geometry and Optics, signifying the crossing of any two lines or rays &c: or the action itself of crossing.—The rays of light decussate in the crystalline, before they reach the retina.—Many of the lines of the 3d order decussate themselves. See Newton's Enumeratio, &c.

Dee (John), a famous mathematician and astrologer, was born at London 1527. In 1542 he was sent to St. John's college, Cambridge. After five years close application to study, chiefly in the mathematical and astronomical sciences, he went over to Holland, to visit some mathematicians on the Continent; whence, after a year's absence, he returned to Cambridge, and was there elected one of the Fellows of Trinity-college, then first erected by King Henry the 8th. In 1548 he left England a second time, his stay at home being rendered uneasy to him, by the suspicions that were entertained of his being a conjurer, arising chiefly from his application to astronomy, and from some of his mechanical inventions.

He now visited the university of Louvain; where he was much caressed, and visited by several persons of high rank. After two years he went into France, and read lectures, in the college of Rheims, on Euclid's Elements. In 1551, he returned to England, and was introduced to King Edward, who assigned him a pension of 100 crowns, which he afterward relinquished for the rectory of Upton-on-Severn. But soon after the accession of Queen Mary, holding some correspondence with her sister Elizabeth, he was accused of practising against the queen's life by enchantment: on which account he suffered a tedious confinement, and was several times examined; till, in the year 1555, he obtained his liberty by an order of council.

When Queen Elizabeth ascended the throne, Dee was consulted concerning a propitious day for the coronation: on which occasion he was introduced to the queen, who made him great promises, which were but ill performed. In 1564, he made another voyage to the continent, to present a book which he had dedicated to the Emperor Maximilian. He returned to England the same year; but in 1571 we find him in Lorrain; where, being dangerously ill, the queen sent over two physicians to his relief. Having once more returned to his native country, he settled at Mortlake in Surrey, where he continued his studies with much ardour, and collected a great library of printed books and manuscripts, with a number of instruments; most of which were afterwards destroyed by the mob, as belonging to one who dealt with the devil.

In 1578, the queen being much indisposed, Mr. Dee was sent abroad to consult with German physicians and philosophers (astrologers no doubt) on the occasion; though some have said she employed him as a spy; probably he acted in a double capacity. We next find him again in England, where he was soon after employed in a more rational service. The queen, desirous to be informed concerning her title to those countries which had been discovered by Englishmen, ordered Dee to consult the ancient records, and to furnish her with proper geographical descriptions. Accordingly, in a short time, he presented to the queen at Richmond, two large rolls, in which the discovered countries were geographically described and

historically illustrated. His next employment was the reformation of the calendar, on which subject he wrote a rational and learned treatise, preserved in the Ashmolean library at Oxford.

Hitherto the extravagancies of our eccentrical philosopher seem to have been tempered with a tolerable proportion of reason and science; but henceforward he is to be considered as a mere necromancer and credulous alchymist. In the year 1581 he became acquainted with one Edward Kelly, by whose assistance he performed divers incantations, and maintained a frequent imaginary intercourse with spirits and angels; one of whom made him a present of a black speculum (a polished piece of cannel-coal), in which these appeared to him as often as he had occasion for them, answering his questions, &c. Hence Butler says,

"Kelly did all his feats upon

The devil's looking-glass, a stone."

In 1583 they became acquainted with a certain Polish nobleman, then in England, named Albert Laski, a person equally addicted to the same ridiculous pursuits: he was so charmed with Dee and Kelly, that he persuaded them to accompany him to his native country; by whose means they were introduced to Rodolph king of Bohemia; who, though a credulous man, was soon disgusted with their nonsense. They were afterwards introduced to the king of Poland, but with no better success. Soon after this they were entertained at the castle of a rich Bohemian nobleman, where they lived for some time in great affluence; owing, as they asserted, to their art of transmutation by means of a certain powder in the possession of Kelly.

Dee, now quarrelling with his companion, quitted Bohemia, and returned to England, where he was once more graciously received by the queen; who, in 1595, made him warden of Manchester college, in which town he resided several years. In 1604 he returned to his house at Mortlake, where he died in 1608, at 81 years of age; leaving a large family and many works behind him.

The books that were printed and published by Dee, are, 1. *Propudumata Aphoristica, &c.* in 1558, in 12mo.—2. *Monas Hieroglyphica ad Regem Romanorum Maximilianum:* 1564.—3. *Epistola ad eximium ducis Urbini mathematicum, Fredericum Commandinum, prefixa libello Machometi Bagdadini de Superficierum Divisionibus &c;* 1570.—4. *The British Monarchy, otherwise called, The Petty Navy Royal;* 1576.—5. *Preface Mathematica to the English Euclid, published by Henry Billingsley,* 1570: certainly a very curious and elaborate composition, and where he says, many more arts are wholly invented by name, definition, property, and use, than either the Grecian or Roman mathematicians have left to our knowledge.—6. Divers and many annotations and inventions dispersed and added after the 10th book of English Euclid; 1570.—7. *Epistola prefixa Ephemeribus Joannis Feldi à 1557, cui rationem declaraverat Ephemerides scribendi;*—8. *Parallatica Commentationis Paxeosque Nucleus quidam;* 1573.

This catalogue of Dee's printed and published works is to be found in his *Compendious Rehearsal &c.* as well as in his letter to App. Whitgift: and from the same places might be transcribed more than 40 titles of books unpublished, which he had written.

DEFENCE, in Sieges, is used for any thing that serves to preserve or screen the soldiers, or the place. So the parapets, flanks, casemates, ravelins, and out-works, that

cover the place, are called the defences, or covers of the place: and when the cannon have beaten down or ruined these works, so that the men cannot fight under cover, the defences of the place are said to be demolished.

Line of DEFENCE, is that which flanks a bastion, being drawn from the flank opposite to it. The line of defence should not exceed a musket shot, i. e. 120 fathoms: indeed Melder allows 130, Scheiter 140, Vauban and Pagan 150.

Line of DEFENCE, greater; or fendant, is a line drawn from the point of the bastion to the concourse of the opposite flank and curtain.

Line of DEFENCE, lesser, or rasant, or flanquant, is the face of the bastion continued to the curtain.

DEFERENT, or DEFERENS, in the Ancient Astronomy, an imaginary circle, which, as it were, carries about the body of a planet, and is the same with the eccentric; being invented to account for the eccentricity, perige, and apoge of the planets.

DEFICIENT Hyperbola, is a curve having only one asymptote, though two hyperbolic legs running out infinitely by the side of the asymptote, but contrary ways. See *CURVE*.

This name was given to the curves by Newton, in his *Enumeratio Linearum tertii Ordinis*. There are 6 different species of them, which have no diameters, expressed by the equation $\frac{xy}{y} + ey = -ax^3 + bx^2 + cx + d$, the term ax^3 being negative. When the equation $ax^3 = bx^2 + cx^2 + dx + \frac{1}{4}ee$ has all its roots real and unequal, the curve has an oval joined to it. When the two middle roots are equal, the oval joins to the legs, which then cut one another in shape of a noose. When three roots are equal, the nodus is changed into a very acute cusp or point. When, of three roots with the same sign, the two greatest are equal, the oval vanishes into a point. When any two roots are imaginary, there is only a pure serpentine hyperbola, without any oval, decussation, cusp, or conjugate point; and when the terms b and d are wanting, it is of the 6th species.

There are also 7 different species of these curves, having each one diameter, expressed by the above equation when the term ey is wanting: according to the various conditions of the roots of the equation $ax^3 = bx^2 + cx + d$, as to their reality, equality, their having the same signs, or two of them being imaginary.

DEFICIENT Numbers, are those whose aliquot parts added together, make a sum less than the whole number: as 8, whose parts 1, 2, 4, make only 7; or the number 16, whose parts 1, 2, 4, 8 make only 15.

DEFILE, in Fortification, a narrow line or passage through which troops can pass only in file, making a small front, so that the enemy may easily stop their march, and charge them with the more advantage, as the front and rear cannot come to the relief of one another.

DEFINITION, an enumeration, or specification of the chief simple ideas of which a compound idea consists, in order to ascertain or explain its nature and character. Definitions are of two kinds; the one nominal, or of the name; the other real, or of the thing.

Nominal DEFINITION, is an enumeration of such known characters as are sufficient for distinguishing any proposed thing from others; as is that of a square, when it is said that it is a quadrilateral, equilateral, rectangular figure.

Real DEFINITION, a distinct notion, explaining the genesis of a thing: that is, how the thing is made or done:

as is this definition of a circle, viz, that it is a figure described by the motion of a right line about a fixed point.

DEFLECTION, the turning any thing aside from its former course, by some adventitious or external cause.—The word is often applied to the tendency of a ship from her true course, by reason of currents, &c, which turn her out of her right way.

DEFLECTION of the Rays of Light, is a property which Dr. Hooke observed in 1675. He found it different both from reflection and refraction; and that it was made perpendicularly towards the surface of the opaque body. This is the same property which Newton calls inflection: and by others it is called diffraction.

DEGREE, in Algebra, is used in speaking of equations, when they are said to be of such a degree, according to the highest power of the unknown quantity. If the index of that power be 2, the equation is of the 2d degree; if 3, it is of the 3d degree, and so on.

DEGREE, in Geometry or Trigonometry, is the 360th part of the circumference of any circle; for every circle is considered as divided into 360 parts, called degrees; which are marked by a small ° near the top of the figure; thus 45° is 45 degrees. The degree is subdivided into 60 smaller parts, called minutes, meaning first minutes; the minute into 60 others called seconds; the second into 60 thirds; &c. Thus $45^\circ 12' 20''$ must be read 45 degrees, 12 minutes, 20 seconds.

The magnitude or quantity of angles is reckoned in degrees; for because of the uniform curvature of a circle in all its parts, equal angles at the centre are subtended by equal arcs, and by similar arcs in peripheries of different diameters; and an angle is said to be of so many degrees, as are contained in the arc of any circle comprehended between the legs of the angle, and having the angular point for its centre. Thus we say an angle of 90° , or of $45^\circ 24'$, or of $12^\circ 20' 30''$. It is also usual to say, such a star is so many degrees above the horizon, or declines so many degrees from the equator; or such a town is situate in so many degrees of latitude or longitude.—A sign of the ecliptic, or zodiac, contains 30 degrees.

The division of the circle into 360 degrees is usually ascribed to the Egyptians, probably from the circle of the sun's annual course, or according to their number of days in the year, allotting a degree to each day. It is a convenient number too, as admitting of a great many aliquot parts, as 2, 3, 4, 5, 6, 8, 9, &c. The sexagesimal subdivision, however, has often been condemned as improper, by many eminent mathematicians, as Stevinus, Oughtred, Wallis, Briggs, Gellibrand, Newton, &c; who advise a decimal division instead of it, or else that of centesims; as the degree into 100 parts, and each of these into 100 parts again, and so on. Stevinus even holds, that this division of the circle which he contends for, obtained in the wise age, in *seculo sapienti*. Stev. Cosmog. lib. 1, def. 6. And several large tables of sines &c have been constructed according to that plan, and published, by Briggs, Newton, and others. And I myself have carried the idea still much farther, in a memoir published in the Philos. Trans. of 1783, containing a proposal for a new division of the quadrant, viz, into equal decimal parts of the radius; by which means the degrees or divisions of the arch would be the real lengths of the arcs, in terms of the radius: and I have since computed those lengths of the arcs, with their sines, &c, to a great extent and accuracy. See my new Tracts, vol. 2, pa. 122. The French mathematicians have

lately calculated their new Trigonometrical Tables on an entire decimal division of arcs; viz, first dividing the quadrant into 100 degrees, and these into decimals of degrees. But it appears by Mr. Crabtree's letter to Mr. Gascoigne (inventor of the micrometer) Aug. 7, 1640, that both these gentlemen, as well as their mutual friend Mr. Horrox, had projected those tables by a complete decimal division, the whole arch being divided into 100,000,000 parts. See Philos. Trans. vol. 27, pa. 230; or my Abridg. vol. 5, pa. 631.

DEGREE of Latitude, is the space or distance on the meridian through which an observer must move, to vary his latitude by one degree, or to increase or diminish the distance of a star from the zenith by one degree; and which, on the supposition of the perfect sphericity of the earth, is the 360th part of the meridian.

The quantity of a degree of a meridian, or other great circle, on the surface of the earth, is variously determined by different observers; and the methods made use of are also various.

Eratosthenes, 250 years before Christ, first determined the measure of a degree of the meridian, between Alexandria and Syene on the borders of Ethiopia, by measuring the distance between those places, and comparing it with the difference of a star's zenith distances in the same places; and found it to be 694½ stadia.

Posidonius, in the time of Pompey the Great, by means of the different altitudes of a star near the horizon, taken at different places under the same meridian, compared in like manner with the distance between those places, determined the length of a degree to be only 600 stadia.

Ptolemy fixes the degree at 68½ Arabic miles, counting 7½ stadia to a mile. The Arabs themselves, who made a computation of the diameter of the earth, by measuring the distance of two places under the same meridian, in the plains of Sennar, by order of Almamon, make it only 56 miles. Kepler determined the diameter of the earth by the distance of two mountains, and makes a degree 13 German miles; but his method is far from being accurate. Snell, by seeking the diameter of the earth from the distance between two parallels of the equator, finds the quantity of a degree, by one method 57064 Paris toises, or 342384 feet; by another meth. 57057 - toises, or 342342 feet. The mean between which two numbers, M. Picard found by mensuration, in 1669, from Amiens to Malvoisin, to be the most accurate, and he makes the quantity of a degree 57060 toises, or 342360 feet. However, M. Cassini, at the king's command, in the year 1700, repeated the same labour, and measuring the space of $6^\circ 18'$, from the observatory at Paris, along the meridian, to the city of Collioure in Roussillon, that the greatness of the interval might diminish the error, found the length of the degree equal to 57292 toises, or 343742 Paris feet, amounting to 365184 English feet.

And this account nearly agrees with that of our countryman Norwood, who, about the year 1635, measured the distance between London and York, and found that distance to be 905751 English feet; the difference of latitude being $29^\circ 28'$; hence, he determined the quantity of one degree at 367196 English feet, or 57300 Paris toises, or 69 miles, 288 yards. See Newt. Princ. Phil. prop. 19; and Hist. Acad. Scien. anno 1790, pa. 153.

M. Cassini, the son, completed the work of measuring the whole arc of the meridian through France, in 1718;

to perform which, he divided the meridian of France into two arcs, which he measured separately.

The one from Paris to Collioure gave him 57097 toises; the other from Paris to Dunkirk - - - 56960; and the whole arc from Dunkirk to Collioure 57060, the same as Picard's.

M. Muschenbroek, in 1700, resolved to correct the errors of Snell, and found by particular observations, that the degree between Alcmaer and Bergen-op-zoom contained 57033 toises.

Messieurs Maupertuis, Clairaut, Camus, Monnier, and Outhier of France, were sent on a northern expedition, and began their operations, assisted by M. Celsus, an eminent astronomer of Sweden, in Swedish Lapland, in July 1736, and finished them by the end of May following. They obtained the measure of that degree, whose middle point was in lat. $66^{\circ} 20' 10''$ north, and found it 57439 toises, when reduced to the level of the sea. About the same time another company of philosophers was sent to South America, viz. Messieurs Godin, Bouguer, and Condamine of France, with whom were Don Jorge Juan, and Don Antonio de Ulloa of Spain. They left Europe in 1735, and began their operations in the province of Quito in Peru, about October 1736, and finished them, after many interruptions, about 8 years after. The Spanish gentlemen published a separate account, and assigned for the measure of a degree of the meridian at the equator 56768 toises. M. Bouguer makes it 56753 toises, when reduced to the level of the sea; and M. Condamine states it at 56749 toises.

M. Lacaillé, being at the Cape of Good Hope in 1752, found the length of a degree of the meridian in lat. $33^{\circ} 18' 30''$ south, to be 57037 toises; but in 1755, father Bosovich found the length of a degree in lat. 43° north to be 56972 toises, as measured between Rome and Rimini in Italy. In the year 1740, Messrs. Cassini and Lacaillé again examined the former measures in France, and, after making all the necessary corrections, found the measure of a degree, whose middle point is in lat. $49^{\circ} 22'$ north, to be 57074 toises; and in the lat. of 45° , it was 57050 toises.

In 1764, F. Beccaria completed the measurement of a portion of the meridian near Turin; from which it is deduced that the length of a degree, whose middle lat. is $44^{\circ} 44'$ north, is 57024 Paris toises.

At Vienna, 3 degrees of the meridian were measured; and the medium, for the latitude of $47^{\circ} 40'$ north may be taken at 57091 Paris toises. See an account of this measurement, by father Joseph Liesganig, in the Philos. Trans. 1768, pa. 15.

In the same vol. there is also an account of the measurement of a part of the meridian in Maryland and Pennsylvania, North America, 1766, by Messrs. Mason and Dixon; from which it appears that the length of a degree whose middle point is $39^{\circ} 12'$ north, is 363763 English feet, or 56904 $\frac{1}{2}$ Paris toises.

From the trigonometrical survey of England and Wales, completed in 1802, under the direction of Lieut.-col. Mudge, four degrees of the meridian were measured; the mean latitude of which was $51^{\circ} 29' 54\frac{1}{2}''$, and the mean length of a degree 691457 English miles.

The remeasurement of a degree in Lapland, as a correction of the former French operations, was performed during the years 1801, 1802, and 1803, by the Swedish mathematicians, Overboom, Swanberg, Holquist, and

Polander; and from the account of their operations, published by M. Swanberg, the length of the degree in lat. $66^{\circ} 20' 10''$, is 692689 English miles. From a comparison of this result, with those from the measurements taken in Peru, the East Indies, and France, M. Swanberg deduces a mean of $69^{\circ} \frac{1}{2}$ for the ellipticity, and 396326 miles for the equatorial radius of the earth.

In 1803 Colonel Lambton also measured a degree in the East Indies, north lat. $12^{\circ} 33'$, which he made 687445 miles. But the latest measurement of this nature is that of the meridian, comprised between Barcelona in Spain and the Balearic isles. This meridian had before been measured by Messrs. Mechain and Delambre, from Dunkirk to Barcelona, and the two French mathematicians Biot and Arago, with the Spanish commissioners Chaix and Rodriguez, were appointed to continue the line to the small island of Formentera. The lat. of this island was found to be $38^{\circ} 40'$, that of Dunkirk $51^{\circ} 5'$; and the distance between the two places 137443873 metres: hence a degree is equal to 68769 English miles; and its middle latitude $44^{\circ} 52\frac{1}{4}'$.

The following table, collected from the preceding accounts, shows at one view the several lengths of a degree, as measured in various parts of the earth, with the line of its measurement, the country in which it was measured, the names of the measurers, and the lat. of the middle point:

Date.	Latitude.	Length, miles.	Measurers.	Countries.
1525	$49^{\circ} 20' N.$	68763	M. Furnel	France.
1620	52° 4 N.	6691	Snell	Holland
1685	$53^{\circ} 15' N.$	69545	Norwood	England
1644		75066	Riecioli	Italy
1669	49° 22' N.	68945	Picard	France
1718	49° 22' N.	69119	Cassini	France
1737	$66^{\circ} 20' N.$	69403	Maupertuis	Lapland
1740	49° 22' N.	69121	{ Cassini &	France.
1740	45° 0 N.	69092	J. Lacaillé	France
1744	0° 0	68751	Juan &c.	Peru
1744	0° 0	68732	Bouguer	Peru
1744	0° 0	68713	Condamine	Peru
1752	$33^{\circ} 18' S.$	69076	Lacaillé	Cape of G.H.
1755	43° 0 N.	68998	Bosovich	Italy
1764	44° 44' N.	69061	Beccaria	Italy
1766	47° 40' N.	69142	Leisganig	Germany
1768	39° 12' N.	68893	Mason & D.	America
1802	51° 30' N.	69146	Mudge	England
1803	66° 20' N.	69292	Swanberg	Lapland
1803	12° 32' N.	68743	Lambton	India
1808	44° 52' N.	68769	Biot and Ar.	France

The difference between Swanberg's and Maupertuis' result, taken in the same place, was owing it seems to the latter having omitted to allow for the difference of level in the measurement base, above the sea.—On the whole, it seems the length of the middle degree, or 45° of lat. may be accounted $69\frac{1}{2}$ miles.

The method of obtaining the length of a degree of the terrestrial meridian, is to measure a certain distance upon it by a series of triangles, whose angles may be found by observation, connected with a base, the length of which may be taken by an actual survey, or otherwise; and to observe the different altitudes of some star at the two extremities of that distance, which gives the difference of latitude between them: then, by proportion, as this difference of latitude is to one degree, so is the measured length

to the length of one degree of the meridian sought; which method was first practised by Eratosthenes, in Egypt. See EARTH, GEOGRAPHY, and the beginning of this article; also Dr. T. Young's Philos. vol. 2, for a list of writings on this subject.

It appears that the meridional degrees of an ellipsoid increase from the equator to the pole very nearly as the square of the sine of the latitude. And the length of the degree at any point, is to the length at the equator, accurately as the cube of a line drawn parallel to the plumb line, from a point in the axis equidistant from the centre with the equator, and terminating in a point of the plane of the equator, to the cube of the line drawn from this point to the true pole. Or, if e be the ellipticity, and s the sine of the latitude, the length of the degree will vary as $(1 + (2e + ee)xx)^{\frac{3}{2}}$.

DEGREE of Longitude, is the space between two meridians that make an angle of 1° with each other at the poles; the quantity or length of which is variable, according to the latitude, being every where as the cosine of the latitude; viz, as the cosine of one lat. is to the cosine of another, so is the length of a degree in the former lat. to that in the latter; and from this theorem is computed the following Table of the length of a degree of long. in different latitudes, supposing the earth to be a perfect sphere.

Degr. lat.	English miles.	Degr. lat.	English miles.	Degr. lat.	English miles.
0	69·07	31	59·13	61	33·45

28	60·93	59	35·54	89	1·21
29	60·35	60	34·50	90	0·00
30	59·75				

Note, This table is computed on the supposition that the length of the degrees of the equator are equal to those of the meridian at the medium latitude of 45° , which length is $69\frac{1}{3}$ English miles nearly.

But, taking the earth as a spheroid, the degree of longitude may be found, in any given latitude l , by saying,

VOL. I.

1st. As the equatorial diameter is to the polar, so is tang. $(90^{\circ} - l)$, to tang. of an angle a : then $2d$. As radius, to sine of a , so is the length of a degree of the equator to the length of a degree on the parallel of the given latitude.

DEINCLINERS, or DEINCLINING Dials, are such as both decline and incline, or recline, at the same time. Suppose, for instance, a plane cutting the prime vertical circle at an angle of 30° , and the horizontal plane at an angle of 24° , the latitude of the place being 52° ; a dial drawn on this plane, is called a deincliner.

DELIACAL Problem, a celebrated problem among the ancients, concerning the duplication of the cube.

DELISLE. See LISLE (DE).

DELPHINUS, the *Dolphin*, a constellation of the northern hemisphere; whose stars, in Ptolemy's catalogue, are 10; in Tycho's the same; in Hevelius's 14; and in Flamsteed's 18.

DEMETRIUS, a Cynic philosopher, and disciple of Apollonius Thyanicus, in the age of Caligula. That emperor wishing to gain the philosopher to his interest by a large present, he refused it with indignation, saying, "If Caligula wishes to bribe me, let him send the his crown." Vespasian was displeased with his insolence, and banished him to an island. The cynic derided the punishment, and bitterly inveighed against the emperor. Demetrius lived to a very great age. And Seneca observes, that "nature had brought him forth to show mankind that an exalted genius can live securely without being corrupted by the vice of the surrounding world."

DEMI-Bastion, in Fortification, that which has only one face and one flank.

DEMI-Cannon, and DEMI-Culverin, names of certain species of cannon, now no longer used.

DEMI-Cross, an instrument used by the Dutch to take the altitude of the sun or a star at sea; instead of which we use the cross-staff, or fore-staff.

DEMI-Gorge, is half the gorge or entrance into the bastion; not taken directly from angle to angle, where the bastion joins the curtain, but from the angle of the flank to the centre of the bastion; or the angle the two curtains would make, were they thus protracted to meet in the bastion.

DEMI-Lane, or Half-moon, an outwork consisting of two faces, and two little flanks. It is often built before the angle of a bastion, and sometimes also before the curtain; though now it is very seldom used.

DEMOCRITUS, one of the greatest philosophers of antiquity, was born at Abdera, a town of Thrace, about the 80th olympiad, or about 400 years before Christ. His father, says Valerius Maximus, was able to entertain the army of Xerxes; and Diogenes Laertius adds, upon the testimony of Herodotus, that the king, in requital, presented him with some Magi and Chaldeans. From these, it seems, Democritus received the first part of his education; and from them, while yet a boy, he learned theology and astronomy. He next applied to Leucippus, from whom he learned the system of atoms and a vacuum. His father dying, he and his two brothers divided his effects. Democritus made choice of that part which consisted in money, as being, though the least share, the most convenient for travelling; and it is said that his portion amounted to more than 100 talents, which is near 20 thousand pounds sterling. His extraordinary inclination for knowledge and the sciences, induced him to travel into all parts of the world where he might find learned men.

He went to visit the priests of Egypt, from whom he learned geometry: he consulted the Chaldean and Persian philosophers; and it is said that he penetrated even into India and Ethiopia, to confer with the Gymnosophists. In these travels he wasted his substance; after which, at his return he was obliged for some time to be maintained by his brother. Settling himself at Abdera, he there governed in the most absolute manner, by virtue of his consummate wisdom. The magistrates of that city made him a present of 500 talents, and erected statues to him, even in his lifetime; but being naturally more inclined to contemplation than delighted with public honours and employments, he withdrew into solitude and retirement.

Democritus always laughed at human life, as a continued farce, which made the people think he was mad; on which they sent for Hippocrates to cure him: but that celebrated physician having discoursed with the philosopher, told the people that he had a great veneration for Democritus; and that, in his opinion, those who esteemed themselves the most healthy, were the most distempered. It is said, though with little probability, that Democritus put out his own eyes, that he might meditate more profoundly on philosophical subjects. He died, according to Diogenes Laertius, in the 361st year before the Christian era, at 109 years of age. He was the author of many books, which are lost; from which Epicurus borrowed his philosophy.

DEMOIVRE (ABRAHAM), a celebrated mathematician, of French original, but who spent most of his life in England. He was born at Vitri in Champagne, 1667. On account of the revocation of the edict of Nantes, in 1685, he determined, with many others, to take shelter in England; where he perfected his mathematical studies, the foundation of which he had laid in his own country. A mediocrity of fortune obliged him to employ his talent in this way in giving lessons, and reading public lectures, for his better support: in the latter part of his life too, he chiefly subsisted by giving answers to questions in chances, play, annuities, &c, and it is said most of these responses were delivered at a coffee-house in St. Martin's-lane, where he spent most of his time. The Principia Mathematica of Newton, which chance is said to have thrown in his way, soon convinced Demoivre how little he had advanced in the science he professed. This induced him to redouble his application; which was attended by a considerable degree of success; and he soon became connected with, and celebrated among, the first-rate mathematicians. His eminence and abilities in this line, opened him an entrance into the Royal Society of London, and into the Academies of Berlin and Paris. By the former his merit was so well known and esteemed, that they judged him a fit person to decide the famous contest between Newton and Leibnitz, concerning the invention of Fluxions.

Demoivre died at London Nov. 1754, at 87 years of age. The Philosophical Transactions of London contain several of his papers, and all of them interesting, viz. in the volumes 19, 20, 22, 23, 25, 27, 29, 30, 32, 40, 41, 43.

He published also some very respectable works, viz,

1. *Miscellanea Analytica, de Seribus et Quadraturis &c;* 1730, in 4to. But perhaps he has been more generally known by his

2. *Doctrine of Chances; or, Method of Calculating the Probabilities of Events at Play.* This work was first printed, 1718, in 4to, and dedicated to Sir Isaac Newton:

it was reprinted in 1738, with great alterations and improvements; and a third edition was afterwards printed.

3. *Annuities on Lives*; first printed 1724, in 8vo.—In 1742 the ingenious Thomas Simpson (then only 33 years of age) published his *Doctrine of Annuities and Reversions*; in which he paid some handsome compliments to our author. Notwithstanding which, Demoivre presently brought out a second edition of his *Annuities*, in the preface to which he passed some harsh reflections upon Simpson. To these the latter gave a handsome and effectual answer, 1743, in *An Appendix*, containing some *Remarks* on a late book on the same subject, with answers to some personal and malignant misrepresentations, in the preface thereof. At the end of this answer, Mr. Simpson concludes, "Lastly, I appeal to all mankind, whether, in his treatment of me, he has not discovered an air of self-sufficiency, ill-nature and inveteracy, unbecoming a gentleman." Here it would seem the controversy dropped: Mr. Demoivre published the 3d edition of his book in 1750, without any farther notice of Simpson, but omitted the offensive reflections that had been in the preface.

DEMONSTRATION, a certain or convincing proof of some proposition: such as the demonstrations of the propositions in Euclid's Elements. The method of demonstrating in mathematics, is the same with that of drawing conclusions from principles in logic. Indeed, the demonstrations of mathematicians are no other than series of enthymemes; every thing is concluded by force of syllogism, only omitting the premises, which either occur to their own accord, or are recollect'd by means of quotations.

DENDROMETER, an instrument lately invented by Messrs. Duncombe and Whittle; so called, from its use in measuring trees.

DENE^B, an Arabic term, signifying tail; used by astronomers as a name to some of the fixed stars, but especially for the bright star in the Lion's tail.

DENOMINATOR, of a *Fraction*, is the number or quantity placed below the line, which shows the whole integer, or into how many parts it is supposed to be divided by the fraction; as that which gives denomination or name to the parts of the fraction. Thus, in the fraction $\frac{5}{12}$ (five-twelfths) the number 12 is the denominator, and shows that the integer is here divided into 12 parts, or that it consists of 12 of those parts of which the numerator contains 5. Also b is the denominator of the fraction $\frac{a}{b}$.

DENOMINATOR of a *Ratio*, is the quotient arising from the division of the antecedent by the consequent. Thus, 6 is the denominator of the ratio 30 to 5, because 30 divided by 5 gives 6. It is otherwise called the exponent of the ratio.

DENSITY, that property of bodies by which they contain a certain quantity of matter, under a certain bulk or magnitude. Accordingly, a body that contains more matter than another, under the same bulk, is said to be denser than the other, and that in proportion to the quantity of matter; or if the quantity of matter be the same, but under a less bulk, it is said to be denser, and so much the more so as the bulk is less. So that, in general, the density is directly proportional to the mass or quantity of matter, and reciprocally or inversely proportional to the bulk or magnitude under which it is contained.

The quantities of matter in bodies, or at least the proportions of them, are known by their gravity or weight; every equal particle of matter being endowed with an equal

gravity, it is inferred that equal masses or quantities of matter have an equal weight or gravity; and unequal masses have proportionally unequal weights. So that, when body, or mass, or quantity of matter is spoken of, we are to understand their weight or gravity.

From the foregoing general proportion of the density of bodies, viz, that it is as the mass directly, and as the bulk inversely, may be inferred the proportion of the masses, or of the magnitudes; viz, that the mass or quantity of matter is in the compound ratio of the bulk and density; and that the bulk or magnitude is as the mass directly, and the density inversely. Hence, if b , b be two bodies, or masses, or weights;

and d , d their respective densities;

also m , m their magnitudes, or bulks:

Then the theorems above are thus expressed,

viz, $d \propto \frac{b}{m}$, and $b \propto dm$, and $m \propto \frac{b}{d}$;

or $d : d :: b : \frac{b}{m}$, and $b : b :: dm : dm$, &c;

or $\frac{d}{d} = \frac{bm}{bm}$, and $\frac{b}{b} = \frac{dm}{dm}$, and $\frac{m}{m} = \frac{bd}{bd}$.

No body is absolutely or perfectly dense; or no space is perfectly full of matter, so as to have no vacuity or interstices; on the contrary, it is the opinion of Newton, that even the densest bodies, as gold, &c, contain but a small portion of matter, and a very great portion of vacuity; or that it contains a great deal more of pores or empty space, than of real substance.

It has been observed above, that the relative density of bodies may be known by their weight or gravity; and hence the most general way of knowing those densities, is by actually weighing an equal bulk or magnitude of the bodies, whether solid or fluid; if solid, by shaping them to the same figure and dimensions; if fluid, by filling the same vessel with them, and weighing it.

For fluids, there are also other methods of finding their density: as 1st, by making an equilibrium between them in tubes that communicate; for, the diameters of the tubes being equal, and the weights or quantities of matter also equal, the densities will be inversely as the altitudes of the liquids in them, that is inversely as the bulk.

2dly, The densities of fluids are also compared together by immersing a solid in them; for if the solid be lighter than the liquids, the part immersed by its own weight will be inversely as the density of the fluid; or if it be heavier, and sink in the liquids, by weighing it in them; then the weights lost by the body will be directly proportional to the densities of the fluids.

DENSITY of the Air, is a property that has much engaged the attention of the later philosophers, since the discovery of the Torricellian experiment, and the air-pump. By means of the barometer it is demonstrated, that the air is of the same density at all places at the same distance from the level of the sea, provided the temperature, or degree of heat, be the same. Also the density of the air always increases in proportion to the compression, or the compressing forces. And hence the lower parts of the atmosphere are always denser than the upper: yet the density of the lower air is not exactly proportional to the weight of the atmosphere, by reason of heat and cold, which make considerable alterations as to rarity and density; so that the barometer measures the elasticity of the air, rather than its density. If the height of the barometer be considered as the measure both of the density and elas-

ticity of the air, when the thermometer is at 31° , and b be any other height of the barometer, when the thermometer is at t degrees; then in this case, b is the measure of the elasticity, and $\frac{466-t}{435}b$ is the measure of the density of the air.

DENSITY of the Planets. In homogeneous, unequal, spherical bodies, the gravities on their surfaces are as their diameters when the densities are equal, or the gravities are as the densities when the bulks are equal; therefore, in spheres of unequal magnitude and density, the gravity is in the compound ratio of the diameters and densities, or the densities are as the gravities divided by the diameters. Knowing therefore the diameters of the planets by observation and comparison, and the gravities at their surface by means of the revolution of the satellites, the relation of their densities becomes known. And as I have found the mean density of the earth to be nearly 5 times that of water (my new Tracts, vol. 2, Tract 27); hence the densities of the planets, with respect to water, become known, and are as below:

	Densities.
Water	1
The Sun	$1\frac{1}{2}$
Mercury	$10\frac{1}{2}$
Venus	$6\frac{1}{2}$
The Earth	5
Mars	$3\frac{1}{2}$
The Moon	$3\frac{1}{2}$
Jupiter	$1\frac{1}{2}$
Saturn	$0\frac{1}{2}$
Herschel	$1\frac{1}{2}$

As it is not likely that any of these bodies are homogeneous, the densities here determined are supposed to be the mean densities, or such as the bodies would have if they were homogeneous, and of the same mass of matter and magnitude.

DENTICLES, or DENTILS, are ornaments in a cornice, cut after the manner of teeth. These are mostly affected in the Ionic and Corinthian orders; and of late also in the Doric. The square member on which they are cut, is called the Denticle.

DEPARTURE, in Navigation, is the easting or westing of a ship, with regard to the meridian she departed or sailed from. Or, it is the difference in longitude, either east or west, between the present meridian the ship is under, and that where the last reckoning or observation was made. This departure, anywhere but under the equator, must be accounted according to the number of miles in a degree proper to the parallel the ship is in.—The Departure, in Plane and Mercator's Sailing, is always represented by the base of a right-angled plane triangle, where the course is the angle opposite to it, and the distance sailed is the hypotenuse, the perpendicular or other leg being the difference of latitude. And then the theorem for finding it, is always this: As radius is to the sine of the course, so is the distance sailed, to the departure.

DEPHLOGISTICATED Air. See OXYGEN.

DEPRESSION of Equations, in Algebra, is the reducing them to lower degrees; as, from biquadratics to cubics, or from cubics to quadratics. It is only in some certain cases that this can be performed; as 1st, When there can be found a compound binomial measure, or divisor of the given equation, of which one term is the unknown letter or quantity; then the other part of the

divisor is one root of the equation, and the whole equation being divided by the divisor, the quotient is the equation depressed one degree lower. So, for example, if the equation be $x^3 - 6x^2 + 11x - 6 = 0$; and it be discovered that $x = 2$, then $x - 2$ will be the divisor, by which dividing the given equation, it is depressed to the quadratic $x^2 - 4x + 3 = 0$, the two roots of which are 1 and 3. So that all the three roots of the given cubic equation, are, 1, 2, 3.—Or, if the given equation were $x^3 - bx^2 - a^2x + a^2b = 0$, and it be found that b is one root of it, or that $x - b$ is a divisor; then making the division, the quotient, $x^2 - a^2 = 0$, is the depressed equation, the two roots of which are $x = +a$ or $-a$: so that the three roots are $+a, -a, +b$.

2d. If an equation contain equal roots, these may be found, and the equation reduced as many degrees or dimensions lower, as there are equal roots. For if the original equation $x^n - cx^{n-1} + bx^{n-2} - \dots - c = 0$, have m equal roots, then $nx^{n-1} - (n-1)ax^{n-2} + (n-2)bx^{n-3} - \dots - c = 0$, has $m-1$ of those roots, as may be readily shown. Hence, when there are two equal roots, the two equations have a common measure of this form $(x - r)^{m-1}$, (r being one of the roots,) which may be obtained in the usual way, and thus m roots of the original equation may be known. Then divide this equation by $(x - r)^m$, and the resulting equation, of $n - m$ dimensions, contains the other roots.

Thus, let the cubic $x^3 - ax^2 + bx - c = 0$, have two equal roots; then $3x^2 - 2ax + b = 0$ has one of them; and the two equations have a common measure, which is a simple equation: the quantities $3x^3 - 3ax^2 + 3bx - 3c$, and $3x^2 - 2ax + b$, have also the same common measure, which being found, we have $\frac{1}{3}(6b - 2a^2)x - \frac{1}{3}(bc - ab)$ for a divisor of the equation $x^3 - ax^2 + bx - c = 0$; this divisor being also put = 0, gives $x = \frac{bc - ab}{6b - 2a^2}$. Thus two roots of the equation are discovered; and, since a is the sum of all the roots, the 3d root is the difference between a and the sum of the two equal roots.

If two roots of the equation be of the form $+a, -a$, differing only in their signs; change the signs of the roots, and the resulting equation has two roots, $-a, +a$; thus we have two equations with a common measure, $x^2 - a^2$, which may be found, and the equation depressed, as in the former case.

To be more particular:—There being only certain cases in which this depression can be effected, viz, 1st. When there is any known relation between two or more of the roots; and, 2dly. When the equation is reciprocal, that is, when each of the terms of the equation, which are equally distant from the first and last terms, have equal co-efficients; under which form the relation of each pair of roots becomes known.

With regard to the first, it seldom happens that any known relation subsists between the roots of an equation if the roots themselves are unknown, except it be that of equality, we shall therefore only consider it under this point of view; namely, when two or more of the roots are equal, having either like, or contrary signs; referring the reader, for further information on this subject, to Lacroix' Complément des Éléments d'Algèbre, art. 38; and to Waring's Meditations Algéb. cap. 3.

1. When an equation has two equal roots, with contrary signs, it may be depressed two degrees.

Let there be given the equation

$x^5 - px^4 - qx^3 + rx^2 + sx - t = 0$, which we are supposed to know contains two equal roots with contrary signs.

This being the case, it is evident that we shall not alter the value of the equation by writing $-x$ instead of x ; which gives us, $-x^5 - px^4 + qx^3 + rx^2 - sx - t = 0$,

$$\text{Or } x^5 + px^4 - qx^3 - rx^2 + sx + t = 0,$$

Also $x^5 - px^4 - qx^3 + rx^2 + sx - t = 0$, being the given equation. Now these two equations have a common measure, which, being obtained by the usual method, will be found to involve the 2d power of x ; whence the equal roots may be determined, and the whole equation being divided by this common measure, will give us the depressed equation. We may also discover the value of the equal roots in equations, not exceeding the 5th degree by the addition and subtraction of the above equations, for by the former we obtain

$$2x^5 - 2qx^3 + 2sx = 0, \text{ or } x^1 - qx^2 + s = 0, \text{ and by the latter } 2px^4 + 2rx^2 - 2t = 0, \text{ or } x^4 - \frac{r}{p}x^2 + \frac{t}{p} = 0.$$

Therefore $-qx^2 + s = -\frac{r}{p}x^2 + \frac{t}{p}$; whence we have

$$x = \pm \sqrt{\frac{t - ps}{r - pq}}, \text{ which are the two equal roots, and consequently } x^2 - \frac{t - ps}{r - pq} = 0 \text{ is a divisor of the original equation, which may thus be depressed to a cube, containing the other three roots.}$$

Suppose, for example, our given equation had been $x^5 - 3x^4 - 17x^3 + 27x^2 + 52x - 60 = 0$.

$$\text{Then } p = 3, q = 17, r = 27, s = 52, t = 60;$$

And $x = \pm \sqrt{\frac{t - ps}{r - pq}} = \pm 2$; the whole equation therefore being divided by $x^2 - 4 = 0$, gives $x^3 - 3x^2 - 3x + 15 = 0$, which is a cubic equation, in which are contained the other three roots.

And exactly in the same manner may any other equation of this kind be depressed two degrees.

2. When two or more of the roots are equal, having like signs, the equation may be depressed as many degrees as there are equal roots.

Let $x^3 - px^2 + qx - r = 0$, be an equation having two equal roots with like signs, and let a and b represent those roots; then we shall have the two following identical equations: $a^3 - pa^2 + qa - r = 0$, $b^3 - pb^2 + qb - r = 0$, whence we draw $(a^3 - b^3) - p(a^2 - b^2) + q(a - b) = 0$, and dividing this by $a - b$, we obtain $(a^2 + ab + b^2) - p(a + b) + q = 0$; or, since $a = b$, $3a^2 - 2pa + q = 0$; which has a common divisor with the original equation, and writing x again instead of a , this divisor will be readily obtained by the rule for finding the greatest common measure of two quantities, which in the present case is

$$\frac{6q - 2p^2}{3} x - \frac{9r - pq}{3} = 0, \text{ whence } x = \frac{9r - pq}{6q - 2p^2}.$$

Thus, two of the roots are discovered, and consequently the equation may be depressed two degrees as before, by dividing the whole of it by $(x - \frac{9r - pq}{6q - 2p^2})$.

But in the present case, as the original equation was only of three dimensions, and p being equal to the sum of all its roots, from the nature of equations; we have

$$x = p - \frac{9r - pq}{3q - p^2}, \text{ for the third root.}$$

Suppose, for example, the proposed equation had been $x^3 - 4x^2 + 5x - 2 = 0$: here $p = 4$, $q = 5$, $r = 2$; and one of the equal roots is $\frac{9r - pq}{3q - p^2} = 1$; the third root therefore is $p - 2 = 4 - 2 = 2$, and the three roots sought are 1, 1, and 2.

We should have obtained exactly the same result, by considering that an equation having two equal roots, is necessarily divisible by a factor of the form $x^2 - 2ax + a^2$, where a represents one of the equal roots; and if three of the roots are equal, the equation has a divisor of the form $x^3 - 3ax^2 + 3a^2x - a^3$, and so on, for any number of equal roots: that is, an equation may always be depressed as many degrees as there are equal roots contained in it.

3 Reciprocal equations may be depressed to others of half the original dimension, when the highest power of the unknown quantity is even. Let the given reciprocal equation be $x^4 + px^3 + qx^2 + px + 1 = 0$; and dividing this by x^4 , we obtain $1 + p\frac{1}{x} + q\frac{1}{x^2} + p\frac{1}{x^3} + \frac{1}{x^4} = 0$; whence it is evident, that if a be one of the roots of this equation, $\frac{1}{a}$ is also a root; and in the same manner if b be one of its roots, then $\frac{1}{b}$ is the other: and so on, for equations of higher dimensions.

We may therefore consider the given equation as generated from the product $(x + a) \cdot (x + \frac{1}{a}) \cdot (x + b) \cdot (x + \frac{1}{b})$, or from the quadratic factors

$$(a^2 + x(a + \frac{1}{a}) + 1) \cdot (x^2 + x(b + \frac{1}{b}) + 1),$$

or making $a + \frac{1}{a} = m$, and $b + \frac{1}{b} = n$, the above becomes $(x^2 + mx + 1) \cdot (x^2 + nx + 1) =$

$x^4 + (m+n)x^3 + (2+mn)x^2 + (m+n)x + 1 = 0$, and equating the coefficients we have $m + n = p$, $mn = q = 2$, whence $m - n = \sqrt{(p^2 - 4q + 8)}$, $m = \frac{1}{2}p + \frac{1}{2}\sqrt{(p^2 - 4q + 8)}$, $n = \frac{1}{2}p - \frac{1}{2}\sqrt{(p^2 - 4q + 8)}$.

Thus m and n are found by a quadratic, that is, by an equation of half the original dimension. As to a and b , those are now readily determined: for since $a + \frac{1}{a} = m$,

we have $a = \frac{1}{2}m \pm \sqrt{(\frac{1}{4}m^2 - 1)}$, and since $b + \frac{1}{b} = n$, we derive $b = \frac{1}{2}n \pm \sqrt{(\frac{1}{4}n^2 - 1)}$. Suppose, for example, our equation was $x^4 + 5\frac{1}{2}x^3 + 10\frac{1}{2}x^2 + 5\frac{1}{2}x + 1 = 0$.

Here $p = 5\frac{1}{2}$, and $q = 10\frac{1}{2}$,

whence $m = \frac{1}{2}p + \frac{1}{2}\sqrt{(p^2 - 4q + 8)} = 3\frac{1}{2}$,

and $n = \frac{1}{2}p - \frac{1}{2}\sqrt{(p^2 - 4q + 8)} = 2\frac{1}{2}$;

therefore $a = \frac{1}{2}m \pm \sqrt{(\frac{1}{4}m^2 - 1)} = 3$ or $\frac{3}{2}$,

and $b = \frac{1}{2}n \pm \sqrt{(\frac{1}{4}n^2 - 1)} = 2$ or $\frac{1}{2}$;

consequently, the four roots are $3, \frac{3}{2}, 2$, and $\frac{1}{2}$.

And in the same manner may any other equation of this kind be depressed to half its original dimension.

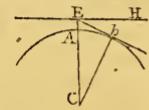

When the highest power of the unknown quantity is uneven, then $+1$ or -1 is a root of the equation, as is evident from inspection; it may therefore be divided by $x \pm 1 = 0$; which will depress it one degree, still leaving it reciprocal, after which, it may be reduced to half that dimension, by the method above explained. Let $x^6 + px^4 + qx^3 + gx^2 + px + 1 = 0$, be the given equation, then $+1$ is one of its roots; dividing it therefore by $x - 1 = 0$, we obtain $x^5 + (p+1)x^4 + (p+q+1)x^3 + (p+1)x^2 + (p+1)x + 1 = 0$, which is still reciprocal, and may therefore be depressed to a quadratic by the method already employed. M. Gauss, in his *Disquisitiones Arithmeticae*, which is mentioned under the article *Algebra*, has shown that every equation of two terms, of which the exponent is a prime number, may be rationally decomposed into other equations, the degrees of which are indicated by the prime factors of the given exponent *minus 1*, by means of which he has been able to

express the side of a regular 17-sided polygon inscribed in a circle, by a quadratic equation; which was before thought impossible. This curious piece of analysis has been translated into French under the title of *Recherches Arithmetiques*, and is highly deserving of an attentive perusal.

DEPRESSION of the Pole. So many degrees &c as you sail or travel from the pole towards the equator, so many is it said you depress the pole, because it becomes so much lower, or nearer the horizon.

DEPRESSION of a Star, or of the Sun, is its distance below the horizon; and is measured by an arc of a vertical circle, intercepted between the horizon and the place of the star.

DEPRESSION of the Visible Horizon, or Dip of the Horizon, denotes its sinking or dipping below the true horizontal plane, by the observer's eye being raised above the surface of the sea; in consequence of which, the observed altitude of an object is by so much too great. Thus, the eye being at E , the height AE above the surface of the earth, whose centre is C ; then EH is the real horizon, and EH the visible one, below the former by the angle HEH' , by reason of the elevation AE of the eye.

To compute the Depression or Dip of the Horizon.

In the right-angled triangle CEH , are given CH the earth's radius $= 2100000$ feet, and the hypotenuse CE = the radius increased by the height AE of the eye; to find the angle c which is = the angle CEH , or the depression sought; viz, as $CH : CE :: \text{radius} : \secant \angle c$,

or, as $CE : CH :: \text{radius} : \cosine \angle c$.

By either of these theorems are computed the numbers in the following table, which shows the depression or dip of the horizon of the sea, for different heights of the eye, from 1 foot to 100 feet.

Height of the eye	Dip of the horizon	Height of the eye	Dip of the horizon	Height of the eye	Dip of the horizon
feet	" "	feet	" "	feet	" "
1	0 57	13	3 26	26	4 52

DEPTH, the opposite of Height, and one of the dimensions of bodies, or of space. See **HEIGHT**, **ALTITUDE**, **ELEVATION**, &c.

DERHAM (Dr. WILLIAM), an eminent English philosopher and divine, was born at Stowton, near Worcester, 1657, and educated in Trinity-college, Oxford. In 1682, he was presented to the vicarage of Wargrave in Berkshire; and, in 1689, to the valuable rectory of Up-

minster in Essex; which, lying at a convenient distance from London, afforded him an opportunity of conversing and corresponding with the principal literary men of the nation. Applying himself there with great eagerness to the pursuit of his studies in natural and experimental philosophy, he soon became a distinguished and useful member of the Royal Society, whose Philosophical Transactions contain a great variety of curious and valuable pieces, the fruits of his laudable industry, in all or most of the volumes, from the 20th to the 39th, both inclusive; the principal of which are :

1. Experiments on Pendulums in vacuo.
2. Of an instrument for finding the Meridian.
3. Experim. and Observat. on the Motion of Sound.
4. On the Migration of Birds.
5. On the Spots in the Sun, from 1703 to 1711.
6. Observations on the Northern Lights, Oct. 8, 1726, and Oct. 13, 1728.
7. Tables of the Eclipses of Jupiter's Satellites.
8. Differnce of Time in the meridian of diff. places.
9. Of the meteor called Ignis Fatuus.
10. The History of the Death Watch.
11. Meteorological Diaries for several years.

In his younger days he published his Artificial Clock-maker, a very useful little work, which has gone through several editions. In 1711, 1712, 1714, he preached those sermons at Boyle's lecture, which he afterwards digested under the well-known titles of Physico-Theology and Astro-Theology, or Demonstrations of the being and attributes of God, from his works of creation, and a survey of the heavens.

In 1716 he was made a canon of Windsor, being at that time chaplain to the prince of Wales; and in 1730 he received, from the university of Oxford, the degree of Doctor of Divinity. He revised the Miscellanea Curiosa, in 3 vols. 8vo, containing many curious papers of Dr. Halley and several other ingenious philosophers. To him also the world is indebted for the publication of the Philosophical Experiments of the late eminent Dr. Hooke, and other ingenious men of his time; as well as notes and illustrations of several other works.

Dr. Derham was very well skilled in medical as well as in physical knowledge; and was constantly a physician to the bodies as well as the souls of his parishioners. This great and good man, after spending his life in the most agreeable and improving study of nature, and the diligent and pious discharge of his duty, died at Upminster in 1735, at 78 years of age.

DERIVATIONS (*Calcul des*), a new species of calculation, which may be considered as an important discovery in analysis.—This method was first published by M. Arbogast, professor of mathematics at Strasburgh, in 1800, and has since been translated into French; but the first idea of this method appears to have been formed by the celebrated Dr. Waring, and is alluded to by him in the conclusion of his *Meditationes Analyticae*.

As the name of this method imports, it depends on the principle of deriving one term of a series from the foregoing ones; and by means of a peculiar notation, this derivation is found to be very simple and commodious. Here, instead of symbols being made use of to represent quantities, they are employed to represent certain operations that are performed upon them. Thus let $r(a + x)$ be any function of the binomial $a + x$, this function may be expanded into a series proceeding according to the powers

of x , as $r(a + x) = a + bx + \frac{c}{1 \cdot 2} x^2 + \frac{d}{1 \cdot 2 \cdot 3} x^3 &c$; whence it will be seen that $a = ra$, that b is derived from a , or from ra ; c from b ; d from c , &c, by the same law: therefore if we conceive the manner in which we derive b from a , in the same manner we derive c from b , d from c , &c. Then representing by δ the operation to be performed on ra , to produce b , we shall have $b = \delta ra$, $c = \delta^2 ra$, $d = \delta^3 ra$, &c; so that the above series is expressed thus, $r(a + x) = ra + \frac{\delta ra}{1} x + \frac{\delta^2 ra}{1 \cdot 2} x^2 + \frac{\delta^3 ra}{1 \cdot 2 \cdot 3} x^3 &c$.

For farther particulars relating to this important branch of analysis, the reader is referred to the work of M. Arbogast, entitled *Des Calcul des Derivations*; also to Mr. Woodhouse's *Analytical Calculations*.

DESAGULIERS (JOHN THEOPHILUS), an eminent experimental philosopher, was the son of the Rev. John Desaguliers, a French Protestant refugee, and born at Rochelle in 1683. His father brought him to England an infant; and having taught him the classics himself, he sent him at a proper age to Christ-church college, Oxford; where in 1702 he succeeded Dr. Keil in reading lectures on experimental philosophy at Hart-Hall. In 1712 he married, and settled in London, when he first of any introduced the reading of lectures in experimental philosophy into the metropolis, which he continued during the rest of his life with the greatest applause, having several times the honour of reading his lectures before the king and royal family. In 1714 he was elected F.R.S., and proved a very useful member, as appears from the great number of his papers that are printed in their Philos. Trans. on the subjects of optics, mechanics, and meteorology. The magnificent Duke of Chandos made Dr. Desaguliers his chaplain, and presented him to the living of Edgware, near his seat at Cannons; and he became afterwards chaplain to Frederick prince of Wales; but in the latter part of his life, he removed to lodgings over the Great Piazza in Covent Garden, where he carried on his lectures with great success till the time of his death in 1749, at 66 years of age.

He was a member of several foreign academies, and corresponding member of the Royal Academy of Sciences at Paris; from which academy he obtained the prize, proposed by them for the best account of electricity. He communicated a multitude of curious and valuable papers to the Royal Society, from the year 1714 to 1743, or from vol. 29 to vol. 42.

Besides those numerous communications, he published a valuable Course of Experimental Philosophy, 1734, in 2 large vols. 4to.; and gave an edition of David Gregory's Elements of Catoptrics and Dioptrics, with an Appendix on Reflecting Telescopes, 8vo, 1735. This appendix contains some Original Letters that passed between Sir Isaac Newton and Mr. James Gregory, relating to those telescopes. He gave also an English translation of Gravestrand's Natural Philosophy, in 2 large volumes in 4to, 1747. A son of Dr. D. was long an officer in the corps of Royal Artillery, was a great favourite with his majesty, and died at an advanced age, colonel of one of the then four regiments or battalions of that corps, about the year 1775.

Recollecting all these favourable circumstances; that Dr. D. was much noticed by the learned and the great, and possessed two church livings, we cannot account for

the circumstance of his dying in obscurity and indigence: yet such it would seem was the case; at least, if we may credit the poet Cawthorne, who, speaking of the neglected Desagulliers, asks,

" How he who taught two gracious kings to view
All Boyle ennobled, and all Bacon knew,
Died in a cell, without a friend to save,
Without a guinea, and without a grave."

DESCARTES. See CARTES.

DESCENDING, a going or moving from above, downwards.—There are ascending and descending stars, and ascending and descending degrees, &c.

DESCENDING Latitude, is the latitude of a planet in its return from the nodes to the equator.

DESCENSION, in Astronomy, is either Right, or Oblique.

Right DESCENSION, is a point, or arch, of the equator, which descends with a star, or sign, below the horizon, in a right sphere; and

Oblique DESCENSION, is a point, or arch, of the equator, which descends at the same time with a star, or sign, below the horizon, in an oblique sphere.

Descensions, both right and oblique, are counted from the first point of Aries, or the vernal intersection, according to the order of the signs, i.e. from west to east. And, as they are unequal, when it happens that they answer to equal arcs of the ecliptic, as for example to the 12 signs of the zodiac, it follows, that sometimes a greater part of the equator rises or descends with a sign, in which case the sign is said to ascend or descend rightly: and sometimes again, a less part of the equator rises or sets with the same sign, in which case it is said to ascend or descend obliquely. See ASCENSION.

Refraction of the DESCENSION. See REFRACTION.

DESCENSIONAL Difference, is the difference between the right and oblique descension of the same star, or point of the heavens.

DESCENT, or Fall, in mechanics, &c, is the motion, or tendency, of a body towards the centre of the earth, either directly or obliquely. Bodies may be considered either as freely descending, as in a vacuum, or as resisted by some external force, as an opposing body, or a fluid medium, &c. 1st, If the body b descend freely, and perpendicularly, by the force of gravity; then the motive force urging it downwards, is equal to its whole weight b ; and the quantity of matter being b also, the accelerative force will be $\frac{b}{b}$ or 1.

2dly, If the body b , descending, be opposed by some mechanical power, suppose a wedge or inclined plane, that is, instead of pursuing the perpendicular line of gravity, it is made to descend in a sloping direction down the inclined plane: then if the natural sine of the angle the plane makes with the horizon be s , the motive force urging the body down the plane will be bs ; and therefore the accelerative force is $\frac{bs}{b}$ or s ; which is less than in the former case in the proportion of s to 1.

3dly, A body immersed in a fluid, loses as much of its weight, as is equal to the weight of a like bulk of the fluid; and when descending, it loses the same, besides the obstruction arising from the cohesion of the parts of the medium, and the opposing force of the particles struck, which last produces a greater or less resistance, according

to the velocity of the motion. But, the weight of the body being b , and that of a like bulk of the fluid medium m , the motive force urging the body to descend, is only $b - m$; that is, the body only falls, by the excess of its weight above that of an equal bulk of the fluid.—Hence, the power that sustains a body in a medium, is equal to the excess of the absolute weight of the body above an equal bulk of the medium. Thus, a piece of copper weighing $47\frac{1}{2}$ lb, loses $5\frac{1}{2}$ lb, of its weight in water: and therefore a power of 42 lb, will sustain it in the water.

4thly, If two bodies have the same specific gravity, the less the bulk of the descending body is, the more of its gravity does it lose, and the slower does it descend, in the same medium. For, though the proportion of the specific gravity of the body to that of the fluid be still the same, whether the bulk be greater or less, yet the smaller the body, the more the surface is, in proportion to the mass; and the more the surface, the more the resistance of the parts of the fluid, in proportion.

5thly, If the specific gravities of two bodies be different; that which has the greatest specific gravity will descend with greater velocity in the air, or resisting medium, than the other body. Thus, a ball of lead descends swifter than wood or cork, because it loses less of its weight, though in a vacuum they both fall equally swift.

The cause of this descent, or tendency downwards, has been greatly controverted. Two opposite hypotheses have been advanced; the one, that it proceeds from an internal principle, and the other from an external one: the first is maintained by the Peripatetics, Epicureans, and the Newtonians; and the latter by the Cartesians and Gassendists. See also ACCELERATION.

Laws of DESCENT of Bodies.

1st, Heavy bodies, in an unresisting medium, fall with an uniformly accelerated motion. For, it is the nature of all constant and uniform forces, such as that of gravity at the same distance from the centre of the earth, to generate or produce equal additions of velocity in equal times. So that, if in one second of time there be produced a certain velocity, in 2 seconds there will be double that velocity, in 3 seconds triple, and so on, the degree or quantity of velocity being always proportional to the length of the time.

2d, The space descended by an uniform gravity, in any time, is just the half of the space that might be uniformly described in the same time by the last acquired velocity at the end of that time, if uniformly continued. For, as the velocity increases uniformly in an arithmetic progression, the whole space descended by the variable velocity, will be equal to the space that would be described with the middle velocity uniformly continued for the same time; and this again will be only half the space that would be described with the last velocity, also uniformly continued for the same time, because the last velocity is double of the middle velocity, being produced in a double time.

3d, The spaces descended by an uniform gravity, in different times, are proportional to the squares of the times, or to the squares of the velocities. For the whole space descended in any time, consists of the sums of all the particular spaces, or velocities, which are in arithmetical progression; but the sum of such an arithmetical progression, beginning at 0, and having the last term and the number of terms the same quantity, is equal to half

the square of the last term, or of the number of terms; therefore the whole sums are as the squares of the times, or of the velocities.

This theory of the descents by gravity was first discovered and taught by Galileo, who afterwards confirmed the same by experiments; which have often been repeated in various ways by many other persons since his time, as Grimaldi, Riccioli, Huygens, Newton, and many others, all confirming the same laws.

The experiments of Grimaldi and Riccioli were made by dropping a number of balls, of half a pound weight, from the tops of several towers, and measuring the times of falling by a pendulum. Riccioli, Almag. Nov. tom. 1, lib. 2, cap. 21, prop. 4. An abstract of their experiments is exhibited here below:

Vibrations of the pendulum	The time	Space at the end of the time	Space descended each time
5	" "	Rom. feet	Rom. feet
10	0 50	10	10
15	1 40	40	30
20	2 30	90	50
25	3 20	160	70
	4 10	250	90
6	1 0	15	15
12	2 0	60	45
18	3 0	135	75
24	4 0	240	105

The space descended by a heavy body in any given time, being determined by experiment, is sufficient, in connexion with the preceding theorems, for determining every inquiry concerning the times, velocities, and spaces descended, depending on a uniform force of gravity. From many accurate experiments made in England, it has been found that a heavy body descends freely through 16 feet 1 inch, or $16\frac{1}{2}$ feet, in the first second of time; and consequently, by theorem 2, the velocity gained at the end of 1 second, is $32\frac{1}{2}$ feet per second. Hence, by the same, and theorem 3, the velocity gained in any other time t is $32\frac{1}{2}t$, and the space descended is $16\frac{1}{2}t^2$. So that, if v denote the velocity, and s the space due to the time t , and there be put $g = 16\frac{1}{2}$; then is

$$v = 2gt = 2\sqrt{gs} = \frac{2s}{t}.$$

$$s = gt^2 = \frac{v^2}{4g} = \frac{1}{2}tv.$$

$$t = \frac{v}{2g} = \sqrt{\frac{s}{g}} = \frac{2s}{v}.$$

The experiments with pendulums give also the same space for the descent of a heavy body in a second of time. Thus, in the latitude of London, it is found by experiment, that the length of a pendulum vibrating seconds is nearly $39\frac{1}{2}$ inches; and it being known that the time of one vibration of any pendulum, is to the time in which a heavy body will fall through half the length of the pendulum, as the circumference of a circle is to its diameter, therefore as $3\cdot1416 : 1 : 1 : \frac{1}{3\cdot1416}$ which is the time of descending through $19\frac{9}{16}$ inches, or half the length of the pendulum; and the spaces being as the squares of the times, we have as $\frac{1}{3\cdot1416} : 1^2 : : 19\frac{9}{16} : 19\frac{9}{16} \times 3\cdot1416^2 = 193$ inches, or 16 feet 1 inch, which therefore is the

space a heavy body will descend through in one second; the very same as before.

4th, For any other constant force, instead of the perpendicular free descent by gravity, find by experiment, or otherwise, the space descended in one second by that force, and substitute that instead of $16\frac{1}{2}$ for the value of g in these formulæ: or, if the proportion of the force to the force of gravity be known, let the value of g be altered in the same proportion, and the same formulæ will still hold good. So, if the descent be on an inclined plane, making, for instance, an angle of 30° with the horizon; then, the force of descent upon the plane being always as the sine of the angle it makes with the horizon, which in the present case will be as the sine of 30° , that is, as $\frac{1}{2}$ the radius; therefore the value of g will be but half the former, $8\frac{1}{2}\pi$, in all the foregoing formulæ.

Or, if one body descending perpendicularly draw another after it, by means of a cord sliding over a pulley; then it will be, as the sum of the two bodies is to the descending body, so is $16\frac{1}{2}$ to the value of g in this case; which value of it being used in the said formulæ, they will still hold good. And in like manner for any other constant forces whatever.

5th, The time of the oblique descent down any chord of a circle, drawn either from the uppermost point or lowermost point of the circle, is equal to the perpendicular descent through the diameter of the circle.

6th, The descent, or vibration, through all arcs of the same cycloid are equal, whether great or small.

7th, But the descent, or vibration, through unequal arcs of a circle, are unequal; the times being greater in the greater arcs, and less in the less.

8th, For Descents by Forces that are variable, see FORCES, &c. See also INCLINED PLANE, CYCLOID, PENDULUM, &c.

Line of Swiftest Descent, is that which a body, falling by the action of gravity, describes in the shortest time possible, from one given point to another. And this line, it is proved by philosophers, is the arc of a cycloid, when the one point is not perpendicularly over the other. See CYCLOID.

DESCRIBENT, a term in Geometry, signifying a line or superficies, by the motion of which a superficies or solid is described.

DETENTS, in a clock, are those stops which, by being lifted up or let down, lock and unlock the clock in striking.

DETENT-Wheel, or **HOOP-WHEEL**, that wheel in a clock which has a hoop almost round it, in which there is a vacancy, where the clock locks.

DETERMINATE Number. See NUMBER.

DETERMINATE Problem, is that which has but one solution, or a certain limited number of solutions; in contradistinction to an indeterminate problem, which admits of infinite solutions. Such, for instance, is the problem, To form an isosceles triangle on a given line, so that each of the angles at the base shall be double of that at the vertex; which has only one solution: or this, To find an isosceles triangle whose area and perimeter are given; which admits of two solutions. But if it had only been required to describe an isosceles triangle on a given base, then it is evident that an infinite number of such triangles might have been constructed, and therefore, the problem would have been an indeterminate one.

DETERMINATE Section, the name of a Tract, or General Problem, written by the ancient geometrician Apollonius. None of this work has come down to us, excepting some extracts, and an account of it by Pappus, in the preface to the 7th book of his Mathematical Collections. He there says that the general problem was, "To cut an infinite right line in one point so, that, of the segments contained between the point of section sought, and given points in the said line, either the square on one of them, or the rectangle contained by two of them, may have a given ratio, either to the rectangle contained by one of them and given line, or to the rectangle contained by two of them."

Pappus further informs us, that this Tract of Apollonius was divided into two books; that the first book contained 6 problems, and the second 3; that the 6 problems of the first book contained 16 epitragmas, or cases, respecting the dispositions of the points; and the second book 9. Further, that of the epitragmas of the 6 problems of the first book, 4 were maxima, and one a minimum: that the maxima are at the 2d epitragma of the 2d problem, at the 3d of the 4th, the 3d of the 5th, and the 3d of the 6th; but that the minimum was at the 3d epitragma of the 3d problem. Also, that the second book contained three determinations; of which the 3d epitragma of the 1st problem, and the 3d of the 2d were minima, and the 3d of the 3d a maximum. Moreover, that the first book had 27 lemmas, and the 2d book 24; and lastly, that both books contained 83 theorems.

From such account of the contents of this Tract, and the lemmas, also given by Pappus, several persons have attempted to restore, or recompose what they thought might be nearly the form of Apollonius's tract, or the subject of each problem, case, determination, &c; among whom are, Snellius, an eminent Dutch mathematician of the 17th century; a translation of whose work was published in English by Mr. John Lawson, in 1772, together with a new restoration of the whole work by his friend Mr. William Wales. A more complete restoration is given in Dr. Simson's posthumous works, in 1776; as also by P. Giannini, at Parma, 1773.

DEVIATION, in Astronomy. See **NUTATION**.

DEVIATION of a falling body from its perpendicular direction. When the notion of the revolution of the earth about its axis was revived by Copernicus, various objections were started against it by the adherents of the old system; and among others, it was asserted that, if the earth did really turn on its own axis, it would have followed as a natural consequence, that a stone or other heavy body, being let fall from an eminence, as the top of a tower, must have struck the earth at a considerable distance from its foot towards the west; for as the motion of the earth was from west to east, they conceived that it must necessarily have passed through a space towards the east, greater or less, according to the height of the tower, or to the time the body was in falling, before the latter reached the ground; and as, from experiments, this was found not to be the case, they considered it as an unanswerable objection to the Copernican system. But as soon as the laws of motion became better known, and the composition of forces was properly understood, it was found that, contrary to the opinions of those objectors, instead of the stone falling considerably to the westward of the tower, it ought to fall a little to the east of it, which is what experiments have since confirmed to be the case.

VOL. I.

And this is what is now generally understood by the deviation of a falling body.

This phenomenon is the natural consequence of the first law of motion, namely, that every body has a tendency to preserve its state, whether it be in motion or at rest. Thus, a bullet let fall from the topmast of a ship, will fall in a direction parallel to the mast, whatever may be the velocity of the vessel, and to those on board it will have the appearance of a perpendicular descent, notwithstanding its real path is that of the curve of a parabola, the same as if it had been projected from a state of rest with a velocity equal to that of the ship.

With respect to a body falling from the top of a tower, the only difference is that, by reason of the revolution of the earth, the higher a body is elevated, the greater will be its velocity, because it describes a greater circle in the same time; therefore the body having previously to its fall acquired a greater velocity, from west to east, than the foot of the tower has, it will naturally be carried a little towards the east. Thus the same circumstance that was considered as an unanswerable objection to the modern system of astronomy, may be now regarded as an additional evidence of its truth.

This fact is confirmed by experiment. M. Guglielmini was the first who drew the attention of philosophers to this subject. On causing bodies to fall from a height of 241 feet, he found a deviation of 8 lines to the east from the vertical. M. Benzenberg, professor of physics and astronomy at Dusseldorf, made 28 experiments with balls well turned and polished, which were dropped from a height of 262 French feet, and which at a medium produced 5 lines of deviation to the east: the theory gives 4 $\frac{1}{2}$ lines. And the last experiments made at Bologna, by Guglielmini, give nearly the same results. Yet so many are the causes of inaccuracy in the experiments, and so small the deviation required by the theory, that we hesitate in laying much stress on the results of these philosophers. Of the truth of the theory, however, there can be no doubt: we may therefore here notice M. Laplace's ultimate theorem. Let h denote the height from which the body falls, g = the space fallen by gravity in the first second, a = the angle of the earth's rotation in the same time, at the rate of $360^\circ \div 0.99727$ in a day, and c = cosine of the latitude of the place, also d = the deviation towards the east: then is the deviation $d = \frac{2}{3}ach\sqrt{\frac{h}{g}}$. (Bulletin des Sciences, N° 75.)—In this theorem, the value of the angle a is $15''0411$, or nearly $15'$; and as a small arc is nearly equal to its sine or tangent, therefore the value of a is the sine of $15''$ to radius 1; that is, $a = .000072725$, the log. of which is 5.8616661 , which will be useful in computing the above theorem.

DEW, a thin light insensible mist, or rain, ascending with a slow motion, and falling while the sun is below the horizon. To us it appears to differ from rain, as less from more. Its origin and matter are doubtless from the vapours and exhalations that rise from the earth and water. See **EXHALATION**. Some define it a vapour liquefied, and let fall in drops. M. Huet, in one of his letters, asserts that dew does not fall, but rises; and others have adopted the same opinion.

M. du Fay made several experiments, first with glasses, then with pieces of cloth stretched horizontally at different heights; and he found that the lower bodies, with their under surfaces, were wetted before those that were placed

higher, or their upper surfaces. And Du Fay and Muschenbroek both found, that different substances, and even different colours, receive the dew differently, and some little or not at all.

From the principles laid down under the article EVAPORATION, the several phenomena of dews are easily accounted for. Such as, for instance, that dews are more copious in the spring, than in the other seasons of the year; there being then a greater stock of vapour in readiness, than at other times, by reason of the small expense of it in the winter's cold and frost. Hence it is too, that Egypt, and some other hot countries, abound with dews throughout all the heats of summer; for the air there being too hot to constipate the vapours in the day-time, they never gather into clouds; and hence they have no rain: but in climates that are excessively hot, the nights are remarkably cold; so that the vapours raised after sun-set, are readily condensed into dews.

It is natural to conclude, from the different substances which are combined with dew, that it must be either salutary or injurious, both to plants and animals.

It is not easy to ascertain the quantity of dew that rises every night, or in the whole year, because of the winds which disperse it, the rains which carry it down, and other inconveniences: but it is known that it rises in greater abundance after rain than after dry weather, and in warm countries than in cold ones. There are some places in which dew is observed only to ascend, and not to fall: and others again in which it is carried upwards in greater plenty than downwards, being dispersed by the winds.

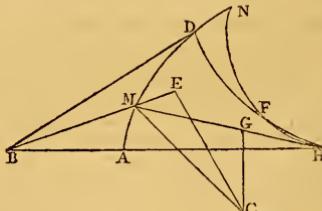

Dr. Hales made some experiments, to determine the quantity of dew that falls in the night; and for this purpose, on the 15th of August, at 7 in the evening, he filled two glazed earthen pans with moist earth; the dimensions of the pans being, 3 inches deep, and 12 inches diameter: and he observes, that the moister the earth, the more dew falls on it in a night; and that more than a double quantity of dew falls on a surface of water, than on an equal surface of moist earth. These pans increased in weight, by the night's dew, 180 grains; and decreased in weight, by the evaporation of the day, 1 oz 282 grs: so that 540 grains more are evaporated from the earth every 24 hours in summer, than the dew that falls in the night; i. e. in 21 days near 26 ounces from a circular area of a foot diameter. Now if 180 grains of dew, falling in one night on such an arca, which is equal to 113 square inches, be equally spread on the surface, its depth will be the 159th part of an inch. He likewise found that the depth of dew in a winter's night was the 90th part of an inch. If therefore we allow 159 nights for the extent of the summer's dew, it will in that time amount to one inch in depth; and reckoning the remaining 206 nights for the extent of the winter's dew, it will produce 2.28 inches depth; and the dew of the whole year will amount to 3.28 inches depth. But the quantity which evaporated in a fair summer's day from the same surface, being 1 oz and 282 grs, gives the 40th part of an inch deep for evaporation, which is 4 times as much as fell at night. Dr. Hales observes, that the evaporation of a winter's day is nearly the same as in a summer's day; the earth's greater moisture in winter compensating for the sun's greater heat in summer. Hales's Vegetable Statics, vol. 1, p. 52 of the 4th edit. See EVAPORATION.

Sigñor Beccaria made several experiments to demonstrate the existence of the electricity that is produced by

dew. He observes in general, that such electricity took place in clear and dry weather, during which no strong wind prevailed; and that it depends on the quantity of the dew, as the electricity of the rain depends on the quantity of the rain. He sometimes found that it began before sun-set; at other times not till 11 o'clock at night. Artificial Electricity, Appendix, letter 3.

DE WIT (JOHN), the famous Dutch pensionary, was born at Dort, in 1625; where he prosecuted his studies so diligently, that at 23 years of age he published Elementa Curvarum Linearum, one of the deepest books in mathematics at that time. After taking his degrees, and travelling, he, in 1650, became pensionary of Dort, and distinguished himself very early in the management of public affairs, which soon after raised him to the rank of pensionary of Holland. After rendering the greatest benefits to his country in many important instances, and serving it in several high capacities, with the greatest ability, diligence, and integrity, by some intrigues of a party, it is said, he and his brother were thrown into prison, from whence they were dragged by the mob, and butchered with the most cruel and savage barbarity.

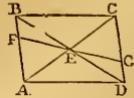

DIACAUSTIC Curve, or the Caustic by Refraction, is a species of caustic curves, the genesis of which is in the following manner. Imagine an infinite number of rays BA, BM, BD, &c, issuing from the same luminous point B, refracted to or from the perpendicular MC, by the given curve AND; and so that CE, the sines of the angles of incidence CME, be always to CG the sines of the refracted angles CMG, in a given ratio; then the curve HFN that touches all the refracted rays AH, MF, DN, &c, is called the Diacaustic, or Caustic by Refraction.

• DIACOUSTICS, or DIAPHONICS, the consideration of the properties of sound refracted in passing through different mediums; that is, out of a denser into a more subtle, or out of a more subtle into a denser medium. See SOUND.

DIAGONAL, is a right line drawn across a figure, from one angle to another; and is sometimes called a diameter. It is used chiefly in quadrilateral figures, viz, in parallelograms and trapeziums.

1. Every diagonal, as AC, divides a parallelogram into two equal parts or triangles ABC, ADC.
2. Two diagonals, AC, BD, drawn in a parallelogram, bisect each other; as in the point E.
3. Any line, as FG, drawn through the middle of the diagonal of a parallelogram, is bisected by it at the point E; and it divides the parallelogram into two equal parts, EFGC and AFGD.
4. The diagonal of a square is incommensurable with its side.

5. The complements about the diagonal of any parallelogram are equal to each other.

6. In any parallelogram, the sum of the squares of the four sides is equal to the sum of the squares of the two diagonals.

7. In any trapezium, the sum of the squares of the four sides is equal to the sum of the squares of the two diagonals, together with 4 times the square of the distance between the middle points of the diagonals.

8. In any trapezium, the sum of the squares of the two diagonals, is double the sum of the squares of two lines bisecting the two pairs of opposite sides.

9. In any quadrilateral inscribed in a circle, the rectangle of the two diagonals is equal to the sum of the two rectangles under the two pairs of opposite sides.

DIAGONAL SCALE. See SCALES.

DIAGRAM, is a scheme for the explanation or demonstration of any figure, or of its properties.

DIAL, or **SUN-DIAL,** an instrument for measuring time by means of the sun's shadow. Or, it is a draught or description of certain lines on the surface of a body, so that the shadow of a style, or ray of the sun through a hole, should touch certain marks at certain hours.

Sun-Dials are doubtless of great antiquity. But the first upon record is, it seems, the dial of Ahaz, who began to reign 400 years before Alexander, and within 12 years of the building of Rome: it is mentioned in Isaiah, chap. 38, ver. 8.

Several of the ancients are spoken of, as the constructors of dials; as Anaximenes Milesius, Thales, &c. Vitruvius mentions one made by the ancient Chaldean historian Berosus, on a reclining plane, almost parallel to the equator. Aristarchus Samius invented the hemispherical dial. And there were at the same time some spherical ones, with a needle for a gnomon. The discus of Aristarchus was an horizontal dial, with its rim raised up all around, to prevent the shadow from stretching too far.

It was late before the Romans became acquainted with dials. The first sun-dial at Rome was set up by Papirius Cursor, about the 460th year of the city; before which time, Pliny says, there is no mention of any account of time but by the sun's rising and setting: the first dial was set up near the temple of Quirinus; but being inaccurate, about 30 years after, another was brought out of Sicily by the consul M. Valerius Messala, which he placed on a pillar near the Rostrum; but neither did this show time truly, because not made for that latitude; and, after using it 99 years, Martius Philippus set up another more exact.

The diversity of sun-dials arises from the different situation of the planes, and from the different figure of the surfaces on which they are described; whence they become denominated Equinoctial, Horizontal, Vertical, Polar, Direct, Erect, Declining, Inclining, Reclining, Cylindrical, &c. For the general principles of their construction, see DIALLING.

Dials are distinguished into Primary and Secondary.

Primary Dials, are such as are drawn either on the plane of the horizon, and thence called horizontal dials; or perpendicular to it, and called vertical dials; or else drawn on the polar and equinoctial planes, though neither horizontal nor vertical.

Secondary Dials, are all those that are drawn on the planes of other circles, besides those last mentioned; or those which either decline, incline, recline, or declinate.

Each of these again is divided into several others, as:

Equinoctial DIAL, is that which is described on an equinoctial plane, or one parallel to it.

Horizontal DIAL, is described on an horizontal plane, or a plane parallel to the horizon.—This dial shows the hours from sun-rise to sun-set.

South DIAL, or an *Erect, Direct South Dial*, is that described on the surface of the prime vertical circle facing towards the south.—This dial shows the time from 6 in the morning till 6 at night.

North DIAL, or an *Erect, Direct North Dial*, is that which is described on the surface of the prime vertical pointing northward. This dial only shows the hours before 6 in the morning, and after 6 in the evening.

East DIAL, or *Erect, Direct East Dial*, is that drawn on the plane of the meridian, directly to the east.—This can only show the hours till 12 o'clock.

West DIAL, or *Erect, Direct West Dial*, is that described on the western side of the meridian.—This can only show the hours after noon. Consequently this, and the last preceding one, will show all the hours of the day between them.

Polar DIAL, is that which is described on a plane passing through the poles of the world, and the east and west points of the horizon. It is of two kinds; the first directed towards the zenith, and called the upper; the latter, down towards the nadir, called the lower. The polar dial therefore is inclined to the horizon in an angle equal to the elevation of the pole.—The upper polar dial shows the hours from 6 in the morning till 6 at night, and the lower one shows the hours before 6 in the morning, and after 6 in the evening, viz, from sun-rise and till sun-set.

Declining DIALS, are erect or vertical dials which decline from any of the cardinal points; or they are such as cut either the plane of the prime vertical, or of the horizon, at oblique angles.

Declining dials are of very frequent use; as the walls of houses, on which dials are mostly drawn, commonly deviate from the cardinal points.

Of declining dials there are several kinds, which are denominated from the cardinal points which they are nearest to; as decliners from the south, and from the north, and even from the zenith.

Inclined DIALS, are such as are drawn on planes not erect, but inclining, or leaning forward towards the south, or southern side of the horizon, in an angle, either greater or less than the equinoctial plane.

Reclining DIALS, are those drawn on planes not erect, but reclined, or leaning backwards from the zenith towards the north, in an angle greater or less than the polar plane.

Declined DIALS, are such as both decline and incline, or recline.—These last three kinds of dials are very rare.

DIALS without Centres, are those whose hour lines converge so slowly, that the centre, or point of their concourse, cannot be expressed on the given plane.

Quadrantal DIAL. See Horodical QUADRANT.

Reflecting DIAL. See REFLECTING DIAL.

Cylindrical DIAL, is one drawn on the curve surface of a cylinder. This may first be drawn on a paper plane, and then pasted round a cylinder of wood, &c. It will show the time of the day, the sun's place in the ecliptic, and his altitude at any time of observation.

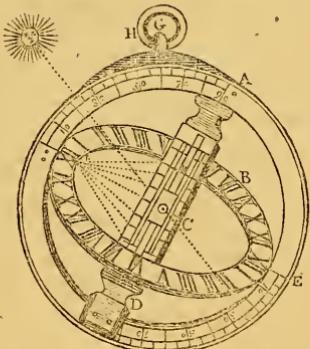

There are also **Portable DIALS**, or on a Card, and **Universal DIALS on a Plain Cross**, &c.

Refracted DIALS, are such as show the hour by means of some refracting transparent fluid.

Ring Dial, is a small portable dial, consisting of a brass ring or rim, about 2 inches in diameter, and one-third of an inch in breadth. In a point of this rim there is a hole, through which the sun-beams pass, and form a bright speck in the concavity of the opposite semi-circle, which gives the hour of the day in the divisions marked within it.

When the hole is fixed, the dial only shows true about the time of the equinox. But to have it perform throughout the whole year, the hole is made moveable, the signs of the zodiac, or the days of the month, being marked on the convex side of the ring; hence, in using it, the moveable hole is set to the day of the month, or the degree of the zodiac the sun is in; then suspending the dial by the little ring, turn it towards the sun, and his rays through the hole will show the hour on the divisions within side.

Universal, or Astronomical Ring-Dial, is a ring dial which shows the hour of the day in any part of the earth; whereas the former is confined to a certain latitude. Its figure see represented below.

It consists of two rings or flat circles, from 2 to 6 inches in diameter, and of a proportionable breadth &c. The outward ring A represents the meridian of any place you are at, and contains two divisions of 90 degrees each, diametrically opposite to each other, the one serving from the equator to the north pole, the other to the south pole. The inner ring B represents the equator, and turns exactly within the outer, by means of two pivots in each ring at the hour of 12.

Across the two circles is placed a thin relet or bridge, with a cursor C, sliding along the middle of the bridge, and having a small hole for the sun to shine through. The middle of this bridge is conceived as the axis of the world, and the extremities as the poles: on the one side are drawn the signs of the zodiac, and on the other the days of the month. On the edge of the meridian a piece slides, to which is fitted a small ring to suspend the instrument by.

In this dial, the divisions on the axis are the tangents of the angles of the sun's declination, adapted to the semi-diameter of the equator as radius, and placed on either side of the centre: but instead of laying them down from a line of tangents, a scale of equal parts may be made, of which 1000 shall answer exactly to the length of the semi-axis, from the centre to the inside of the equinoctial ring; and then 434 of these parts may be laid down from the centre towards each end, which will limit all divisions on

the axis, because 434 is the natural tangent of $23^{\circ} 28'$. And thus, by a nonius fixed to the sliding piece, and taking the sun's declination from an ephemeris, and the tangent of that declination from the table of natural tangents, the slider may be always set true within 2 minutes of a degree. This scale of 434 equal parts might be placed directly against the $23^{\circ} 28'$ of the sun's declination, on the axis, instead of the sun's place, which is there of little use. By this means the slider might be set in the usual way, to the day of the month, for common use; or to the natural tangent of the declination, when great accuracy is required.

To use this Dial: Place the line a (on the middle of the sliding piece) over the degree of latitude of the place, as for instance $51\frac{1}{2}$ degrees for London: put the line which crosses the hole of the cursor to the degree of the sign, or day of the month. Open the instrument so as that the two rings be at right angles to each other, and suspend it by the ring H, that the axis of the dial, represented by the middle of the bridge, may be parallel to the axis of the earth. Then turn the flat side of the bridge towards the sun, so that his rays, striking through the small hole in the middle of the cursor, may fall exactly on a line drawn round the middle of the concave surface of the inner ring; in which case the bright spot shows the hour of the day in the said concave surface of the ring.

Nocturnal or Night-DIAL, is that which shows the hour of the night, by the light, or shadow projected from the moon or stars.

Lunar or Moon Dials may be either purposely described and adapted to the moon's motion; or the hour may be found on a sun-dial by the moon shining upon it, thus: Observe the hour which the shadow of the index points to by moon-light; find the days of the moon's age in the calendar, and take 3-4ths of that number, for the hours to be added to the time shown by the shadow, to give the hour of the night. The reason of which is, that the moon comes to the same horary circle later than the sun by about three quarters of an hour every day; and at the time of new moon the solar and lunar hours coincide.

DIAL PLATES, are the plane superficies on which the hour lines of dials are drawn.

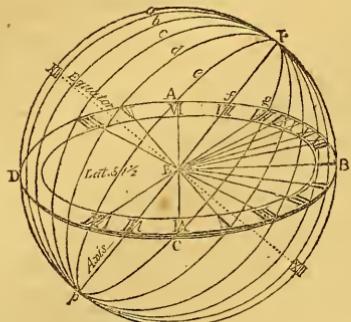

Tide Dial. See *TIDE Dial*.

DIALLING, the art of drawing dials on any kind of surface, whether plane or curv'd.

Dialling is wholly founded on the first motion of the heavenly bodies, and chiefly the sun; or rather on the diurnal rotation of the earth: so that the elements of spheries, and spherical trigonometry, should be understood, before a person attempts to enter upon the doctrine of dialling.

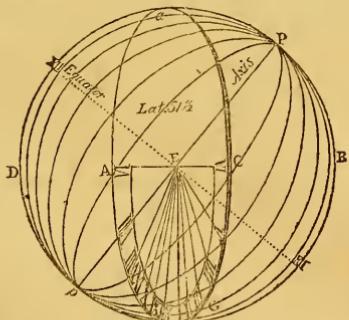

The principles of dialling may be aptly deduced from, and illustrated by, the phenomena of a hollow or transparent sphere, as of glass. Thus, suppose *arcP* to represent the earth as transparent; and its equator as divided into 24 equal parts, by so many meridian semicircles *a*, *b*, *c*, *d*, *e*, &c, one of which is the geographical meridian of any given place, as London, which it is supposed is at the point *a*; and if the hour of 12 were marked at the equator, both on that meridian and the opposite one, and all the rest of the hours in order on the other meridians, those meridians would be the hour circles of London: because, as the sun appears to move round the earth, which is in the centre of the visible heavens, in 24 hours, he will pass from one meridian to another in one hour. Then, if

the sphere had an opake axis, as $\text{P}EP$, terminating in the poles P and p , the shadow of the axis, which is in the

same plane with the sun and with each meridian, would fall upon every particular meridian and hour, when the sun came to the plane of the opposite meridian, and would consequently show the time at London, and at all other places on the same meridian. If this sphere were cut through the middle by a solid plane $AECB$ in the rational horizon of London, one half of the axis EP would be above the plane, and the other half below it; and if straight lines were drawn from the centre of the plane to those points where its circumference is cut by the hour circles of the sphere, those lines would be the hour lines of an horizontal dial for London; for the shadow of the axis would fall upon each particular hour line of the dial, when it fell upon the like hour circle of the sphere.

If the plane which cuts the sphere be upright, as AFCG , touching the given place, for example, London, at F , and

directly opposite to the meridian of London, it will then become the plane of an erect direct south dial; and if right lines be drawn from its centre E , to those points of its circumference where the hour circles of the sphere cut it, these will be the hour lines of a vertical or direct south dial for London, to which the hours are to be set in the figure, contrary to those on an horizontal dial; and the lower half zp of the axis will cast a shadow on the hour of the day in this dial, at the same time that it would fall upon the like hour circle of the sphere, if the dial plane was not in the way.

If the plane, still facing the meridian, be made to incline, or recline, any number of degrees, the hour circles of the sphere will continue to cut the edge of the plane in those points to which the hour lines must be drawn straight from the centre; and the axis of the sphere will cast a shadow on these lines at the respective hours. The like will still hold, if the plane be made to decline by any number of degrees from the meridian towards the east or west; provided the declination be less than 90 degrees, or the reclinatio be less than the co-latitude of the place; and the axis of the sphere will be the gnomon: otherwise, the axis will have no elevation above the plane of the dial, and cannot be a gnomon.

Thus it appears that the plane of every dial represents the plane of some great circle on the earth, and the gnomon the earth's axis; the vertex of a right gnomon the centre of the earth or visible heavens; and the plane of the dial is just as far from this centre as from the vertex of the stile. The earth itself, compared with its distance from the sun, is considered as a point; and therefore, if a small sphere of glass be placed upon any part of the earth's surface, so that its axis be parallel to the axis of the earth, and the sphere have such lines upon it, and such planes within it, as above described; it will show the hours of the day as truly as if it were placed at the earth's centre, and the shell of the earth were as transparent as glass. Ferguson, lect. 10.

The principal writers on Dials, and Dialling, are the following: Vitruvius, in his Architecture, cap. 4 and 7, lib. 9: Sebastian Munster, his Horolographia: John Dryander de Horologiorum varia Compositione: Conrade Gesner's Pandectæ: Andrew Schoner's Gnomonicæ: Fred. Commandine de Horologiorum Descriptione: Joan. Bapt. Benedictus de Gnomonum Umbrarumque Solarium Usu: Joannes Georgius Schomberg, Exgesis Fundamentorum Gnomonicorum: Solomon de Caus, Traité des Horologes Solaires: Joan. Bapt. Trotta, Praxis Horologiorum: Desargues, Manière Universelle pour poser l'Essieu et placer les Heures et autres Choses aux Cadans Solaires: Ath. Kircher, Ars magna Lucis et Umbrae: Hallum, Explicatio Horologii in Horto Regio Londini: Tractatus Horologiorum Joannis Mark: Clavius, Gnomonices de Horologis; in which he demonstrates both the theory and the operations after the rigid manner of the ancient mathematicians: Dechales, Ozanam, and Schottus, gave much easier treatises on this subject; as did also Wolfius in his Elementa: M. Picard gave a new method of making large dials, by calculating the hour lines; and M. Lahire, in his Dialling, printed in 1683, gave a geometrical method of drawing hour lines from certain points, determined by observation. Everhard Walper, in 1625, published his Dialling, in which he lays down a method of drawing the primary dials on very simple principles; and the same principles are also described at length by Sebastian Munster, in his Rudimenta Mathematica, published in 1651. In 1672, Sturmius published a new edition of Walper's Dialling, with the addition of a whole second part, concerning inclining and declining dials, &c. In 1708, the same work was re-published, with Sturmius's additions, and likewise a 4th part, containing Picard's and Lahire's methods of drawing large dials, which forms much the best and ablest work on the subject. Paterson, Michael, and Muller, have each written on Dialling, in the German language: Coetsius, in his Horologographia Plana, printed in 1689:

Gauppen, in his *Gnomonica Mechanica*: Leybourn, in his Dialling: Bion, in his *Use of Mathematical Instruments*: Wells, in his *Art of Shadows*. There is also a treatise by M. Deparceux, 1740. Mr. Ferguson has also written on the same subject, in his *Lectures on Mechanics*; besides Emerson, in his Dialling; and Mr. W. Jones, in his *Instrumental Dialling*. See also my *Recreations*, vol. 3.

Universal DIALLING Cylinder, is represented in fig. 2, plate ix, where ABCD is a glass cylindrical tube, closed at both ends with brass plates, in the centres of which a wire or axis EFG is fixed. The tube is either fixed to an horizontal board II, so that its axis may make an angle with the board equal to that which the earth's axis makes with the horizon of any given place, being thus parallel to the axis of the earth; or it may be made to move on a joint, and elevated for any particular latitude. The 24 hour lines are drawn with a diamond on the outside of the glass, equidistant from each other, and parallel to the axis. The XII next B stands for midnight, and the XII next the board II for noon. When the axis of this instrument is elevated according to the latitude, and the board set level, with the line HX in the plane of the meridian, and the end towards the north; the axis EFG, when the sun shines on the instrument, will serve as a gnomon or stile, and cast a shadow on the hour of the day among the parallel hour lines. As the plate AD at the top is parallel to the equator, and the axis EFG perpendicular to it, right lines drawn from the centre to the extremities of the parallels will be the hour lines of an equinoctial dial, and the axis will be the stile. An horizontal plate EF put down into the tube, with lines drawn from the centre to the several parallels, cutting its edge, will be an horizontal dial for the given latitude; and a vertical plate GC, fronting the meridian, and touching the tube with its edge, with lines drawn from its centre to the parallels, will be a vertical south dial: the axis of the instrument serving in both cases for the stile of the dial: and if a plate be placed within the tube, so as to decline, incline, or recline, by any given number of degrees, and lines be drawn, as above, a declining, inclining, or reclining dial will be formed for the given latitude. If the axis with the several plates fixed to it be drawn out of the tube, and set up in sunshine in the same position as they were in the tube, AD will be an equinoctial dial, EF an horizontal dial, and GC a vertical south dial; and the time of the day will be shown by the axis EFG. If the cylinder were wood, instead of glass, and the parallel lines drawn upon it in the same manner, it would serve to facilitate the operation of making these several dials. The upper plate with lines drawn to the several intersections of the parallels, which appear obliquely in fig. 2, would be an equinoctial dial as in fig. 3, and the axis perpendicular to it be its stile. An horizontal dial for the latitude of the elevation of the axis might be made, by drawing out the axis and cutting the cylinder, as at EFGH, parallel to the horizontal board II; the section would be elliptic as in fig. 4. A circle might be described on the centre, and lines drawn to the divisions of the ellipse would be the hour lines; and the wire put in its place again, as E, would be the stile. If this cylinder were cut by a plane perpendicular to the horizontal board II, or to the line SH, beginning at G, the plane of the section would be elliptical as in fig. 5, and lines drawn to the points of intersection of the parallels on its edge would be the hour lines of a vertical direct south dial, which might be made of any shape, either circular or

square, and F the axis of the cylinder would be its stile. Thus also inclining, declining, or reclining dials might be easily constructed, for any given latitude. Ferguson, ubi supra.

DIALLING Globe, is an instrument made of brass, or wood, with a plane fitted to the horizon, and an index; particularly contrived to draw all sorts of dials, and to give a clear exhibition of the principles of the art.

DIALLING Lines, or *Scales*, are graduated lines, placed on rules or the edges of quadrants, and other instruments, to expedite the construction of dials. The principal of these lines are, 1. A scale of six hours, which is only a double tangent, or two lines of tangents each of 45 degrees, joined together in the middle, and equal to the whole line of sines, with the declination set against the meridian altitudes in the latitude of London, suppose, or any place for which it is made: the radius of which line of sines is equal to the dialling scale of six hours. 2. A line of latitudes, which is fitted to the hour scale, and is made by this canon: as the radius is to the chord of 90 degrees; so are the tangents of each respective degree of the line of latitudes, to the tangents of other arcs: and then the natural sines of those arcs are the numbers, which, taken from a diagonal scale of equal parts, will graduate the divisions of the line of latitude to any radius. The line of hours and latitudes is generally for pricking down all dials with centres. For the method of constructing these scales, see *SCALE*.

DIALLING Sphere, is an instrument made of brass, with several semicircles sliding over each other, on a moveable horizon, to demonstrate the nature of the doctrine of spherical triangles, and to give a true idea of the drawing of dials on all kinds of planes.

DIAMETER, of a *Circle*, is a right line passing through the centre, and terminated at the circumference on both sides.

The diameter divides the circumference, and the area of the circle, into two equal parts. And half the diameter, or the semi-diameter, is called the radius.

For the proportion between the diameter and the circumference of a circle, see *CIRCLE* and *CIRCUMFERENCE*.

DIAMETER of a Conic Section, or *Transverse Diameter*, is a right-line passing through the centre of the section, or the middle of the axis.—The diameter bisects all ordinates, or lines drawn parallel to the tangent at its vertex. See *CONIC Sections*.

Conjugate DIAMETER, is a diameter, in Conic Sections, parallel to the ordinates of another diameter, called the transverse; or parallel to the tangent at the vertex of this other.

DIAMETER, of any Curve, is a right line which divides two other parallel right lines, in such manner that, in each of them, all the segments or ordinates on one side, between the diameter and different points of the curve, are equal to all those on the other side, according to Newton's definition of a Diameter.

But some define a diameter to be that line, whether right or curved, which bisects all the parallels drawn from one point to another of a curve. So that in this way every curve will have a diameter; and hence the curves of the 2d order have, all of them, either a right-lined diameter, or else the curves of some one of the conic sections for diameters. And many geometrical curves of the higher orders, may also have for diameters, curves of more inferior orders.

DIAMETER of Gravity, is a right line passing through the centre of gravity.

DIAMETER, in Astronomy. The diameters of the heavenly bodies are either apparent, i. e. such as they appear to the eye; or real, i. e. such as they are in themselves.

The apparent diameters are best measured with a micrometer, and are estimated by the measure of the angle they subtend at the eye. These are different in different circumstances and parts of the orbits, or according to the various distances of the luminary; being in the inverse ratio of the distance.

The sun's vertical diameter is found by taking the height of the upper and lower edge of his disk, when he is in the meridian, or near it; correcting the altitude of each edge on account of refraction and parallax; then the difference between the true altitudes of the two, is the true apparent diameter sought. Or the apparent diameter may be determined by observing, with a good clock, the time which the sun's disc takes in passing over the meridian: and here, when the sun is in or near the equator, the following proportion may be used; viz, as the time between the sun's leaving the meridian and returning to it again, is to 360 degrees, so is the time of the sun's passing over the meridian, to the number of minutes and seconds of a degree contained in his apparent diameter: but when the sun is in a parallel at some distance from the equator, his diameter measures a greater number of minutes and seconds in that parallel than it would do in a great circle, and takes up proportionally more time in passing over the meridian; in which case we have this proportion: as radius is to the cosine of the sun's declination, so is the time of the sun's passing the meridian reduced to minutes and seconds of a degree, to the arc of a great circle which measures the sun's apparent horizontal diameter. See TRANSIT.

The sun's apparent diameter may also be taken by the projection of his image in a dark room. There are several ways of finding the apparent diameters of the planets; but the most certain method is that with the micrometer. In these diameters considerable errors were made by the more ancient astronomers; but, according to the best of the modern observations, those diameters are as below: viz, the sun's diameter is found to vary from $32^{\circ} 38' 6''$ in January, to $31^{\circ} 33' 8''$ in July: the apparent diameter of the moon varies from about $29^{\circ} 28'$ to $33^{\circ} 36''$; her real diameter being about 2180 miles. The apparent diameters of the planets, when at their respective mean distances from the earth, are as follow:

Mercury,	Venus,	Mars,	Jupiter,	Saturn,	Herschel,
11"	58"	27"	39"	18"	3" 54"

And from these apparent diameters, with the respective distances from the Earth, the real diameters of the sun and planets have been determined in English miles as below:

Mercury,	Venus,	Mars,	Jupiter,	Saturn,	Herschel,
3224	7687	4189	89170	79042	35112 883246.

Observations on the planets Herschel, Saturn, Jupiter, Mars, and the Earth, prove that there is a sensible difference between their equatorial and polar diameters; and it is probable that there is a like difference between the diameters of the other planets, but this has not yet been determined by observation. The mean apparent diameters of the planets, as seen from the sun, have been thus given:

Mercury,	Venus,	Earth,	Mars,	Jupiter,	Saturn,	Herschel,
20"	30"	17"	10"	37"	16"	4".

DIAMETER of a Column, is its thickness just above the

base. From this the module is taken, which measures all the other parts of the column.

DIAMETER of the Diminution, is that taken at the top of the shaft.

DIAMETER of the Swelling, is that taken at the height of one third from the base.

DIPASION, a musical interval, otherwise called an octave, or eighth; so called, because it contains all the possible diversities of sound. If the lengths of two strings be to each other as 1 to 2, the tensions being equal, their tones will produce an octave.

DIPENTE, is the perfect fifth, or second of the concords, making an octave with the Diatessaron. The lengths of the chords are as 3 to 2.

DIAPHANOUS Body or Medium, one that is translucent, or through which the rays of light easily pass; as water, air, glass, talc, fine porcelain, &c. See TRANSPARENCY.

DIAPHONICS, is sometimes used for the science of refracted sound, as it passes through different mediuns.

DIASTYLE, a sort of edifice, in which the pillars stand at such a distance from one another, that three diameters of their thickness are allowed for the intercolumniation.

DIATESSARON, is the perfect fourth; or a musical interval, consisting of one greater tone, one lesser, and one greater semitone. The lengths of strings to sound the diatessaron, are as 3 to 4.

DIATONIC, a term signifying the ordinary sort of music, which proceeds by tones or degrees, both ascending and descending. It contains or admits only the greater and lesser tone, and the greater semitone.

DIESIS, a division of a tone, less than a semitone; or an interval consisting of a lesser, or imperfect semitone. The Diesis is the smallest and softest change, or inflexion, of the voice imaginable. It is also called a feint, and is expressed by a St. Andrew's cross, or saltier.

DIFFERENCE, is the excess by which one magnitude or quantity exceeds another. When a less quantity is subtracted from a greater, the remainder is otherwise called difference.

Ascensional DIFFERENCE. See ASCENSIONAL.

DIFFERENCE of Latitude, in Geography, &c, is an arch of the meridian included between the parallels of latitude in which any two places lie. When the latitudes are both north or both south, the less lat. taken from the greater leaves the difference of latitude; but when the one lat. is north, the other south, their sum shows the dif. of lat.

DIFFERENCE of Longitude, of two places, is an arch of the equator contained between the meridians of those two places, or the measure of the angle formed by their meridians. When the longitudes are both east or both west, the one taken from the other leaves the dif. of longitude; but when the one is east and the other west, they are then to be added together for the dif. of longitude.

DIFFERENTIAL, an indefinitely small quantity, part, or difference. By some, the Differential is considered as infinitely small, or less than any assignable quantity; and also as of the same import as fluxion. It is called a Differential, or Differential Quantity, because often considered as the difference between two quantities; and as such it is the foundation of the Differential Calculus. Newton used the term Moment in a like sense, as being the momentary increase or decrease of a variable quantity. M. Leibnitz and others call it also an infinitesimal.

Differential of the 1st, 2d, 3d, &c, degree. See DIFFERENTIO-DIFFERENTIAL.

Differential Calculus, is a method of differencing quantities. See DIFFERENTIAL Method, CALCULUS, and FLUXIONS.

Differentialio-Differential Calculus, is a method of differencing differential quantities. As the sign of a differential is the letter d prefixed to the quantity, as dx the differential of x ; so that of a differential of dx is ddx , and the differential of ddx is ddd , &c; similar to the fluxions $\dot{x}, \ddot{x}, \dddot{x}, \&c.$ Thus we have degrees of differentials. The differential of an ordinary quantity, is a differential of the first order or degree, as dx ; that of the 2d degree is ddx ; that of the 3d degree is ddd , &c. The rules for differentials, are the very same as those for fluxions. See FLUXIONS.

Differential, in Logarithms. Kepler calls the logarithms of tangents, Differentiales; which we usually call artificial tangents.

Differential Equation, is an equation involving or containing differential quantities; as the equation $3x^2dx - 2axdx + aydx + axdy = 0.$ Some mathematicians, as Stirling, &c, have also applied the term differential equation in another sense, to certain equations defining the nature of series.

Differential Method, a method of finding quantities by means of their successive differences. This method is of very general use and application, but especially in the construction of tables of numbers, and the summation of series, &c. It was first used, and the rules of it laid down, by Briggs, in his Construction of Logarithms and other Numbers, much the same as they were afterwards taught by Cotes, in his Constructio Tabularum per Differencias; as is shown in the Introduction to my Logs. pa. 69 et seq. See Briggs's Arithmetica Logarithmica, cap. 12 and 13, and his Trigonometria Britannica.

The method was next treated in another form by Newton, in the 5th Lemma of the 3d book of his Principia, and in his Methodus Differentialis, published by Jones in 1711, with the other tracts of Newton. This author here treats it as a method of describing a curve of the parabolic kind, through any given number of points. He distinguishes two cases of this problem; the first, when the ordinates drawn from the given points to any line given in position, are at equal distances from one another; and the 2d, when these ordinates are not at equal distances. He has given a solution of both cases, at first without demonstration, which was afterwards supplied by himself and others: see his Methodus Differentialis above mentioned; and Stirling's Explanation of the Newtonian Differential Method, in the Philos. Trans. N° 362; Cotes, De Methodo Differentiali Newtoniana, published with his Harmonia Mensurorum; Herman's Phoronoma; and Le Scur and Jacquier, in their Commentary on Newton's Principia. It may be observed, that the methods there demonstrated, by some of these authors, extend to the description of any algebraic curve through a given number of points, which Newton, writing to Leibnitz, mentions as a problem of the greatest use.

By this method, some terms of a series being given, and conceived as placed at given intervals, any intermediate term may be found; which therefore gives a method for interpolations. Briggs's Arith. Log. ubi supra; Newton, Meth. Diffr. prop. 5; Stirling, Methodus Differentialis.

Thus also may any curvilinear figure be squared nearly, having some few of its ordinates. Newton, ibid. prop. 6; Cotes De Method. Diffr.; Simpson's Mathematical Dissertation. pa. 115. And thus may mathematical tables be constructed by interpolations: Briggs, ibid. Cotes Canonotechnia. The successive differences of the ordinates of parabolic curves, becoming ultimately equal, and the intermediate ordinate required being determined by these differences of the ordinates, is the reason for the name Differential Method.

To be a little more particular.—The first case of Newton's problem amounts to this: A series of numbers, placed at equal intervals, being given, to find any intermediate number of that series, when its interval or distance from the first term of the series is given. Subtract each term of the series from the next following term, and call the remainders first differences; then subtract in like manner each of these differences from the next following one, calling these remainders 2d differences; again, subtract each 2d difference from the next following, for the 3d differences; and so on: then if a be the 1st term of the series, d' the first of the 1st differences, d'' the first of the 2d differences, d''' the first of the 3d differences, &c; and if x be the interval or distance between the first term of the series and any term sought, r , that is, let the number of terms from a to r , both included, be $= x + 1$; then will the term sought, r , be =

$$a + \frac{x}{1}d' + \frac{x}{1} \cdot \frac{x-1}{2}d'' + \frac{x}{1} \cdot \frac{x-1}{2} \cdot \frac{x-2}{3}d''' + \&c.$$

Hence, if the differences of any order become equal, that is, if any of the diff's. d' , d'' , &c, become = 0, the above series will give a finite expression for r , the term sought; it being evident, that the series must terminate when any of the diff's. d'' , d''' , &c, become = 0.

It is also evident that the co-efficients $\frac{x}{1}, \frac{x}{1} \cdot \frac{x-1}{2}$, &c of the differences, are the same as the terms of the binomial theorem.

For Example, Suppose it were required to find the log. tangent of $5^{\circ} 1' 12'' 24'''$, or $5^{\circ} 1^{\frac{1}{2}} 24'''$, or $5^{\circ} 1^{\frac{1}{2}} 2066$, &c.

Take out the log. tangents to several minutes and seconds, and take their first and second differences, as below:

	Tang.	d'	d''
5° 0'	- - - 71626964	14453	
5 1	- - - 71641417	14404	49 }
5 2	- - - 71655821	14357	47 }
5 3	- - - 71670178		—48

Here $A = 71641417$; $x = \frac{1}{30}$; $d' = 14404$; and the mean second difference $d'' = - 48.$ Hence

$$\begin{aligned} A &= - - - - - 71641417 \\ xd' &= - - - - - 2977 \\ \frac{x}{1} \cdot \frac{x-1}{1} d'' &= - - - - - 4 \end{aligned}$$

Theref. the tang. of $5^{\circ} 1' 12'' 24'''$ is 71644398

Hence may be deduced a method of finding the sums of the terms of such a series, calling its terms $a, b, c, d, &c.$ For, conceive a new series having its 1st term = 0, its 2d = a , its 3d = $a + b$, its 4th = $a + b + c$, its 5th = $a + b + c + d$, and so on; then it is plain that assigning one term of this series, is finding the sum of all the terms $a, b, c, d, &c.$ Now since these terms are the differences of the sums, 0, a , $a + b$, $a + b + c$, &c;

and as some of the differences of a , b , c , &c, are = 0 by supposition; it follows that some of the differences of the sums will be = 0; and since in the series $a + \frac{x}{1}d' + \frac{x}{1} \cdot \frac{x-1}{2}d''$ &c, by which a term was assigned, a represented the 1st term; d' the 1st of the 1st differences, and x the interval between the first term and the last; we are to write 0 instead of a , A instead of d' , d' instead of d'' , d'' instead of d''' , &c, also $x + 1$ instead of x ; which being done, the series expressing the sums will be $0 +$

$$\frac{x+1}{1}A + \frac{x+1}{1} \cdot \frac{x}{2}d' + \frac{x+1}{1} \cdot \frac{x}{2} \cdot \frac{x-1}{3}d'', \text{ &c.}$$

Or, if the real number of terms of the lines be called z , that is, if $z = x + 1$, or $x = z - 1$, the sum of the series will be $Az + \frac{z}{1} \cdot \frac{z-1}{2}d' + \frac{z}{1} \cdot \frac{z-1}{2} \cdot \frac{z-2}{3}d''$ &c. See De Moivre's Doct. of Chances, pa. 59, 60; or his Miscel. Analyt. pa. 153; or Simpson's Essays, pa. 95.

For Example. To find the sum of six terms of the series of squares $1 + 4 + 9 + 16 + 25 + 36$, of the natural numbers.

Terms	d'	d''	d'''
1	3		
4	5	2	0
9	7	2	0
16	9		
25			

Here $A = 1$, $d' = 3$, $d'' = 2$, $d''' = 0$, and $z = 6$; therefore the sum is $6 + \frac{6}{1} \cdot \frac{5}{2} \cdot 3 + \frac{6}{1} \cdot \frac{5}{2} \cdot \frac{4}{3} \cdot 2 = 6 + 45 + 40 = 91$ the sum required, viz, of $1 + 4 + 9 + 16 + 25 + 36$.

A variety of examples may be seen in the places above cited, or in Stirling's Methodus Differentialis, &c.

As to the Differential method, it may be observed, that though Newton and some others have treated it as a method of describing an algebraic curve, at least of the parabolic kind, through any number of given points; yet the consideration of curves is not at all essential to it, though it may help the imagination. The description of a parabolic curve through given points, is the same problem as the finding of quantities from their given differences, which may always be done by algebra, by the resolution of simple equations. See Stirling's Method. Differ. pa. 97. This ingenious author has treated very fully of the differential method, and shown its use in the solution of some difficult problems. See also SERIES.

DIFFERENTIAL Scale, in Algebra, is used for the scale of relation subtracted from unity. See *Recurring Series*.

DIFFRACTION, a term first used by Grimaldi, to denote that property of the rays of light, which others have called Inflection; the discovery of which is attributed by some to Grimaldi, and by others to Dr. Hooke.

DIGBY (*Sir KENELM*), a celebrated English philosopher, was born at Gothurst in Buckinghamshire, 1603. He was the descendant of an ancient family: his great-grandfather, with six of his brothers, fought valiantly at Bosworth-field on the side of Henry 7th, against Richard the 3d. His father, Sir Everard, engaged in the gunpowder plot against James the 1st, for which he was beheaded; but the son was restored to his estate, and had afterwards several appointments under King Charles the 1st, who granted him letters of reprisal against the Venetians, from whom he took several prizes with a small fleet which he commanded. He fought the Venetians near the

port of Scanderoon, and bravely made his way through them with his booty.

In the beginning of the civil wars, he exerted himself greatly in the king's cause, and was afterwards imprisoned, by order of the parliament; but was set at liberty in 1643. He afterwards compounded for his estate; but being banished from England, he retired to France, and was sent on two embassies to Pope Innocent the 10th, from the queen, widow to Charles the 1st, whose chancellor he then was. On the restoration of Charles the 2d, he returned to London; where he died in 1665, at 62 years of age.

Digby was a great lover of learning, and translated several authors into English, as well as published several works of his own; as, 1. Observations upon Dr. Brown's Religio Medici, 1643.—2. Observations on part of Spenser's Fairy Queen, 1644.—3. A Treatise of the Nature of Bodies, 1644.—4. A Treatise declaring the Operations and Nature of Man's Soul, out of which the Immortality of reasonable souls is evinced: works that discover great penetration and extensive knowledge.

He applied much to chemistry; and found out several useful medicines, which he distributed with a liberal hand. He particularly distinguished himself by his sympathetic powder for the cure of wounds at a distance; his discourse concerning which made great noise for a while. He held several conferences with Descartes, about the nature of the soul, and the principles of things. At the beginning of the Royal Society, he became a distinguished member, being one of the first council. And he had at his own house regular levees or meetings of learned men, to improve themselves in knowledge, by conversing with one another.

This eminent person was, for the early pregnancy of his talents, and his great proficiency in learning, compared to the celebrated Picus de Mirandola, who was one of the wonders of human nature. Yet his knowledge, though various and extensive, probably appeared greater than it really was; as he had all the powers of elocution and address to recommend it. He knew how to shine in a circle, either of ladies or philosophers; and was as much attended to when he spoke on the most trivial subjects, as when he spoke on the most important. It has been said that one of the princesses of Italy, who had no child, was desirous that his princess should bring him a son by Sir Kenelm, whom he esteemed a just model of perfection.

DIGGES (LEONARD), an ingenious mathematician in the 16th century, was descended from an ancient family, and born at Digges-court in the parish of Barham in Kent; but in what year is not known; and died about the year 1574. He was educated for some time at Oxford, where he laid a good foundation of learning; but retiring from thence, he prosecuted his studies, and became an excellent mathematician, a skilful architect, and an expert surveyor of land, &c. He composed several books: as, 1. Tectonicum: briefly showing the exact Measuring, and speedy Reckoning of all manner of Lands, Squares, Timber, Stones, Steeples, &c; 1556, 4to.; this was augmented and published again by his son Thomas Digges, in 1592; and also reprinted in 1647.—2. A Geometrical Practical Treatise, named Pantometria, in three books, which he left in manuscript; but after his death, his son supplied such parts of it as were obscure and imperfect, and published it in 1591, folio; subjoining, "A Discourse Geometrical of the five regular and Platonic bodies, containing

sundry theoretical and practical propositions, arising by mutual conference of these solids, Inscription, Circumscription, and Transformation."—3. Prognostication Everlasting of right good effect: or Choice Rules to judge the weather by the Sun, Moon, and Stars, &c; in 4to, 1555, 1556, and 1564: corrected and augmented by his son, with divers general tables, and many compendious rules, in 4to, 1592.

DIGGES (THOMAS), only son of Leonard Digges, after a liberal education from his tenderest years, went and studied for some time at Oxford; and by the improvements he made there, and the subsequent instructions of his learned father, became one of the best mathematicians of his age. When Queen Elizabeth sent some forces to assist the oppressed inhabitants of the Netherlands, Mr. Digges was appointed muster-master-general of them; by which he became well skilled in military affairs; as his writings afterwards showed. He died in 1595.

Mr. Digges, beside revising, correcting, and enlarging some pieces of his father's, already mentioned, wrote and published the following learned works himself: viz, 1. Alæsive Scaleæ Mathematicæ: or Mathematical Wings or Ladders, 1573, 4to. A book which contains several demonstrations for finding the parallaxes of any comet, or other celestial body, with a correction of the errors in the use of the radius astronomicus.—2. An Arithmetical Military Treatise, containing so much of Arithmetic as is necessary towards military discipline, 1579, 4to.—3. A Geometrical Treatise, named Stratoticos, requisite for the perfection of Soldiers, 1579, 4to. This was begun by his father, but finished by himself. They were both reprinted together in 1590, with several additions and amendments, under this title: "An Arithmetical Warlike Treatise, named Stratoticos, compendiously teaching the Science of Numbers, as well in Fractions as Integers, and so much of the Rules and Equations Algebraical, and Art of Numbers Cossical, as are requisite for the profession of a soldiier. Together with the Moderne militaire discipline, offices, lawes, and orders in every well-governed camp and armie, inviolably to be observed." At the end of this work there are two pieces; the first, "A briefe and true report of the proceedings of the Earle of Leycester, for the relief of the towne of Sluce, from his arrival at Vlissing, about the end of June 1587, until the surrendrie thereof 26 Julii next ensuing. Whereby it shall plainelie appear, his excellencie was not in anie fault for the losse of that towne;" the second, "A briefe discourse what orders were best for repulsing of foraine forces, if at any time they should invade us by sea in Kent, or elsewhere."—4. A perfect Description of the Celestial Orbz, according to the most ancient doctrine of the Pythagoreans, &c. This was placed at the end of his father's "Prognostication Everlasting, &c." printed in 1592, 4to.—5. A humble Motive for Association to maintain the religion established, 1601, 8vo. To which is added, his Letter to the same purpose to the archbishops and bishops of England.—6. England's Defence; or, A Treatise concerning Invasion. This is a tract of the same nature with that printed at the end of his Stratoticos, and called, A briefe Discourse, &c. It was written in 1599, but not published till 1686.—7. A Letter print-ed before Dr. John Dee's Parallaticos Commentationis præcoscope nucleus quidam, 1573, 4to.—Beside these, and his Nova Corpora, he left several methematical treatises ready for the press; which, by reason of law-

suits and other avocations, he was hindered from publishing.

If our author was great in himself, he was not less so in his son, Sir Dudley Digges, so celebrated as a politician and elegant writer; and also in his grandson Dudley.

DIGIT, in Arithmetic, one of the ten characters 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, by means of which all numbers are expressed.

DIGIT, in Astronomy, is the measure by which the part of the luminaries in eclipses is estimated, being the 12th part of the diameter of the luminary. Thus, an eclipse is said to be of 10 digits, when 10 parts out of 12 of the diameter are in the eclipsed part; when the whole of the luminary is exactly covered, the digits eclipsed are just 12; and when the luminary is more than covered, as often happens in lunar eclipses, then more than 12 digits are said to be eclipsed: Thus, if the diameter or breadth of the earth's shadow, where the moon passes through, be equal to one diameter and a half of the moon, then 18° or digits are said to be eclipsed. These digits are by Wolfius, and some others, called *Digitæ Eclipticæ*.

DILATATION, a motion of the parts of a body by which it expands, or opens itself, so as to occupy a greater space.—Many authors confound dilatation with rarefaction; but the more accurate writers distinguish between them; defining dilatation to be the expansion of a body into a greater bulk, by its own elastic power; and rarefaction, the like expansion produced by means of heat.

The moderns have observed, that bodies which, after being compressed, and again left at liberty, restore themselves perfectly, do endeavour to dilate themselves with the same force by which they are compressed; and accordingly they sustain a force, and raise a weight equal to that with which they are compressed.

Again, bodies, in dilating by their elastic power, exert a greater force at the beginning of their dilatation, than towards the end; as being at first more compressed; and the greater the compression, the greater the elastic power and endeavour to dilate. So that these three, the compressing power, the compression, and the elastic power, are always equal.

Finally, the motion by which compressed bodies restore themselves, is usually accelerated: thus, when compressed air begins to restore itself, and dilate into a greater space, it is still compressed; and consequently a new impetus is still impressed upon it, from the dilatative cause; and the former remaining, with the increase of the cause, the effect, that is the motion and velocity, must be increased also. Indeed it may happen, that where the compression is only partial, the motion of dilatation shall not be accelerated, but retarded; as is evident in the compression of a sponge, soft bread, gauze, &c.

DIMENSION, the extension of a body, considered as measurable. Hence, as we conceive a body extended, and measurable in length, breadth, and depth, dimension is considered as threefold, viz, length, breadth, and thickness. So a line has one dimension only, viz, length; a superficies two, length and breadth; and a body or solid has three, viz, length, breadth, and thickness.

DIMENSION is also particularly used with regard to the powers of quantities in equations. Thus, in a simple equation $x = a + b$, the unknown quantity is only of one dimension; in a quadratic equation, $x^2 = a^2 + b^2$, it is of two dimensions; in a cubic $x^3 = a^3 + b^3$, it is of three dimensions; and so on.

DIMINISHED Angle, in Fortification. See **ANGLE**.
DIMINUTION, in Music, is the abating something of the full value or quantity of any note.

DIMINUTION, in Architecture, is a contraction of the upper part of a column, by which its diameter is made less than that of the lower part.

DINOCRATES, a celebrated ancient architect of Macedonia, of whom several extraordinary things are related. He was taken, by Alexander the Great, into Egypt, where he employed him in marking out and building the city of Alexandria: here he formed a design, in which Mount Athos was to be laid out into the form of a man, in whose left hand were to be represented the walls of a great city; and all the rivers of the mount flowing into his right, and from thence into the sea. Another memorable instance of Dinocrates's architectonic skill, is his restoring and building, in a more august and magnificent manner than before, the celebrated temple of Diana at Ephesus, after Herostratus, for the sake of immortalizing his name, had destroyed it by fire. A third instance, more extraordinary and wonderful than either of the former, is related by Pliny in his Natural History; who says he had formed a scheme for building the dome of the temple of Arsinœ at Alexandria of loadstone, in order that her image made entirely of iron should hang in the middle of it, as if it were in the air; but the king's death, and his own, prevented the execution or attempt of this project.

DIOCLES, a Greek mathematician of some celebrity, but more particularly remembered for his invention of the curve called the *cycloid* or the *Cissoid of Diocles*. See *CIS-*
SOID.

DIONYSIUS, the *Periegetic*, an ancient geographer and poet. Pliny says, he was a native of the Persian Alexandria, afterwards called Antioch, and at last Charax; that he was sent by Augustus, to survey the eastern part of the earth. Dionysius wrote a great number of pieces, enumerated by Suidas and his commentator Eustathius: but his *Periegesis*, or *Survey of the World*, is the only one now extant; which may be well esteemed one of the most exact systems of ancient geography, since Pliny himself proposed it as his pattern.

DIONYSIAN, or *Victorian Period*. See *PERIOD*.

DIOPHANTINE Problems, are certain questions relating to square and cubic numbers, and to right-angled triangles, &c; the nature of which were first and chiefly treated by Diophantus, in his *Arithmetic*, or rather *Algebra*.

In these questions, it is chiefly intended to find commensurable numbers to answer indeterminate problems; which often bring out an infinite number of incommensurable quantities. For example, If it be proposed to find a right-angled triangle, whose three sides x, y, z are expressed by rational numbers; from the nature of the figure it is known that $x^2 + y^2 = z^2$, where z denotes the hypotenuse. Now it is plain that x and y may also be so taken, that z shall be irrational; for if $x=1$, and $y=2$, then is $z=\sqrt{5}$.

Now the art of resolving such problems, consists in ordering the unknown quantity or quantities, in such a manner, that the square or higher power may vanish out of the equation, and then by means of the unknown quantity in its first dimension, the equation may be resolved without having recourse to incommensurables. For example, in the equation above, $x^2 + y^2 = z^2$, suppose $z = x + u$, then is $x^2 + y^2 = x^2 + 2xu + u^2$, out of which equation x^2 vanishes, and then it is $y^2 = 2xu + u^2$, which gives $x = \frac{y^2 - u^2}{2u}$: hence,

assuming y and u equal to any numbers at pleasure, the three sides of the triangle will be $y, \frac{y^2 - u^2}{2u}$, and $\frac{y^2 + u^2}{2u}$, or out of fractions, $2vy$, and $y^2 - u^2$, and $y^2 + u^2$, which are all rational whenever y and u are rational. For example, if $y=2$, and $u=1$, then $y^2 - u^2 = 3$, and $2vy = 4$, and $y^2 + u^2 = 5$. It is evident that this problem admits of infinite numbers of solutions, as y or u may be assumed any numbers at pleasure.

But, in questions of this kind, very few directions can be given, as the method of solution must be left, in a great measure, to the skill and ingenuity employed in the substitution &c, for unknown quantities. Thus, a person acquainted with this branch of algebra, would have immediately substituted in the above equation,

$$x^2 = v^2 - u^2, \text{ or } x^2 = v^2 - 2v^2u^2 + u^4,$$

$$\text{and } y = 2vu, \text{ or } y^2 = 4v^2u^2,$$

$$\text{hence } z = v^2 + u^2, \text{ or } z^2 = v^4 + 2v^2u^2 + u^4.$$

where v and u may be taken at pleasure.

Or if the equation had been $x^2 - y^2 = z^2$. Then by making $x^2 = (v^2 + u^2)^2$, and $y^2 = 4v^2u^2$, we should have $z^2 = (v^2 - u^2)^2$; where v and u may be taken any numbers whatever, as before.

Ex. 2. To find the general values of x and y , such that $x^2 + y$, and $x^2 - y$, may be both complete squares. Or, which is the same thing, to find three square numbers in arithmetical progression.

First, put $x^2 + y = w^2$ Then $2x^2 = w^2 + z^2$,
 $\text{and } x^2 - y = z^2$ or $2x^2 - w^2 = z^2$. Now make $x = w + m$, or $2x^2 = 2w^2 + 4wm + 2m^2$; hence $z^2 = w^2 + 4wm + 2m^2$, which must be a complete square; therefore substitute $z = w + r$, and we obtain $w^2 + 4wm + 2m^2 = w^2 + 2wr + r^2$, or $(4m - 2r)w = r^2 - 2m^2$; hence we have $w = \frac{r^2 - 2m^2}{4m - 2r}$; $w + m + x = \frac{r^2 - 2rm + 2m^2}{4m - 2r}$; $w + r + z = \frac{-r^2 + 4rm - 2m^2}{4m - 2r}$.

Or, since the denominators are equal, we may make $w = r^2 - 2m^2$, $x = r^2 - 2rm + 2m^2$, and $z = -r^2 + 4rm - 2m^2$; where r and m may be assumed at pleasure, either integral or fractional. In the first values of w , x , and z ; by assuming $r = 6$, and $m = 4$, we have $w = 1$, $x = 5$, and $z = 7$; and therefore

1, 25, and 49, the three square numbers required.

Now some of those general expressions being once obtained, they may be frequently introduced to abbreviate the operations in more intricate questions. For an example of which we will propose the following problem.

Ex. 3. To find the values of x and y , such, that unity being added to each of them, as also to their sum, and difference, the four numbers thus arising shall be square numbers.

$$\begin{cases} x + 1 = l^2 \\ y + 1 = n^2 \\ x + y + 1 = p^2 \\ x - y + 1 = s^2 \end{cases}$$

Here, we see that the three squares s^2 , l^2 , and p^2 , are in arithmetical progression, their common difference being y .

The question therefore is reduced to the finding of three square numbers in arithmetical progression, whose common difference + 1 may be a square; therefore from the foregoing example let $s^2 = (r^2 - 2m^2)^2$, $l^2 = (r^2 - 2rm + 2m^2)^2$, $p^2 = (-r^2 + 4rm - 2m^2)^2$, which we know are in arithmetical progression, their common difference being $4r^3m - 12r^2m^2 + 8rm^3 = y$; and we have to find $4r^3m - 12r^2m^2 + 8rm^3 = y$

$-12r^2m^2 + 8rm^2 + 1$ a square. Substitute its root $= 1 + 4rm^2$, and we thus obtain $16r^2m^6 - 4r^2m - 12r^2m^2$; or dividing by $4r^2m$, we have $r = 4m^5 + 3m$: where m may be assumed at pleasure. By taking $m = 1$, we have $r = 7$, also $p^2 = 529$, and $l^2 = 1369$; again $l^2 - 1 = 1368 = x$, and $l^2 - p^2 = 840 = y$, which are the two numbers sought,

$$\left\{ \begin{array}{l} 1368 + 1 = 37^2 \\ 840 + 1 = 29^2 \\ 1368 + 840 + 1 = 47^2 \\ 1368 - 840 + 1 = 23^2. \end{array} \right.$$

the four squares being

The operations in the solution of Diophantine problems may also be frequently simplified, from certain known properties of numbers, when they are included under peculiar forms, particularly when the answer is required to be given in integers; many ingenious specimens of which may be seen in the solution of Diophantine problems in the New Series of the Mathematical Repository, by Mr. Leybourn, of the Royal Military College.

Another method, which is frequently adopted to considerable advantage, is by means of the development of certain algebraical functions; an example of which will be seen in the following problem.

Ex. 4. To find a number, from which two given squares being severally subtracted, each of the remainders may be a square.

Theorem. Let a^2 and b^2 represent the given squares. Resolve $\frac{1}{2}a - \frac{1}{2}b$ into any two unequal factors m and m' ; and $\frac{1}{2}a + \frac{1}{2}b$ into any two unequal factors n and n' ; then will $(m^2 + n^2) \cdot (m'^2 + n'^2)$ be the number required.

Demonstration. For $(m^2 + n^2) \cdot (m'^2 + n'^2)$

$$= \left\{ \begin{array}{l} (mn' + mn')^2 + (mn' - mn)^2 \\ \text{or } (mm' - nn')^2 + (mn' + mn)^2, \end{array} \right.$$

as is immediately seen by the development of the above formulae. And since $\frac{1}{2}a + \frac{1}{2}b = mn'$, and $\frac{1}{2}a - \frac{1}{2}b = mn$, therefore $a = mn' + mn$ and $b = mn' - mn$. Consequently, the square of each being taken from the above product, will leave a square remainder.

Suppose, for example, 4 and 36 were the two squares, then $\frac{6+2}{2} = 4.1$, and $\frac{6-2}{2} = 2.1$, therefore $(4^2 + 1^2) \cdot (2^2 + 1^2) = 85$ the number sought; for $85 - 4 = 81 = 9^2$ and $85 - 36 = 49 = 7^2$.

For further information on this interesting branch of algebra, the reader may consult Fermat, Bachet, Ozanam, Kensey, Saunderson, and Euler, particularly the latter, who in the 2d vol. of his Algebra has carried this subject to a considerable length, which, with the additions by La Grange, may be considered as one of the most complete pieces of Diophantine algebra. But with regard to the Theory of Numbers, which is intimately connected with the above subject, the best works are Le Gendre's *Essai sur la Théorie des Nombres*; and the *Recherches arithmétiques* par M. Gauss.

DIOPHANTUS, a celebrated mathematician of Alexandria, who has commonly been reputed to be the inventor of algebra; but notwithstanding his is the earliest work extant on that science, there appears to be no reason for supposing that he was the inventor of it: indeed the work itself is almost a proof to the contrary; for though he does not mention any other authors in the course of his book, yet he evidently treats the subject as one already known. It is not certain when Diophantus lived. Some have placed him before Christ, and some after, in the reigns of Nero and the Antonines; but all with equal uncertainty.

It seems he is the same Diophantus who wrote the *Canon Astronomicus*, which Suidas says was commented on by the celebrated Hypatia, daughter of Theon of Alexandria. His reputation must have been very high among the ancients, since they ranked him with Pythagoras and Euclid in mathematical learning. Bachet, in his notes upon the 5th book *De Arithmetica*, has collected, from Diophantus's epitaph in the Anthologia, the following circumstances of his life; namely, that he was married when he was 33 years old, and had a son born 5 years after; that this son died when he was 42 years of age, and that his father did not survive him above 4 years; from which it appears, that Diophantus lived to the age of 84 years.

This epitaph as translated by Bachet is as follows:

Hic Diophantus habet tumulum, qui tempora vita

Illiū mutā denotat arte tibi

Egit sextam juvenis, lanugine malas

Vestire hinc caput parte duodecimā

Septante uxori pos hac sociatur, et anno

Formosus quinto nascitur indē puer

Semimes etatis postquam attigit illę paterna,

In felix subit̄ morte peremptus obit

Quatuor testates genitor lugere superstes

Cogitū; hic annos illius assequere.

Diophantus wrote 13 books of *Arithmetica*, or *Algebra*, which Regiomontanus, in his preface to Alfraganus, tells us, are still preserved in manuscript in the Vatican library: indeed we are informed by Diophantus himself that his work consisted of 13 books, viz, at the end of his address to Dionysius, placed at the beginning of the work, and hence Regiomontanus might be led to say the 13 books were in that library; but no more than 6 whole books, with part of a seventh, have ever been published; and I am of opinion there are no more in being; indeed Bombelli, in the preface to his *Algebra*, written 1572, says there were but 6 of the books then in the library, and that he and another person were about a translation of them.

Those 6 books, with the imperfect 7th, were first published at Basil by Xylander in 1575, but in a Latin version only, with the Greek scholia of Maximus Planudes on the first two books, and observations of his own; the same books were afterwards published in Greek and Latin at Paris in 1621, by Bachet, an ingenious and learned Frenchman, who made a new Latin translation of the work, and enriched it with learned commentaries; and although he did not entirely neglect the notes of Xylander in his edition, yet he treated the scholiast Planudes with the utmost contempt. He seems to intimate, in what he says upon the 28th question of the 2d book, that the 6 books which we have of Diophantus, may be nothing more than a collection made by some novice, of such propositions as he judged proper, out of the whole 13: but Fabricius thinks there is no just ground for such a supposition. This work was afterwards (1670) revised and republished by Fermat, who added many excellent notes in addition to those of Bachet.

DIOPTER, or **DIOPTRA**, the same with the index or alidade of an astrolabe, or other such instrument.

DIOPTRA was an instrument invented by Hipparchus, which served for several uses; as, to level water-courses; to take the height of towers, or places at a distance; to determine the places, magnitudes, and distances of the planets, &c.

DIOPTRICS, called also *Anaclastics*, is the doctrine of refracted vision; or that part of optics which explains the

effects of light as refracted by passing through different mediums, as air, water, glass, &c, and especially lenses.

Dioptrics is one of the most useful and pleasant of all the human sciences; as it brings the remotest objects near hand, enlarging the smallest objects so as to show their minute parts, and even giving sight to the blind; and all this by the simple means of the attractive power in glass and water, causing the rays of light in their passage through them to alter their course according to the different substances of the medium; whence it happens that the objects seen through them, do, in appearance, alter their magnitude, distance, and situation.

The ancients have treated of direct and reflected vision; but what we have of refracted vision, is very imperfect. J. Baptista Porta wrote a treatise on refraction, in 9 books, but without any great improvement. Kepler was the first who succeeded in any great degree, on this subject; having demonstrated the properties of spherical lenses very accurately, in a treatise first published anno 1611. After Kepler, Galileo gave somewhat of this doctrine in his Letters; as also an Examination of the Preface of Johannes Pena upon Euclid's Optics, concerning the use of optics in astronomy. Descartes also wrote a treatise on Dioptrics, commonly annexed to his Principles of Philosophy, which is one of his best works; where the true manner of vision is more distinctly explained than by any former writer, and in which is contained the true law of refraction, which was first discovered by Snell, though the name of the inventor is suppressed: here are also laid down the properties of elliptical and hyperbolical lenses, with the practice of grinding glasses. Dr. Barrow has treated on Dioptrics in a very elegant manner, though rather too briefly, in his Optical Lectures, read at Cambridge. Huygen's Dioptrics, is also an excellent work of its kind. Molyneux's Dioptrics is a work rather heavy and dull. Beside these, there are several other treatises on Dioptrics, such as Hartsoeker's Essai de Dioptrique, Cherubin's Dioptrique Oculaire, et La Vision Parfaite, David Gregory's Elements of Dioptrics. Traber's Nervus Opticus. Zahn's Oculus Artificialis Teledioptricus. Dr. Smith's Optics, which is a complete work of its kind. Wolfius's Dioptrics, contained in his Elementa Matheseos Universalis. But especially the Treatise on Optics, and the Optical Lectures of Newton, in whose experiments are contained far more discoveries than in all the former writers. Lastly, this science was perfected by Dollond's discovery of the achromatic glasses, by which the colours are obviated in refracting telescopes.

The laws of Dioptrics are delivered under the article REFRACTION, LENS, &c; and the application of them in the construction of telescopes, microscopes, and other di-optical instruments, under the articles TELESCOPE and MICROSCOPE.

DIP of the Horizon. See DEPRESSION.

DIPPING-Needle, or Inclivatory Needle, a magnetical needle, so hung, as that, instead of playing horizontally, and pointing out north and south, one end dips, or inclines to the horizon, and the other points to a certain degree of elevation above it.

The inventor of the dipping-needle was Robert Norman, a compass-maker at Ratcliffe, about the year 1580: this is not only testified by his own account, in his New Attractive, but also by Dr. Gilbert, Mr. William Burrowes, Mr. Henry Bond, and other writers of that time, or soon after it. The occasion of the discovery he him-

self relates, viz, that it being his custom to finish, and hang the needles of his compasses, before he touched them, he always found that, immediately after the touch, the north point would dip or decline downward, pointing in a direction under the horizon; so that, to balance the needle again, he was always obliged to put a piece of wax on the south end, as a counterpoise. The constancy of this effect led him, at length, to observe the precise quantity of the dip, or to measure the greatest angle which the needle would make with the horizon. This, in the year 1576, he found at London was $71^{\circ} 50'$. It is not quite certain whether the dip varies, as well as the horizontal direction, in the same place. Mr. Graham made a great many experiments with the dipping-needle in 1723, and found the dip between 74 and 75 degrees. Mr. Nairne, in 1772, found it somewhat above 72° . And by many observations made since that time at the Royal Society, the medium quantity is $72^{\circ}\frac{1}{2}$. Indeed, in 1812 it is only stated at $70^{\circ} 32'$ at the Royal Society. The trifling difference between the first observations of Norman, and the last of Mr. Nairne and the Royal Society, lead to the opinion that the dip is unalterable; and yet it may be difficult to account for the great difference between these and Mr. Graham's numbers, considering the well-known accuracy of that ingenious gentleman. Philos. Trans. vol. 45, pa. 279, vol. 62, pa. 476, vol. 69, 70, 71. See also the description of a new dipping-needle, by Dr. Lorimer, in the Philosophical Transactions 1775; and in the supplement to Cavallo's Treatise on Magnetism.

It is certain however, from many experiments and observations, that the dip is different in different latitudes, and that it increases in going northward. It appears from a table of observations made with a marine dipping-needle of Mr. Nairne's, in a voyage towards the north pole, in 1773, that

in latitude $60^{\circ} 18'$ the dip was $73^{\circ} 0'$,
in latitude $70^{\circ} 45'$ the dip was $77^{\circ} 52'$,
in latitude $80^{\circ} 12'$ the dip was $81^{\circ} 52'$, and
in latitude $80^{\circ} 27'$ the dip was $82^{\circ} \frac{1}{2}$.

See Phipps's Voyage, pa. 122. See also the Observations of Mr. Hutchins, made in Hudson's Bay and Straits, Philos. Trans. vol. 65, pa. 129.

Burrowes, Gilbert, Ridley, Bond, &c, endeavoured to apply this discovery of the dip to the finding of the latitude; and Bond, going still farther, first of any proposed finding the longitude by it; but for want of observations and experiments, he could not go any length. Mr. Whiston, being furnished with the further observations of Colonel Windham, Dr. Halley, Mr. Pound, Mr. Cunningham, M. Noel, M. Feuille, and his own, made great improvements in the doctrine and use of the dipping-needle, brought it to more certain rules, and endeavoured in good earnest to find the longitude by it. For this purpose, he observes, 1st, That the true tendency of the north or south-end of every magnetic needle, is not to that point of the horizon, to which the horizontal needle points, but towards another, directly under it, in the same vertical, and in different degrees under it, in different ages, and at different places. 2dly, That the power by which the horizontal-needle is governed, and all our navigation usually directed, it is proved is only one quarter of the power by which the dipping-needle is moved; which should render the latter far the more effectual and accurate instrument. 3dly, That a dipping-needle of a foot long will plainly show an alteration of the angle of inclination, in these parts of the

world, in half a quarter of a degree, or $7\frac{1}{2}$ geographical miles; and a needle of 4 feet, in 2 or 3 miles; i. e. supposing these distances taken along, or near a meridian. 4thly, A dipping-needle, 4 feet long, in these parts of the world, will show an equal alteration along a parallel, as another of a foot long will show along a meridian; i. e. that will, with equal exactness, show the longitude, as this the latitude.

This depends on the position of the lines of equal dip, in these parts of the world, which are found to lie about 14 or 15 degrees from the parallels. Hence he argues, that as we can have needles of 5, 6, 7, 8, or more feet long, which will move with strength sufficient for exact observation; and since microscopes may be applied for viewing the smallest divisions of degrees on the limb of the instrument, it is evident, that the longitude at land may thus be found to less than 4 miles.

And as there have been many observations made at sea with the same instrument by Noel, Feuille, &c, which have determined the dip usually within a degree, sometimes within $\frac{1}{2}$ or $\frac{1}{3}$ of a degree, and this with small needles, of 5 or 6, or at the most 9 inches long; it is inferred, that the longitude may be found, even at sea, to less than half a quarter of a degree. This premised, the observation itself follows.

To find the Longitude or Latitude by the Dipping-Needle. —If the lines of equal dip, below the horizon, be drawn on maps, or sea-charts, from good observations, it will be easy, from the longitude known, to find the latitude; and from the latitude known, to find the longitude, either at sea or land.—Suppose, for example, a person travelling or sailing along the meridian of London, should find that the angle of dip, with a needle of one foot, was 75° ; the chart will show that this meridian, and the line of dip, meet in the latitude of $53^{\circ} 11'$; which is therefore the latitude sought.—Or if he be travelling or sailing along the parallel of London, i. e. in $51^{\circ} 31'$ north latitude, and find the angle of dip 74° ; then this parallel, and the line of this dip, will meet on the map in $1^{\circ} 46'$ of east longitude from London; which therefore is the longitude sought.

Many other persons have uselessly endeavoured to determine the longitude of places from the dip of the magnetic needle. One among this number, was Mandillo, a Genoese pilot, who contrived a small weight for measuring the degree of inclination of the needle; and though nothing could be much more absurd, he continued in his opinion to the last, and died under the persuasion that he had truly discovered a method of determining the longitude, and that justice had not been done him, nor his merits fairly appreciated.

DIRECT, in Arithmetic, is when the proportion of any terms, or quantities, is in the natural or direct order in which they stand; being the opposite to *inverse*, which considers the proportion in the inverted order of the terms. So, $3 : 4 :: 6 : 8$ directly; or $3 : 4 :: 8 : 6$ inversely.

Rule of Three DIRECT, is when both pairs of terms are in direct proportion.

DIRECT, in Astronomy. A planet is said to be direct, or its motion direct, when it goes forward by its proper motion in the zodiac, according to the succession or order of the signs; or when it appears so to do, to an observer standing on the earth. Whereas it is said to be, or to move, retrograde, when it appears to go the contrary way, or backward; and to be stationary, when it seems not to move either way.

DIRECT Dials. See DIAL and DIALLING.

DIRECT, in Optics. Direct vision is that performed by direct rays; in contradistinction to vision by refracted, or reflected rays. Direct vision is the subject of optics, which prescribes the laws and rules of it.

DIRECT Rays, are those which pass on in right lines from the object to the eye, without being turned out of their rectilinear direction by any intervening body, either opaque or pellucid; or without being either reflected or refracted.

DIRECT Sphere. See RIGHT Sphere.

DIRECTION, in Astronomy, the motion and other phenomena of a planet, when direct.

Line of DIRECTION, in Gunnery, is the direct line in which a piece is pointed. Sometimes a line of direction is marked on the upper side of the gun, by a small notch or slit, or knob, in the base and muzzle rings: but, unless the two wheels of the carriage stand equally high, this line will be fallacious; for which reason gunners commonly find a new line of direction every time, by means of a plummet.

Line of DIRECTION, in Mechanics, denotes the line in which a body moves, or endeavours to proceed.

Angle of DIRECTION, is that comprehended between the lines of direction of two conspiring powers.

Quantity of DIRECTION, is used for the product arising from multiplying the velocity of the common centre of gravity, in a system of bodies, by the sum of their masses. In the collision of bodies, the quantity of direction is the same both before and after the impulse.

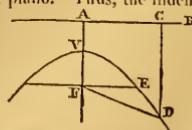

DIRECTION of the Loadstone, that property by which the magnet, or a needle touched by it, always presents one of its ends towards one of the poles of the world, and the opposite end to the other pole. This is also called the polarity of the magnet or needle. The attractive property of the magnet was known long before its directive; and the directive long before the inclinatory.

Number of DIRECTION, is the number of days that Septuagesima Sunday falls after the 17th of January. See NUMBER.

DIRECTLY, in Geometry: We say two lines lie directly against each other, when they are parts of the same right line: also quantities are said to be directly proportional, when the proportion is according to the order of the terms; in contradistinction to inversely, or reciprocally proportional, which is taking the proportion contrary to the order of the terms.

In Mechanics, a body is said to strike or impinge directly against another body, when the stroke is in a direction perpendicular to the surface at the point of impact. And a sphere, in particular, strikes directly against another, when the line of direction passes through both their centres.

DIRECTRIX, a particular right line, perpendicular to the axis of a conic section, and much referred to by the authors who demonstrate the properties of those curves from the description of them in plano. Thus, the indefinite right line AB is the directrix, and is so placed, that if any point E be assumed without it, and while the line ED revolves around E as a centre, a point D moves in it in such a manner, that its distance from E shall always be to CD, its distance from the line AB, in a constant

ratio; then the curve vn , described by the point n , is a conic section. And the curve is an ellipse, or a parabola, or an hyperbola, according as FD is less than, equal to, or greater than, CD , or FV than VA . The constant ratio of FD to CD , or of FV to VA , is called the determining ratio. In the ellipse, the distance AV of the directrix from the vertex, is greater than VF the distance of the focus from the vertex; in the parabola AV is equal to VF ; but in the hyperbola AV is less than VF .

DIRECTRIX, in a Parabola, a line perpendicular to the axis produced, at the distance of the focus without the vertex; as shown above.

DIRIGENT, a term expressing the line of motion, along which a descriptible line, or surface, is carried in the genesis of any plane or solid figure. Thus, if the line AB move parallel to itself, and along the line AD , so that the point A always keeps in the line AD , and the point B in the line BC ; a parallelogram $ABCD$ will be formed; of which the line AB is the descriptible, and the line AD the dirigent. So also, if the surface AEG be supposed carried along the line AD , in a position always parallel to itself at its first situation, the solid AF will be formed; where the surface AE is the descriptible, and the line AD is the dirigent.

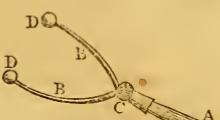

DISC, or **DISK**, the body or face of the sun or moon; such as it appears to us; for though they be really spherical bodies, they are apparently circular planes.—The diameter of the disc is considered as divided into 12 equal parts, called digits; by means of which it is, that the magnitude of an eclipse is measured, or estimated.—In a total eclipse of either of those luminaries, the whole disc is obscured, or darkened; in a partial eclipse, only part of them.

Illuminated Disc of the Earth. See CIRCLE of Illumination.

Disc, in Optics, the magnitude of a telescope glass, or the width of its aperture, whatever its figure be, whether a plane, convex, meniscus, or the like.

DISCHARGER, or **DISCHARGING Rod**, in Electricity, consists of a handle of glass or baked wood, A , and two bent metal rods, BB , terminating in points, and capable of being screwed into the knobs DD , which move by a joint C , fixed to the handle A . Thus it may be used either with the points or balls, as occasion requires; and by being made moveable on a joint, it may be applied to larger or smaller jars at pleasure. By bringing one of these knobs or points to one coated side of a charged electric, and the other to the other side, or to any conductor connected with it, the communication is completed between the two sides, and the electric is discharged.—For the description and use of a Universal Discharger, by Mr. Henly, with which many curious experiments may be performed, see Cavallo's Electricity, pa. 164.

DISCORD, the relation of two sounds which are always, and of themselves disagreeable, whether applied in succession or consonance.

DISCOUNT, or **Rebate**, is used for an allowance made on a bill, or any other debt not yet become due, in consideration of making present payment of the bill or debt.

Among merchants and traders, it is usual to allow a sum for discount that is equal to the interest of the debt, calculated for the time till it becomes due: but this is not the correct or just sum; for, as the true value of the discount is equal to the difference between the debt and its present worth, it is equal only to the interest of that present worth, instead of the interest on the whole debt. And therefore the rule for finding the true discount is this;

As the amount of $100l$, for the given rate and time :
Is to the given sum or debt :

So is the interest of $100l$, for the given rate and time :
To the discount of the debt.

So that, if p be the principal or debt, r the rate of interest per cent, and t the time;

then as $100 + rt : p :: rt : \frac{prt}{100 + rt}$, which is the true discount. Hence also $p - \frac{prt}{100 + rt} = \frac{100p}{100 + rt}$ is the present worth, or sum to be received.

For Ex. Suppose it be required to find the discount of $250l$, for five months, at the rate of 5 per cent per annum interest. Here $p = 250$, $r = 5$, and $t = \frac{5}{12}$ or 5 months; then $\frac{prt}{100 + rt} = \frac{250 \times 5 \times \frac{5}{12}}{100 + 5 \times \frac{5}{12}} = \frac{250 \times 25}{1200 + 25} = \frac{250}{49} = 5l 2s \frac{2}{49}$ the discount sought.

A Table of Discounts may be seen in Smart's Tables of Interest, the use of which makes calculations of discount very easy.

DISCOUNT is also the name of a rule in books of Arithmetic, by which calculations of Discount are made.

DISCRETE, or **DISJUNCT**, **Proportion**, is that in which the ratio between two or more pairs of numbers is the same, and yet the proportion is not continued, so that the ratio may be the same between the consequent of one pair and the antecedent of the next pair.

Thus, if the numbers or proportion $6 : 8 :: 3 : 4$ be considered: the ratio of 6 to 8 is the same as that of 3 to 4, and therefore these four numbers are proportional: but it is only discretely or disjunctly, and not continued; for 8 to 3 is not the same ratio as the former; that is, the proportion is broken off between 8 and 3, and not continued throughout, as it is in these following four numbers, which are called continual proportionals, viz, $3 : 6 :: 12 : 24$.

DISCRETE Quantity, is such as is not continued and joined together. Such for instance is any number; for its parts, being distinct units, cannot be united into one continuum; for in a continuum there are no actual determinate parts before division, but they are potentially infinite; so that it is usually and truly said that continued quantity is divisible in infinitum.

DISDIAPASON, in Music, a compound concord, in the quadruple ratio of 4 to 1, being a fifteenth or double eighth, and is produced when the voice goes from the first tone to the fifteenth.

DISJUNCT Proportion. See **DISCRETE Proportion**.
DISK. See Disc.

DISPART, a term in Gunnery, used for a mark set upon the muzzle-ring of a piece of ordnance, of such height, that a sight-line taken from the top of the base ring near the vent or touch-hole, to the top of the dispart near the muzzle, may be parallel to the axis of the con-

cave cylinder; for which reason it is evident, that the height of the dispart is equal to the difference between the radii of the piece at the base and muzzle-rings, or to half the difference of the diameters there. Hence comes the common method of disparting the gun, which is this: Take, with the calipers, the two diameters, viz., of the base ring and the place where the dispart is to stand, subtract the less from the greater, and take half the difference, which will be the length of the dispart; this is commonly cut to that length from a small bit of wood, and so fixed upright in its place with a bit of wax or pitch.

DISPERSION, in Dioptrics, is the divergency of refracted rays of light.

Point of Dispersion, is a point from which refracted rays begin to diverge, when their refraction renders them divergent.—It is called point of dispersion, in opposition to the point of concourse, or point in which converging rays concur after refraction. But it is more usual to call the latter the focus, and the former the virtual focus.

Dispersion of Light, occasioned by the refrangibility of the rays, or the nature of the refracting medium. See **ABERRATION**, and **INFLECTION**.

Dr. Wollaston's mode of examining refractive and dispersive powers is described in Philos. Trans. for 1802, or Nicholson's Journ. vol. 4, pa. 89. Extensive tables of refractive and dispersive powers are given in Dr. T. Young's Nat. Philos. vol. 2, pa. 296, 299.

DISSIPATION, in Physics, a gradual, slow, insensible loss or consumption of the minute parts of a body; or, more properly, the flux by which they fly off and are lost. See **EFLUVIA**.

Circle of DISSIPATION of ABERRATION, in Optics, denotes that circular space on the retina of the eye, which is occupied by the rays of each pencil in indistinct vision; thus, if the distance of the object, or the constitution of the eye, be such, that the image falls beyond the retina, as when objects are too near; or before the retina, when the rays have not a sufficient divergency; the rays of a pencil, instead of being collected into a central point, will be dissipated over this circular space: and, all other circumstances being alike, this circle will be greater or less, according to the distances from the retina of the foci of refracted rays. But this circle causes no perceptible difference in the distinctness of vision, unless it exceed a certain magnitude: as soon as that is the case, we begin to perceive an indistinctness, which increases as that circle increases, till at length the object is lost in confusion. This circle is also greater or less, according to the greater or less magnitude of the visible object; and though it be not easy to assign the diameter of the said circle, it seems very probable that vision continues distinct for all such distances, or so long as these circles, or the pencils of light from them, do not touch one another on the retina; and the indistinctness begins when the said circles begin to interfere. It has been often observed, that a precise union of the respective rays on the retina, is not necessary to distinct vision; but the first author who ascertained the fact beyond all doubt, was Dr. Jurin. See a variety of observations and experiments on this subject, in his Essay on Distinct and Indistinct Vision, in Smith's Optics, Appendix. In the Philos. Trans. for 1789, pa. 256, is an excellent paper on this subject by Dr. Maskelyne; in which he computes the diameter of the circle of dissipation at .002667 of an inch, making it answer to an external

angle of 15°, which he shows is very compatible with distinct vision. See also **MOON**, and **VISION**.

Radius of DISSIPATION, is the radius of the circle of dissipation.

DISSOLVENT, something that dissolves; i.e. divides, and reduces a body into its smallest parts.

DISSOLUTION, is a separation of the structure of a body, into small or minute parts. According to Newton, and others, this is effected by certain powerful attractions.

DISSONANCE, or **DISCORD**, is a false consonance or concord; being produced by the mixture or meeting of two sounds which are disagreeable to the ear.

DISTANCE, properly speaking, denotes the shortest line between two points, objects, &c.

DISTANCE, in Astronomy, as of the sun, planets, comets, &c. The Real Distances are found from the parallaxes of the planets, &c. See **PARALLAX**, **PLANET**, and **TRANSIT**. The distance of the earth from the sun has been determined at 95 millions of miles, by the late transits of Venus; and from this one real distance, and the several relative distances, by analogy are found all the other real distances, as in the table below.

The Proportional or Relative Distances of the planets are very well deduced from the theory of gravity: for Kepler has long since discovered, and Newton has demonstrated, that the squares of their periodical times are proportional to the cubes of their distances. Kepler's Epit. Astron. lib. 4; Newton's Principia, lib. 3, phæn. 4; and Gregory's Astron. book 1, prop. 40. If therefore the mean distance of the earth from the sun be assumed, or supposed 100000, we shall then, from the foregoing analogy, and the known periodical times, obtain the relative distances of the other planets: thus,

The Periodical Revolutions in Days and Parts.

Mercury, Venus, Earth, Mars, Jupiter, Saturn, Herschel,
87 $\frac{2}{3}$ 224 $\frac{4}{7}$ 365 $\frac{1}{4}$ 686 $\frac{2}{3}$ 4332 $\frac{1}{2}$ 10759 $\frac{1}{4}$ 30445.

Relative Distance of the Planets.

	Kepler.	Cassini.	Halley.	De la Lande.	Log. of those distances.
Mercury	38806	38806	38710	38710	9 \cdot 5878221
Venus	72413	72340	72333	72333	9 \cdot 8593379
Earth	100000	100000	100000	100000	10 \cdot 0000000
Mars	152350	152373	152369	152369	10 \cdot 1828973
Vesta	-	-	-	-	235513
Juno	-	-	-	-	266400
Pallas	-	-	-	-	276500
Ceres	-	-	-	-	277600
Jupiter	520000	520290	520098	520279	10 \cdot 7162364
Saturn	951000	954180	954007	954072	10 \cdot 9795813
Uranus or Herschel	-	-	-	1908180	11 \cdot 2806193

And from these relative distances, the real distance of any planet is easily found, that of the earth being known, by the following proportion, namely; as 100000 : 95000000, or as 1 to 950, so is the relative distance in the table, to the real distance required.

Hence we find the real distances expressed in even millions to be,

Mercury,	Venus,	Earth,	Mars,	Vesta,	Juno,	Pallas,	
37	66	95	145	223 $\frac{1}{2}$	253 $\frac{1}{2}$	262 $\frac{1}{2}$	
				Ceres,	Jupiter,	Saturn,	Uranus,
				262 $\frac{1}{2}$	493 $\frac{1}{2}$	903 $\frac{1}{2}$	1813.

For the distances of the secondary planets from the centres of their respective primaries, see **SATELLITES**.

As to that of the fixed stars, as having no sensible parallax, little more can be done than to guess at it.

Distance of the Sun from the Moon's node, or apogee, is an arch of the ecliptic, intercepted between the sun's true place and the moon's node, or apogee. See *Node*.

Curtate Distance. See *CURTATE*.

Distance of the Bastions, in Fortification, is the side of the exterior polygon.

Accessible Distances, in Geometry, are measured with the chain, decempeda or ten-foot rod, or the like.

Inaccessible Distances, are found by taking bearings to them, from the two extremities of a line whose length is given. Various ways of performing this may be seen in my Treatise on Mensuration, sect. 3, on Heights and Distances.

Distance, in Geography, is the arch of a great circle intercepted between two places.

To find the distance of two places, A and B, far remote from each other. Assume two stations, c and d, from which both the places A and B may be seen; and there, with a theodolite, observe the quantity of the angles $\angle ACD$, $\angle BCD$, $\angle ADC$, $\angle BDC$, and measure any distance as AC. Then, in the triangle ACD, there are given the angles $\angle ACD$, $\angle ADC$, and the side AC; to find the side CD.—Next, in the triangle BCD, there are given the angles $\angle BCD$, $\angle BDC$, and the side CD; to find the side BC.—Lastly, in the triangle ABC, there are given the angle $\angle ACB$, and the sides AC, CB; to find the side AB, which is the distance sought. And in these operations, the triangles may be computed either as plane triangles, or as spherical ones, as the case may require, or according to the magnitude of the distances.

The Distance of a remote object may also be found from its height. This admits of several cases, according as the distances are large or small, &c. 1st, Suppose that from the top of a tower at A, whose height AB is 120 feet, there be taken the angle $\angle BAC = 33^\circ$, and the angle $\angle BAD = 64^\circ\frac{1}{2}$, to two trees, or other objects, c, d; to find the distance between them cd, and the distance of each from the bottom of the tower at B.

First, rad. : tang. $\angle BAD$:: AB : BD = 251:585,
next, rad. : tang. $\angle BAC$:: AB : BC = 77:929,
their difference is the distance CD = 173:656.

2d, Suppose it be required to find the distance to which an object can be seen, by knowing its altitude; ex. gr. the Peak of Teneriffe, whose height is said to be 3 miles above the level of the sea, supposing the circumference of the earth 25,000 miles, or the diameter 7958 miles. Let FG be the radius = 3979, EF = 3 the height of the mountain, and EH a tangent to the earth at the point H, which is the farthest point to which the top of the mountain e can be seen. Here, in the right-angled triangle EGH, are given the hypotenuse EG = 3982, and the leg GH = 3979; to find the other leg HE = 154 $\frac{1}{2}$ miles = the distance sought nearly. Or, rather, as EG : GH :: rad. : cosin. $\angle G = 29^\circ 13'\frac{1}{2}$; then as $360^\circ : 29^\circ 13'\frac{1}{2} :: 25,000 : 154\frac{1}{2}$ miles = the arch of dist. HE sought, the same as before.

Vol. I.

3d, If the eye, instead of being in the horizon at H, were elevated above it at I, any known height, as suppose 264 feet, or $\frac{1}{25}$ th of a mile, as on the top of a high eminence; then the mountain can be seen much farther off along the line IE, and the distance will be the two tangents IH and HE, or rather the two arcs KH and HE. Hence, as above, as IG : GH :: rad. : cosin. $\angle IGH = 17^\circ\frac{1}{2}$; then as $360^\circ : 17^\circ\frac{1}{2} :: 25,000 : 20$ miles = the arc KH; this added to the former arc HE = 154 $\frac{1}{2}$, makes the whole arc KE = 174 $\frac{1}{2}$ miles, for the whole distance to which the top of the mountain can be seen in this case.

Apparent Distance, in Optics, that distance which we judge an object is placed at when seen afar off. This is usually very different from the true distance; because we are apt to think that all very remote objects, whose parts cannot well be distinguished, and which have no other object in view near them, are at the same distance from us, though perhaps the one is thousands of miles nearer than the other, as is the case with regard to the sun and moon.

M. Lohire enumerates five circumstances, which assist us in judging of the distance of objects; viz, their apparent magnitude, the strength of the colouring, the direction of the two eyes, the parallax of the objects, and the distinctness of their small parts. On the contrary, Dr. Smith maintains, that we judge of distance principally, or solely, by the apparent magnitude of objects; and concludes universally, that the apparent distance of an object seen in a glass, is to its apparent distance seen by the naked eye, as the apparent magnitude to the naked eye is to its apparent magnitude in the glass. But it was long since observed by Alhazen, that we do not judge of distance merely by the angle under which objects are seen; and Mr. Robins clearly shows that Dr. Smith's hypothesis is contrary to fact, in the most common and simple cases. Thus, if a double convex glass be held upright before some luminous object, as a candle, there will be seen two images, one erect, and the other inverted; the first is made simply by reflexion from the nearest surface; the second by reflexion from the farther surface, the rays undergoing a refraction from the first surface both before and after the reflexion. If this glass has not too short a focal distance, when it is held near the object, the inverted image will appear larger than the other, and also nearer; but if the glass be carried off from the object, though the eye remain as near to it as before, the inverted image will be diminished so much faster than the other, that at length it will appear much less than it, but still nearer. Here, says Mr. Robins, two images of the same object are seen under one view, and their apparent distances immediately compared; and it is evident that those distances have no necessary connexion with the apparent magnitude. This experiment may be made still more convincing, by sticking a piece of paper on the middle of the lens, and viewing it through a short tube. He observes further, that the apparent magnitude of very distant objects is neither determined by the magnitude of the angle only under which they are seen, nor is the exact proportion of that angle compared with their true distance, but is compounded also with a deception concerning that distance; so that if we had no idea of difference in the distance of objects, each would appear in magnitude proportional to the angle under which it was seen; and if our supposition of the distance were always just, our idea of their magnitude would be unvaried, in all distances; but in proportion as we err in our conception of their distance, the greater angle sug-

31

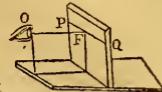

gests a greater magnitude. By not attending to this compound effect, Mr. Robins apprehends that Dr. Smith was led into his mistake.

Dr. Porterfield has made several remarks on the five methods of judging concerning the distance of objects above recited from M. Lahire; and he has also added to them one more, viz, the conformation of each eye. See *Circle of DISSIPATION*. This, he says, can be of no use to us, with respect to objects that are placed without the limits of distinct vision. But the greater or less confusion with which the object appears, as it is more or less removed from those limits, will assist the mind in judging of its distance; and the more confused it appears, the farther we shall imagine it to be from us. However, this confusion has its limits; for when an object is placed at a certain distance from the eye, to which the breadth of the pupil bears no sensible proportion, the rays proceeding from a point in the object may be considered as parallel; in which case, the picture on the retina will not be sensibly more confused, though the object be removed to a much greater distance. The most universal, and often the most sure means of judging of the distance of objects, he says, is the angle made by the optic axes: our two eyes are like two different stations, by the assistance of which, distances are taken; and this is the reason why those persons who have lost the sight of one eye so frequently miss their mark in pouring liquor into a glass, snuffing a candle, and such other actions as require that the distance be exactly distinguished. With respect to the method of judging by the apparent magnitude of objects, he observes that this can only serve when we are otherwise acquainted with their real magnitude. Thus he accounts for the deception to which we are liable in estimating distances, by any extraordinary magnitudes that terminate them; as, in travelling towards a large city, castle, or cathedral, we fancy they are nearer than they really are. Hence also, animals and small objects seen in a valley contiguous to large mountains, or on the top of a mountain or high building, appear exceedingly small. Dr. Jurin accounts for the last-mentioned phenomenon, by observing that we have no distinct idea of distance in that oblique direction, and therefore judge of them merely by their pictures on the eye.

Dr. Porterfield observes, with respect to the strength of colouring, that if we are assured they are of a similar colour, and one appears more bright and lively than the other, we judge that the brighter object is the nearer. When the small parts of objects appear confused, or do not appear at all, we judge that they are at a great distance, and *vice versa*; because the image of any object, or part of an object, diminishes as the distance of it increases. Finally, we judge of the distance of objects by the number of intervening bodies, by which it is divided into separate and distinct parts; and the more this is the case, the greater will the distance appear. Thus distances upon uneven surfaces appear less than upon a plane, because the inequalities do not appear, and the whole apparent distance is diminished by the parts that do not appear in it; and thus the banks of a river appear contiguous as viewed at a distance, when the river is low and not seen. *Accidens de la Vue*, pa. 358. See Priestley's Hist. of Vision, pa. 205, and pa. 689.

DISTANCE, in Navigation, is the number of miles or leagues that a ship has sailed from any point or place. See *SAILING*.

Line of DISTANCE, in Perspective, is a right line drawn from the eye to the principal point: as the line oF , drawn between the eye at o , and the principal point F ; which being perpendicular to the plane, rq is therefore the distance of the eye from that plane.

Point of DISTANCE, in Perspective, is a point in the horizontal line at the same distance from the principal point, as the eye is from the same. Such are the points P and Q , in the horizontal line rq , whose distance from the principal point F , is equal to that of the eye from the same point.

DISTINCT Base, in Optics, is that distance from the pole of a convex glass, at which objects, beheld through it, appear distinct and well defined: so that the distinct base is the same with what is otherwise called the focus. The distinct base is caused by the collection of the rays proceeding from a single point in the object, into a single point in the representation: and therefore concave glasses, which do not unite, but scatter and dissipate the rays, can have no real distinct base.

DISTINCT Vision. See *VISION*.

DITCH, in Fortification, called also Foss, and Moat, is a trench dug round the rampart, or wall of a fortified place, between the scarp and countescarp.

Ditches are either dry, or wet, that is having water in them; both of which have their particular advantages. The earth dug out of the ditch serves to raise the rampart. The ditch in front should be of such breadth as that tall trees may not reach over it, being from 12 to 24 fathoms wide, and 7 or 8 feet deep. The ditches on the sides are made smaller; but the most general rule is perhaps, that the dimensions of the ditch should be such as that the earth dug out may be sufficient to build the rampart of a proper magnitude. The space sometimes left between the rampart and ditch, being about 6 or 8 feet, is called the berm, or list, serving to pass and repass, and to prevent the earth from rolling into the ditch.

DITONE, in Music, an interval comprehending two tones, a greater and a less. The ratio of the sounds that form the ditone, is 4 to 5; and that of the semi-ditone, 5 to 6.

DITTON (HUMPHREY), an eminent mathematician, was born at Salisbury, May 29, 1675. Being an only son, and his father observing in him an extraordinary good capacity, determined to cultivate it with a good education. For this purpose he placed him in a reputable private academy; on quitting of which, at the desire of his father, though against his own inclination, he engaged in the profession of divinity, and began to exercise his function at Tunbridge in the county of Kent, where he continued to preach some years; during which time he married a lady of that place.

But a weak constitution, and the death of his father, induced Mr. Dutton to quit that profession; and at the persuasion of Dr. Harris and Mr. Whiston, both eminent mathematicians, he engaged in the study of mathematics, a science to which he had always a strong inclination. In the prosecution of this science, he was much encouraged by the success and applause he received; being greatly esteemed by the chief professors of it, and particularly by

Sir Isaac Newton, by whose interest and recommendation he was elected master of the new Mathematical School in Christ's Hospital; where he continued till his death, which happened in 1715, in the 40th year of his age, much regretted by the philosophical world, who expected many useful and ingenious discoveries from his assiduity, learning, and penetrating genius.

Mr. Ditton published several mathematical and other tracts, as below.—1. Of the Tangents of Curves, &c. Philos. Trans. vol. 23.

2. A Treatise on Spherical Catoptrics, published in the Philos. Trans. for 1705; from whence it was copied and reprinted in the Acta Eruditorum, 1707, and also in the Memoirs of the Academy of Sciences at Paris.

3. General Laws of Nature and Motion; 8vo, 1705. Wolfius mentions this work, and says that it illustrates and renders easy the writings of Galileo, Huygens, and the Principia of Newton. It is also noticed by La Roche, in the Memoires de Literature, vol. 8, pa. 46.

4. An Institution of Fluxions, containing the first Principles, Operations, and Applications, of that admirable Method, as invented by Sir Isaac Newton; 8vo, 1706. This work, with additions and alterations, was again published by Mr. John Clarke, in the year 1726.

5. In 1709 he published the Synopsis Algebraica of John Alexander, with many additions and corrections.

6. His Treatise on Perspective was published in 1712. In this work he explained the principles of that art mathematically; and besides teaching the methods then generally practised, gave the first hints of the new method afterward enlarged upon and improved by Dr. Brook Taylor; and which was published in the year 1715.

7. In 1714, Mr. Ditton published several pieces, both theological and mathematical; particularly his Discourse on the Resurrection of Jesus Christ; and The New Law of Fluids, or a Discourse concerning the Ascent of Liquids, in exact Geometrical Figures, between two nearly contiguous Surfaces. To this was annexed a tract, to demonstrate the impossibility of thinking or perception being the result of any combination of the parts of matter and motion: a subject which was much agitated about that time. To this work also was added an advertisement from him and Mr. Whiston, concerning a method for discovering the longitude, which it seems they had published about half a year before. This attempt probably cost our author his life; for though it was approved and countenanced by Sir Isaac Newton, before it was presented to the Board of Longitude, and the method has since been successfully put in practice, in finding the longitude between Paris and Vienna, yet that board determined against it: so that the disappointment, together with some public ridicule (particularly in some verses written by Dean Swift), affected his health, that he died the ensuing year, 1715.

In an account of Mr. Ditton, prefixed to the German translation of his Discourse on the Resurrection, it is said that he had published, in his own name only, another method for finding the longitude; but this Mr. Whiston denied. However, Raphael Levi, a learned Jew, who had studied under Leibnitz, informed the German editor, that he well knew that Ditton and Leibnitz had corresponded on the subject; and that Ditton had sent to Leibnitz a delineation of a machine he had invented for that purpose; which was a piece of mechanism constructed with many wheels like a clock, and which Leibnitz highly approved of for land use; but doubted whether it would

answer on ship-board, on account of the motion of the ship.

DIVERGENT Point. See *Virtual Focus*.

DIVERGENT, or DIVERGING Lines, in Geometry, are those whose distance is continually increasing.—Lines which diverge one way, converge the other.

DIVERGENT, or DIVERGING, in Optics, is particularly applied to rays which, issuing from a radiant point, or having, in their passage, undergone a refraction, or reflexion, do continually recede farther from each other.

In this sense the word is opposed to convergent, which implies that the rays approach each other, or that they tend to a centre, where they intersect, and, being continued, go on diverging. Indeed all intersecting rays, or lines, diverge both ways from the centre, or point of intersection.

Concave glasses render the rays diverging; and convex ones, converging.—Concave mirrors make the rays converge; and convex ones, diverge.—It is demonstrated in Optics, that as the diameter of a pretty large pupil does not exceed $\frac{1}{3}$ of a digit; diverging rays, flowing from a radiant point, will enter the pupil as parallel, to all intents and purposes, if the distance of the radiant from the eye amount to 40,000 feet. See *Focus, Light, and Vision*.

DIVERGING HYPERBOLA, is one whose legs turn their convexities toward each other, and run out contrary ways. See *Hyperbola*.

DIVERGING Parabola. See *Diverging PARABOLA*.

DIVERGING Series, is a series whose terms always become larger the farther they are continued.

DIVIDEND, in Arithmetic, is the number given to be divided by some other number, called the divisor. Or it is the number given to be divided, or separated, into a certain number of equal parts, viz. as many as the divisor contains units; and the number of such equal parts is called the quotient. Or, more generally, the dividend contains the divisor, as many times as the quotient contains unity.—The dividend is the numerator of a fraction, whose denominator is the divisor, and the quotient is the value of the fraction. Thus, $\frac{2}{3} = 4$, and $\frac{3}{2} = 75$.

DIVING. The art, or act of descending under water, to considerable depths, and remaining there for a certain time. The uses of diving are very considerable, particularly in the fishing for pearls, corals, sponges, &c.

Various methods have been proposed, and engines contrived, to render the business of diving more safe and easy. The great point in all these, is to furnish the diver with fresh air, without which he must either make but a short stay, or perish. Those who dive for sponges in the Mediterranean, help themselves by carrying down sponges dipped in oil in their mouths; but considering the small quantity of air that can be contained in the pores of a sponge, and how much that little will be contracted by the pressure of the incumbent water, it is evident that such a supply cannot be very useful; since it is found by experiment, that a gallon of air included in a bladder, and by a pipe reciprocally inspired and expired by the lungs, becomes unfit for respiration in little more than one minute; for though its elasticity be but little altered in passing the lungs, yet it loses its vivifying spirit, and is rendered unfit for the support of animal life. Dr. Halley assures us, a naked diver, without a sponge, cannot remain above two minutes inclosed in water; nor much longer with one, without suffocating; nor, without long practice, near so long: per-

sons unaccustomed to diving generally begin to be suffocated in about half a minute. Besides, if the depth be considerable, the pressure of the water on the vessels makes the eyes blood-shotten, and frequently occasions a spitting of blood: hence, where there has been occasion to continue long at the bottom, some have contrived double flexible pipes, to circulate air down into a cavity inclosing the diver, as with armour, both to furnish air, and to bear off the pressure of the water, and give leave to his breast to dilate upon inspiration; the fresh air being forced down one of the pipes with bellows, and returning by the other, not unlike to an artery and vein.

But this method is impracticable when the depth exceeds three fathoms; the water embracing the bare limbs so closely, as to obstruct the circulation of the blood in them; and withal pressing so strongly on all the junctures where the armour is made tight with leather; that if there be the least defect in any of them, the water rushes in, and instantly fills the whole engine, to the great danger of the diver's life.

Diving-Bell, is a machine contrived to remedy all these inconveniences. In this the diver is safely conveyed to any reasonable depth, and may stay more or less time under the water, as the bell is greater or less; and it is most conveniently made in form of a truncated cone, the smaller base being closed, and the larger open; being weighed with lead, and so suspended, that it may sink full of air, with its open basis downward, and as near as may be in a situation parallel to the horizon, so as to close with the surface of the water all at once.

The diver sitting under this machine, sinks down with the included air to the depth desired; and if the cavity of the vessel can contain a ton of water, a single man may remain a full hour, without much inconvenience, at five or six fathoms deep; but the lower he goes, still the more the included air contracts itself, according to the weight of the water that compresses it; so that at thirty-three feet deep, the bell becomes half-full of water; the pressure of the incumbent fluid being then equal to that of the atmosphere; and at all other depths, the space occupied by the compressed air in the upper part of its capacity, is to the space filled with water, as thirty-three feet to the depth of the surface of the water in the bell below its common surface; and this condensed air, being taken in with the breath, soon insinuates itself into all the cavities of the body, and has no ill effect, provided the bell be permitted to descend so slowly as to allow time for that purpose.

One inconvenience that attends it, is found in the ears, within which there are cavities which open only outwards, and that by pores so small, as not to give admission even to the air itself, unless they be dilated and distended by a considerable force; hence, on the first descent of the bell, a pressure begins to be felt on each ear, which by degrees becomes painful, till the force overcoming the obstacle, that constricts these pores, yields to the pressure, and letting some condensed air slip in, presently ease ensues; the bell descending lower, the pain is renewed, and afterwards it is again eased in the same manner. But the greatest inconvenience of this engine is, that the water entering it, contracts the bulk of air into so small a compass, that it soon heats, and becomes unfit for respiration: so that there is a necessity for its being drawn up to recruit it; besides the uncomfortable situation of the diver, who is almost covered with water.

To obviate the difficulties of the diving-bell, Dr. Halley,

to whom we owe the preceding account, contrived some further apparatus, by which not only to recruit and refresh the air from time to time, but also to keep the water wholly out of it at any depth; which he effected after the following manner:—His diving-bell (plate ix, fig. 6) was of wood, 3 feet wide at top, 5 feet at bottom, and 8 feet high, containing about 63 cubic feet in its concavity, coated externally with lead so heavy, that it would sink empty; a particular weight being distributed about its bottom B , to make it descend perpendicularly, and no otherwise. In the top was fixed a meniscus glass D , concave downwards, like a window, to let in light from above; with a cock, as at E , to let out the hot air; and a circular seat, as at LM , for the divers to sit on: and below, about a yard under the bell, was a stage suspended from it by three ropes, each charged with a hundred weight, to keep it steady, and for the divers to stand upon to do their business. The machine was suspended from the mast of a ship by a sprit, which was secured by stays to the mast-head, and was directed by braces to carry it overboard clear of the side of the vessel, and to bring it to anchor.

To supply air to this bell when under water, he had two barrels, as C , holding 36 gallons each, cased with lead, so as to sink empty, each having a bung-hole at bottom, to let in the water as they descended, and let it out again as they were drawn up. In the top of the barrels was another hole, to which was fixed a leatherine pipe, or hose, well prepared with bees wax and oil, long enough to hang below the bung-hole; being kept down by a weight for that purpose; so that the air driven to the upper part of the barrel by the influx of the water, in the descent, could not escape up this pipe, unless the lower end were lifted up.

These air-barrels were fitted with tackle, to make them rise and fall alternately, like two buckets; being directed in their descent by lines fastened to the under edge of the bell: so that they came readily to the hand of a man placed on the stage, to receive them; who taking up the ends of the pipes, as soon as they came above the surface of the water in the barrels, all the air included in the upper part of it was blown forcibly into the bell; the water taking its place.

One barrel thus received, and emptied; on a signal given, it was drawn up, and at the same time the other let down; by which alternate succession, fresh air was furnished so plentifully, that the learned Doctor himself was one of five, who were all together in nine or ten fathoms deep of water for above an hour and a half, without the least inconvenience; the whole cavity of the bell being perfectly dry.

All the precaution he observed, was, to be let down gradually about 12 feet at a time, and then to stop, and drive out the water that had entered, by taking in three or four barrels of fresh air, before he descended farther. And, being arrived at the depth intended, he let out as much of the hot air that had been breathed, as each barrel would replace with cold, by means of the cock n , at the top of the bell, through whose aperture, though very small, the air would rush with so much violence, as to make the surface of the sea boil.

Thus he found any thing could be done that was required to be done underneath; and by taking off the stage, he could, for a space as wide as the circuit of the bell, lay the bottom of the sea so far dry as not to be over shoed in water. Besides, by the glass window so much light was

transmitted, that when the sea was clear, and especially when the sun shone, he could see perfectly well to write or read, much more to fasten or lay hold of any thing under him that was to be taken up; and by the return of the air-barrel he often sent up orders written with an iron pen on a plate of lead, directing how he would be moved from place to place. At other times, when the water was troubled and thick, it would be as dark as night below; but in such cases he was able to keep a candle burning in the bell.

Dr. Halley observes, that they were subject to one inconvenience in this bell; they felt at first a small pain in their ears, as if the end of a tobacco-pipe were thrust into them; but after a little while there was a small puff of air, with a little noise, and they were easy.

This he supposes to be occasioned by the condensed air shutting up a valve leading from some cavity in the ear, full of common air; but when the condensed air pressed harder, it forced the valve to yield, and filled every cavity. One of the divers, in order to prevent this pressure, stopped his ear with a pedgeot of paper; which was pushed in so far, that a surgeon found considerable difficulty in extracting it.

The same author intimates, that by an additional contrivance he has found it practicable for a diver to go out of the bell to a good distance from it; the air being conveyed to him in a continued stream by small flexible pipes, which serve him as a clue to direct him back again to the bell. For this purpose, one end of these pipes, kept open against the pressure of the sea by a small spiral wire, and made tight without by painted leather and sheep's guts drawn over it, being open, was fastened in the bell, as at r, to receive air, and the other end was fixed to a leaden cap on the man's head, reaching down below his shoulders, open at bottom, to serve him as a little bell, full of air, for him to breathe at his work, which would keep out the water from him, when at the level of the great bell, because the density of the air in both was the same: but when he stooped down lower than the level of the great bell, he shut the cock r, to cut off the communication between the two. Phil. Trans. abr. vol. vi. pa. 258, 522.

The air in this bell would serve him for a minute or two; and he might instantly change it, by raising himself above the great bell, and opening the cock r. The diver was furnished with a girdle of large leaden weights, and clogs of lead for the feet, which, with the weight of the leaden cap, kept him firm on the ground; he was also well clothed with thick flannels, which being first made wet, and then warmed in the bell by the heat of his body, kept off the chill of the cold water for a considerable time, when he was out of the bell.

Mr. Martin Triegwald, F. R. S., and military architect to the king of Sweden, contrived to construct a diving-bell on a smaller scale, and at a less expence, than that of Dr. Halley, and yet capable of answering the same purposes. This bell, AB (fig. 7.) sinks with leaden weights DD, suspended from the bottom of it. It is made of copper, and tinned all over on the inside; and it is illuminated by three strong convex lenses CCG, defended by the copper lids NNN. The iron plate E serves the diver to stand upon, when he is at work; and this is suspended by the chains FFF, at such a distance from the bottom of the bell, that when he stands upright, his head is just above the water within it, where he has the advantage of air more proper for respiration, than when he is much higher up;

but as there is occasion for the diver to be wholly in the bell, and consequently his head in the upper part of it, Mr. Triegwald also contrived, that even there, after he has breathed the hot air as long as he can, by means of a spiral copper tube placed close to the inside of the bell, he may draw the cooler and fresher air from the lowermost parts; for which purpose a flexible leather pipe, about two feet long, is fixed to the upper end of the tube at b; and to the other end of the pipe is fastened an ivory mouth-piece, for the diver to hold in his mouth, by which to respire the air from below. We shall only remark, that as air rendered effete by respiration is somewhat heavier than common air, it must naturally subside in the bell; but it may probably be restored by the agitation of the sea-water, and thus become more fit for respiration. See Fixed Air, Phil. Trans. abr. vol. viii. pa. 634. Or Desaguliers's Exper. Phil. vol. ii. pa. 220, &c. Several other persons have practised with diving-machines, on the same principles.

The famous Corn. Drebell had an expedient in some respects superior even to the diving-bell, if what is related of it be true. He contrived not only a vessel to be rowed under water, but also a liquor to be carried in the vessel, which supplied the place of fresh air. The vessel was made for King James the 1st, carrying 12 rowers, besides the passengers. It was tried in the river Thames; and one of the persons in that submarine navigation, then living, told it me, from whom Mr. Boyle had the relation. As to the liquor, Mr. Boyle assures us, he discovered by a physician, who married Drebell's daughter, that it was used from time to time, when the air in that submarine boat was clogged by the breath of the company, and rendered unfit for respiration: at which time, by unstopping the vessel full of this liquor, he could speedily restore to the troubled air such a proportion of vital parts, as would make it serve again a good while. The secret of this liquor Drebell would never disclose to above one person, who himself assured Mr. Boyle what it was. Boyle's Exp. Phys. Mech. of the Spring of the Air.

We have had many projects of diving-machines, and diving-ships of various kinds, which have proved abortive.

DIVING-Bladder, a term used by Borelli for a machine which he contrived for diving under water to great depths, with considerable facility, which he prefers to the common diving-bell. The vesica, or bladder, as it is usually called, is of brass or copper, and about two feet in diameter, which is to contain the diver's head; and this is fixed to a goat's skin habit, exactly fitted to the shape of the body of the person. Within this vesica there are pipes, by means of which a circulation of air is contrived; and the person carries an air-pump by his side, by means of which he may make himself heavier or lighter, as the fishes do, by contracting or dilating their air-bladder: by this means, the objections all other diving-machines are liable to are obviated, and particularly that of the air; the moisture by which it is clogged in respiration, and by which it is rendered unfit for the same use again, being here taken from it by its circulation through the pipes, to the sides of which it adheres, and leaves the air as free as before. Borelli Opera Posthuma.

DIVINI (EUSTACCHIO), an ingenious Italian artist, very eminent for his telescopes, though, it seems, inferior to Campani. He wrote a book (published at the Hague 1660, in 4to) against the discovery of Saturn's ring, made

by the celebrated Huygens, contesting the truth of it; to which the latter wrote a reply. Divini was living in 1663; though Moreri thinks he died about that time.

DIVISIBILITY, a property in quantity, body, or extension, by which it becomes separable into parts; either actually, or at least mentally. Such divisibility is infinite, if not actually, at least potentially; as no part can be conceived so small, but another may be conceived still smaller; for every part of matter must have some finite extension, and that extension may be bisected, or otherwise divided; for the same reason, these parts may be divided again, and so on without end.

It is not here contended for the possibility of an actual division in infinitum: it is only asserted that however small a body is, it may be still farther divided; which it is presumed may be called a division in infinitum, because what has no limits, is called infinite. The infinite, or indefinite divisibility of mathematical quantity is thus proved, and illustrated by mathematicians: Suppose a line AD perpendicular to BF ; and another as GH also perpendicular to the same BF ; with the centres $C, C, C, C, &c.$, and distances $CA, CA, CA, &c.$, describe circles cutting the line GH in the points $c, e, &c.$. Now, the greater the radius AC is, the less is the part eg ; but the radius may be augmented in infinitum, and therefore the part eg may be diminished in the same manner; and yet it can never be reduced to nothing, because the circle can never coincide with the right line BF . Consequently the parts of any magnitude may be diminished in infinitum.

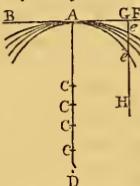

All that is supposed, in strict geometry, concerning the divisibility of magnitude, amounts to no more, than that a given magnitude may be conceived as divided into a number of parts, equal to any given or proposed number. It is true, that there are no such things as parts infinitely small; yet the subtlety of the particles of several bodies is such, that they far surpass our conception; and there are innumerable instances in nature of such parts actually separated from one another.

Several instances of this are given by Mr. Boyle. He speaks of a silken thread 300 yards long, that weighed but two grains and a half. He measured leaf-gold, and found by weighing it, that 50 square inches weighed but one grain; if the length of an inch be divided into 200 parts, the eye may distinguish them all; therefore in one square inch there are 40,000 visible parts; and in one grain of it there are two millions of such parts; which visible parts no one will deny are still farther divisible.

Again, an ounce weight of silver may be gilt over with 8 grains of gold, which may be afterwards drawn into a wire 13,000 feet long, and still be all covered with the same gilding.

In odoriferous bodies a still greater subtlety of parts is perceived, and even such as are actually separated from one another; several bodies scarce lose any sensible part of their weight in a long time, and yet continually fill a very large space with odoriferous particles. Dr. Keil, in his *Vera Physica*, Lect. 5, has calculated the magnitude of a particle of assalætida, which will be the

$\frac{57}{1000000000000000000}$ th part of a cubic inch. And in the game Lecture, he shows that the particles of the blood in

animalculæ, observed in fluids by means of microscopes, must be less than that part of a cubic inch which is expressed by a fraction whose numerator is 8, and denominator unity with 30 ciphers after it.

The particles of light, if light consist of real particles, furnish another surprising instance of the minuteness of some parts of matter. A small lighted candle placed on a plain, will be visible two miles, and consequently its light fills a sphere of 4 miles diameter, before it has lost any sensible part of its weight. Now, as the force of any body is directly in proportion to its quantity of matter multiplied by its velocity; and since it is demonstrated that the velocity of the particles of light is at least a million of times greater than the velocity of a cannon-ball, it is plain, that if a million of these particles were round, and of the size of a small grain of sand, we durst no more open our eyes to the light, than expose them to sand shot point-blank from a cannon.

By help of microscopes, such objects as would otherwise escape our sight, appear very large: there are some small animals scarce visible with the best microscopes; and yet these have all the parts necessary for life, as blood, and other fluids. How wonderful then must the subtlety of the parts be, which make up such fluids! Whence is deducible the following theorem:

Any particle of matter, however small, and any finite space, however large, being given; it is possible for that small particle of matter to be diffused through that space, and to fill it so as that there shall be no pore in it, whose diameter shall exceed any given line; as is demonstrated by Dr. Keil, *Introduct. ad Ver. Phys.*

DIVISIBLE, the faculty or quality of being capable of being divided.

DIVISION, is one of the four principal rules of arithmetic, being that by which we find how often one quantity is contained in another; so that division is in reality only a compendious method of subtraction; its effect being to take one number from another as often as possible; that is, as often as it is contained in it. There are therefore three numbers concerned in division: 1st, That which is given to be divided, called the dividend; 2d, That by which the dividend is to be divided, called the divisor; 3d, That which expresses how often the divisor is contained in the dividend; or the number resulting from the division of the dividend by the divisor, called the quotient.

There are various ways of performing division, one called the English, another the Flemish, another the Italian, another the Spanish, another the German, and another the Indian way, all equally just, as finding the quotient with the same certainty, and only differing in the manner of arranging and disposing the numbers.

There is also division in integers, division in fractions, and division in species, or algebra, &c.

Division is performed by seeking how often the divisor is contained in the dividend; and when the latter consists of a greater number of figures than the former, the dividend must be taken into parts, beginning on the left, and proceeding to the right, and seeking how often the divisor is found in each of those parts; after the manner as taught in all books of arithmetic, as well as various contractions adapted to particular cases: such as, 1st, when the divisor has any number of ciphers at the end of it, they are cut off, with the same number of figures from the end of the dividend, and then the work is performed without them both, annexing only the figures last cut off, to the last re-

mainder; 2d, when the divisor is equal to the product of several single digits, it is easier to divide successively by those digits, instead of the divisor at once; 3d, when it is required to continue a quotient to a great many places of figures, as in decimals, a very expeditious method of performing it, is as follows: Suppose it were required to divide 1 by 29, to a great many places of decimals. Adding ciphers to the 1, first divide 10000 by 29 in the common way, till the remainder become a single figure, and annex the fractional supplement to complete the quotient, which gives $\frac{1}{29} = 0\cdot0344827586\frac{8}{29}$; next multiply each of these by the numerator 8, so shall $\frac{8}{29} = 0\cdot275842\frac{4}{29}$ or rather $0\cdot27586\frac{8}{29}$; which figures substituted instead of the fraction $\frac{8}{29}$ in the first value of $\frac{1}{29}$, it becomes $\frac{1}{29} = 0\cdot0344827586\frac{8}{29}$; again, multiply both of these by the last numerator 6, and it will be $\frac{6}{29} = 0\cdot2068965517\frac{7}{29}$; which figures substituted for $\frac{6}{29}$ in the last-found value of $\frac{1}{29}$, it becomes $\frac{1}{29} = 0\cdot03448275862068965517\frac{7}{29}$; and again, multiplying these by the numerator 7, gives $\frac{7}{29} = 0\cdot24137931034482758620\frac{1}{29}$; which figures substituted instead of $\frac{7}{29}$ in the last-found value of $\frac{1}{29}$, it becomes $\frac{1}{29} = 0\cdot0344827586206896551724137931034482758620\frac{1}{29}$, and so on; where every operation will at least double the number of figures before found by the last one.

Proof of Division. In every example of division, unity is always in the same proportion to the divisor, as, the quotient is to the dividend; and therefore the product of the divisor and quotient is equal to the product of 1 and the dividend, that is, the dividend itself. Hence, to prove division, multiply the divisor by the quotient, to the product add the remainder, and the sum will be equal to the dividend when the work is right; if not, there is a mistake.

Division, in Vulgar Fractions, is performed by dividing the numerators by each other, and the denominators by each other, if they will exactly divide; but if not, then the dividend is multiplied by the reciprocal of the divisor, that is, having its terms inverted; for, taking the reciprocal of any quantity, converts it from a divisor to a multiplier, and from a multiplier to a divisor. For Ex. $\frac{15}{16} \div \frac{3}{4}$ gives $\frac{5}{4}$, by dividing the numerators and denominators; but $\frac{15}{16} \div \frac{3}{4}$ is the same as $\frac{15}{16} \times \frac{4}{3}$, which is $= \frac{5}{4}$. Where \times is the sign of multiplication, and the character \div is the mark of division. Or division is also denoted like a vulgar fraction; so 3 divided by 2, is $\frac{3}{2}$.

Division, in Decimal Fractions, is performed the same way as in integers, regard being had to the number of decimals, viz., making as many in the quotient as those of the dividend exceed those in the divisor.

But in this case we sometimes make use of a contracted method, which it may not be amiss to explain. Thus, when there are many figures in the divisor, or when only a certain number of decimals are necessary to be retained in the quotient; then take only as many of the left-hand figures of the divisor as will exceed the number of figures, both integers and decimals, to be retained in the quotient by unity, and find how many times they are contained in the first figures of the dividend as usual.

Let each remainder form a new dividend; and for every such dividend, leave out one figure more on the right-hand side of the divisor, observing to carry for the increase of the figures cut off as follow: namely, 1, from 5 to 14; 2, from 15 to 24; 3, from 25 to 34, &c.

But when there are not so many figures in the divisor as

are required to be in the quotient, then the operation must be begun with all the figures, continuing it the same as in the common rule, till the number of figures in the divisor exceed those remaining to be found in the quotient by unity, after which begin the contraction. See the following example, where 5 figures are to be retained in the quotient.

$$92\cdot4103.5 \) \ 2508\cdot92806 \ (\ 27\cdot149 \\ 660721 \\ 13849 \\ 4608 \\ 912 \\ 80$$

Division, in Algebra, is performed like that of common numbers, either making a fraction of the dividend and divisor, and cancelling or dividing by the terms or parts that are common to both; or else dividing after the manner of long division, when the quantities are compound ones. Thus,
 ab divided by a , gives b for the quotient;
and $12ab$ divided by $4b$, gives $3a$ for the quotient:

$$16abc^2 \text{ divided by } 8ac, \text{ gives } 2bc:$$

$$a \text{ divided by } 3b, \text{ gives } \frac{a}{3b};$$

$$15abc^3 \text{ divided by } 12bc^2, \text{ gives } \frac{15abc^3}{12bc^2} = \frac{5ac}{4};$$

$$\text{and } a^2 - b^2 \text{ by } a + b, \text{ gives } a - b; \text{ thus, } \\ a + b) \ a^2 - b^2 \ (a - b \\ \overline{a^2 + ab} \\ \overline{-ab - b^2} \\ \overline{-ab - b^2:}$$

$$\text{again, to divide } x^6 - 8x^4 - 124x^2 - 64 \text{ by } x^4 - 16; \\ x^4 - 16) \ x^6 - 8x^4 - 124x^2 - 64 \ (x^4 + 8x^2 + 4 \\ \overline{x^6 - 16x^4} \\ \overline{8x^4 - 128x^2} \\ \overline{4x^2 - 64} \\ \overline{4x^2 - 64}$$

In some cases, the quotient will run out to an infinite series; and then, after continuing it to any certain number of terms, it is usual to annex, by way of a fraction, the remainder with the divisor set under it.—It is to be noted that, in dividing any terms by one another, if the signs be both alike, either both plus or both minus, the sign of the quotient will be plus; but when the signs are different, the one plus and the other minus, the sign of the quotient is minus.

Division by Logarithms. See LOGARITHMS.

Division of Mathematical Instruments. See GRADUATION, and MURAL Arc or Quadrant.

Division in Music, is the dividing the interval of an octave into a number of lesser intervals.

Division by Napier's Bones. See NAPIER'S BONES.

Division of Powers, is performed by subtracting their exponents. Thus, $a^6 \div a^4 = a^2$; and $4a^{\frac{3}{2}}b^{\frac{1}{2}} \div 2a^{\frac{1}{2}}b^{\frac{1}{2}} = 2a^{\frac{1}{2}}b^{\frac{1}{2}}$.

Division of Proportion, is comparing the difference between the antecedent and consequent, with either of them. Thus,

$$\text{if } \left\{ \begin{array}{l} a : b :: c : d, \\ 12 : 4 :: 6 : 2, \end{array} \right. \\ \text{then by division } \left\{ \begin{array}{l} a-b : a :: c-d : c, \\ 8 : 12 :: 4 : 6, \end{array} \right. \\ \text{or } \left\{ \begin{array}{l} a-b : b :: c-d : d, \\ 8 : 4 :: 4 : 2. \end{array} \right.$$

DIVISOR, is the dividing number; or that which shows how many parts the dividend is to be divided into.

DIVISORS of a Number, are those numbers by which it is exactly divisible; thus, 1, 2, 3, 4, 6 and 12, are divisors of the number 12, because 12 may be divided by each of those numbers, without leaving a remainder. But if we take a prime number, as for example 13, we shall find that it has only two divisors; namely, 1 and 13, or unity and itself, which is indeed what constitutes a prime number.

In composite numbers, it is frequently necessary to know what those numbers are by which they are divisible, the sum of all those divisors, how many such divisors belong to a given number, their forms, and other particulars, which find their application in various branches of analysis. In order to enter into these particulars, it is necessary that we know all the prime divisors of a number, which are found by dividing it by all those prime numbers, less than the square root of itself, by which it is divisible; repeating the division by each, as often as it can be done without leaving a remainder: by which means every number n is reduced to the following form, $n = a^m b^n c^p d^q \&c$; where $a, b, c \&c$ are the prime divisors of n , and $m, n, p \&c$ the powers of those divisors, or the number of times that n is divisible by $a, b, c \&c$.

This reduction being made, it is evident from inspection only, that by the developement of the formula $(1 + a + a^2 + \dots + a^m) \cdot (1 + b + b^2 + \dots + b^n) \cdot (1 + c + c^2 + \dots + c^p) \&c$, we shall obtain every possible combination, that can be formed with m -as, n -bs, p -cs &c, and consequently, every divisor of n is contained in the result obtained from this developement, and which will therefore express the sum of all the divisors of the given number n .

Suppose, for example, the sum of all the divisors of 360 were required.

Here $360 = 2^4 \cdot 3^2 \cdot 5^1$, that is $a = 2$, $b = 3$, and $c = 5$; also $m = 4$, $n = 2$, and $p = 1$: therefore $(1 + 2 + 2^2 + 2^3 + 2^4) \cdot (1 + 3 + 3^2) \cdot (1 + 5 + 5^2) = 31 \cdot 13 \cdot 31 = 12493$, which is the sum of all the divisors of 360. But if, instead of 360, the sum of the divisors of 361 had been required, we should have found it equal only to 362, because 361 is a prime. From which circumstance we should be led to conclude, that no order could be observed between the sum of the divisors of the consecutive numbers; but Euler has proved in his Introduction to the Analysis Infinitorum, tom. 1, p. 355, that these sums follow a certain law, after the manner of a recurring series.

We may also from our first formula find the number of divisors of any given number, which is evidently expressed by $(m + 1) \cdot (n + 1) \cdot (p + 1) \&c$. Suppose, for example, it were required to find how many divisors belong to the number 1800.

First $1800 = 2^3 \cdot 3^2 \cdot 5^1$; that is, $m = 3$, $n = 2$, and $p = 1$: therefore $(3 + 1) \cdot (2 + 1) \cdot (2 + 1) = 36$, the number of divisors of 1800. Hence again, we may readily find a number that shall have any given number of divisors. Thus, let it be required to find a number that shall have 20 divisors. Here, it is only necessary to resolve 20 into any number of factors, as $20 = 4 \cdot 5$; subtract 1 from each of those factors, and make $m = 3$, $n = 4$; then will a^m, b^n be the number sought; where a and b may be taken any prime numbers at pleasure. If $a = 3$, and $b = 2$, we have $27 \cdot 16 = 432$, for the number required.

Various other properties of divisors might be here enumerated, but we shall only mention a few of those which have been most successfully employed in the Theory of Numbers.

1. If a be a prime number, and x not divisible by a , then is a a divisor of the formula $(x^{a-1} - 1)$.

2. If a be a prime number, it is a divisor of the formula $(1 \cdot 2 \cdot 3 \cdots a - 1) + 1$.

3. If a be a prime number, it is a divisor of the formula $(1^2 \cdot 2^2 \cdot 3^2 \cdots - (\frac{a-1}{2})^2) \pm 1$, the upper sign having place when a is of the form $4n + 1$; and the under one when a is of the form $4n - 1$.

4. The divisors of every number comprised under any of the forms $p^2 + a^2$, $p^2 + 2n^2$, $p^2 - 2n^2$, are always of the same form, as the numbers that they divide. That is, the sum of two squares can only be divided by numbers that are also the sum of two squares, &c. It being always understood that p and n are prime to each other.

5. Every prime number is a divisor of the formula $p^2 + n^2 + 1$.

6. Every odd number, except 5 and its multiples, is a divisor of any repetend digit; and the number of digits necessary to form the dividend, never exceeds the number expressed by the divisor.

7. If the sum of the digits of any number is divisible by 3 or 9, the number itself is divisible by the same number 3 or 9.

8. If the sum of the digits in the even places, are equal to the sum of those in the odd places, in any number, that number is divisible by 11.

9. If the n right-hand digits of any number be divisible by 2^n , the whole number is divisible by 2^n .

The reader is referred for further information on this subject, to Euler's Introduction to the Analysis Infinitorum, also to the 2d vol. of his Algebra; to Waring's Meditationes Algebraicae; Le Gendre's Essai sur la Théorie des Nombres; and to the Recherches Arithmetiques, par M. Gauss. See also NUMBERS in this Dictionary.

DIURNAL, something relating to the day; in opposition to Nocturnal, relating to the night.

DIURNAL Arch, is the arch described by the sun, moon, or stars, between their rising and setting.

DIURNAL Circle, is the apparent circle described by the sun, moon, or stars, in consequence of the rotation of the earth.

DIURNAL Motion of a Planet, is so many degrees and minutes &c as any planet moves in 24 hours.

The DIURNAL Motion of the Earth, is its rotation round its axis, the duration of which constitutes the natural day.

DIURNAL Parallax. See PARALLAX.

DIURNAL is also used in speaking of what belongs to the nycthemeron, or natural day of 24 hours: in which sense it is opposed to annual, menstrual, &c. The diurnal phenomena of the heavenly bodies are solved from the diurnal revolution of the earth; that is, from the rotation of the earth round its own axis in 24 hours; which rotation is equable, and from west to east, about an axis whose inclination to the ecliptic is now $66^{\circ} 32'$. Now since the earth is an opaque body, that small part of its surface which comes at the same time under the confined view of the spectator, though really spherical, seems to be extended like a plane: and the eye, taking an entire view of the heavens, they seem to form a concave spherical surfaces, concentric with the earth, or rather with the

eye, which the said plane of the earth's superficies divides into two equal parts, the one of which is visible, but the other, because of the earth's opacity, is hid from the view.

And as the earth revolves about its axis, the spectator, together with the said plane he stands upon, called his horizon, dividing the visible from the invisible hemisphere of the heavens, is carried round the same way, viz. towards the east: hence it is, that the sun and stars, placed towards the east, being before hid, now become visible, the horizon as it were sinking below them; and the stars &c towards the west are covered or hid, and become invisible, the horizon being elevated above them: so that the former stars, to the spectator, who reckons the place he stands on as immovable, appear to ascend above the horizon, or rise; and the latter to descend below the horizon, or set.

Since the earth, with the horizon of the spectator, continues to move always towards the same parts, and about the same axis equally; all bodies, and all phenomena, that do not partake of the said motion, (that is, all such things as are entirely separate from the earth,) seem to move in the same time uniformly, but towards the opposite parts, or from east to west: and every one of these objects, according to sense, describes the circumference of a circle, whose plane is perpendicular to the axis of the earth. And because all these circles, together with the visible objects describing them, appear to be in the concave spherical superficies of the heavens, every visible object seems to describe a greater or less circle, according to its greater or less distance from the poles, or extremities of the earth's axis produced; the middle circle between these poles, called the equator, being consequently the greatest.

DODECAGON, a regular polygon of 12 equal sides and angles. If the side of a dodecagon be 1, its area will be equal to 3 times the tang. of $75^{\circ} = 3 \times (2 + \sqrt{3}) = 11.1961524$ nearly; and, the areas of plane figures being as the squares of their sides, therefore 11.1961524 multiplied by the square of the side of any dodecagon, will give its area. See my Mensuration, pa. 85, 4th edit.

To inscribe a Dodecagon in a given Circle. Carry the radius 6 times round the circumference, which will divide it into 6 equal parts, or will make a hexagon; then bisect each of those parts, which will divide the whole into 12 parts, for the dodecagon. See also other methods of describing the same figure in my Mensuration, pa. 16, &c. See **POLYGON**.

DODECAHEDRON, one of the Platonic bodies, or five regular solids, being contained under a surface composed of twelve equal and regular pentagons.

To form a Dodecahedron. See **Regular Body**.

If the side, or linear edge, of a dodecahedron be s , its surface will be $15s^2\sqrt{(1 + \frac{2}{5}\sqrt{5})} = 20.6457788s^2$, and its solidity $\frac{5\sqrt{3}}{3}\sqrt{(4\cdot7 + 2\cdot1\sqrt{5})} = 7.66311896s^3$.

If the radius of the sphere that circumscribes a dodecahedron be r , then is

$$\text{its side or linear edge} = (\sqrt{15 - \sqrt{3}}) \times \frac{4}{3}r;$$

$$\text{its superficies} = 10r^2\sqrt{(2 - \frac{2}{5}\sqrt{5})};$$

$$\text{and its solidity} = \frac{20r^3}{3}\sqrt{\frac{3 + \sqrt{5}}{30}}.$$

The side of a dodecahedron inscribed in a sphere, is equal to the greater part of the side of a cube inscribed in the same sphere, cut in extreme and mean proportion.—If a line be cut according to extreme and mean ratio, and the less segment be taken for the side of a do-

decahedron, the greater segment will be the side of a cube inscribed in the same sphere.—The side of the cube is equal to the right line which subtends the angle of a pentagon of the dodecahedron, inscribed in the same sphere. See **POLYHEDRON**; also my **Mensur**, pa. 188, &c.

DODSON (JAMES), was an ingenious and very industrious mathematician, as well as author of several useful books; but we are acquainted with very few particulars of his life. He was some time master of the Royal Mathematical School in Christ's Hospital, London. His publications chiefly were, 1. The Antilogarithmic Canon, folio, 1742.—2. The Calculator, a collection of useful tables, large 8vo, 1747.—3. Mathematical Repository, being a collection of analytical questions and solutions, in 3 vols. 12mo. an. 1748, 1753, 1755.

DOG, a name common to two constellations, called the Great and Little Dog; but more usually **Canis Major**, and **Canis Minor**.

DOLLOND (JOHN), the celebrated optician, was born in Spitalfields, in June, 1706: his parents were French protestants, who quitted Normandy at the revocation of the edict of Nantz, in 1685.

The first years of Mr. Dollond's life were employed at the loom; but, being of a very studious and philosophic turn of mind, his leisure hours were engaged in mathematical pursuits; and though by the death of his father, which happened in his infancy, his education gave way to the necessities of his family, yet at the age of fifteen, before he had an opportunity of seeing works of science or elementary treatises, he amused himself by constructing sun-dials, drawing geometrical schemes, and solving problems. Under the pressure of a close application to business for the support of his family, he found time, by abridging the hours of his rest, to extend his mathematical knowledge, and made a considerable proficiency in optics and astronomy, to which he now principally devoted his attention, having in the earlier stages of his life prepared himself for the higher parts of those subjects, by a correct knowledge of algebra and geometry. He also acquired a very respectable knowledge of the Latin and Greek languages.

He designed his eldest son, Peter Dollond, for the same business with himself; and for several years they carried on their manufacture together in Spitalfields; but the employment neither suited the expectations nor disposition of the son, who, having received much information on mathematical and philosophical subjects, from the instruction of his father, and observing the great value which was set upon his father's knowledge in the theory of optics by professional men, determined to apply that knowledge to the benefit of himself and his family; and accordingly, under the directions of his father, commenced optician. Success attended every effort; and in the year 1752, John Dollond, embracing the opportunity of pursuing a profession congenial with his mind, joined his son, and in consequence of his theoretical knowledge, soon became a proficient in the practical parts of optics.

His first attention was directed to improve the combination of the eye-glasses of refracting telescopes; and having succeeded in his system of four eye-glasses, he proceeded one step further, and produced telescopes furnished with five eye-glasses, which considerably surpassed the former; and of which he gave a particular account in a paper presented to the Royal Society, and which was printed in the **Philos. Trans.** vol. 48, pa. 103.

Soon after this he made a very useful improvement in Mr. Savery's micrometer: for, instead of employing two entire object-glasses, as Mr. Savery and M. Bouguer had done, he used only one glass cut into two equal parts, one of them sliding or moving laterally by the other. This was considered to be a great improvement, as the micrometer could now be applied to the reflecting telescope with much advantage, and which Mr. James Short immediately did. An account of the same was given to the Royal Society, in a paper, which was afterwards printed in the Philos. Trans. vol. 48, pa. 178.

Mr. Dollond's celebrity in optics now became universal; and the friendship and protection of the most eminent men of science flattered and encouraged his pursuits. Surrounded by these enlightened men, in a state of mind prepared for the severest investigation of philosophic truths, and in circumstances favourable to liberal inquiry, Mr. Dollond engaged in the discussion of a subject, which at that time not only interested this country, but all Europe. Sir Isaac Newton had declared, in his Treatise on Optics, page 112, "That all refracting substances diverge the prismatic colours in a constant proportion to their mean refraction;" and drew this conclusion, "that refraction could not be produced without colour;" and consequently, "that no improvement could be expected in the refracting telescope." No one doubted the accuracy with which Sir Isaac Newton had made the experiment; yet some men, particularly M. Euler and others, were of opinion that the conclusion which Newton had drawn from it, went too far, and maintained, that in very small angles refraction might be obtained without colour. Mr. Dollond was not of that opinion, but defended Newton's doctrine with much learning and ingenuity, as may be seen by a reference to the letters which passed between Euler and Dollond on that occasion, and which were published in the Philos. Trans. vol. 48, pa. 287, and contended that, "If the result of the experiment had been as described by Sir Isaac Newton, there could not be refraction without colour."

A mind constituted like Mr. Dollond's could not remain satisfied with arguing in this manner from an experiment made by another, but determined to try it himself: and accordingly, in the year 1757, he began the examination; and, to use his own words, with "a resolute perseverance," continued during that year, and a great part of the next, to bestow his whole mind on the subject, until in the month of June, 1758, he found, after a complete course of experiments, the result to be very different from that which he expected, and from that which Sir Isaac Newton had related. He discovered "the difference in the dispersion of the colours of light, when the mean rays are equally refracted by different mediums." The discovery was complete, and he immediately drew from it this practical conclusion, "That the object-glasses of refracting telescopes were capable of being made without being affected by the different refrangibility of the rays of light." His account of this experiment, and of others connected with it, was given to the Royal Society, and printed in their Transactions, vol. 50, pa. 733, and he was presented, in the same year, by that learned body, with Sir Godfrey Copley's medal, as a reward of his merit, and a memorial of the discovery, though not at that time a member of the Society.

This discovery no way affected the points in dispute between Euler and Dollond, respecting the doctrine ad-

vanced by Sir Isaac Newton. A new principle was in a manner found out, which had no part in their former reasonings, and it was reserved for the accuracy of Dollond to have the honour of making a discovery which had eluded the observation of Newton. This new principle being now established, he was soon able to construct object-glasses, in which the different refrangibility of the rays of light was corrected, and the name of achromatic given to them by the late Dr. Bevis, on account of their being free from the prismatic colours.

As usually happens on such occasions, no sooner was the achromatic telescope made public, than the rivalship of foreigners, and the jealousy of philosophers at home, led them to doubt of its reality; and Euler himself, in his paper read before the Academy of Sciences at Berlin, in the year 1764, says, "I am not ashamed frankly to avow, that the first accounts which were published of it, appeared so suspicious, and even so contrary to the best established principles, that I could not prevail upon myself to give credit to them;" and he adds, "I should never have submitted to the proofs which Mr. Dollond produced to support this strange phenomenon, if M. Clairaut, who must at first have been equally surprised at it, had not most positively assured me, that Dollond's experiments were but too well founded." And when the fact could no longer be disputed, they endeavoured to find a prior inventor, to whom it might be ascribed, and several conjecturers were honoured with the title of discoverers.

In the beginning of the year 1761, Mr. Dollond was elected Fellow of the Royal Society, and appointed optician to his majesty, but did not live to enjoy those honours long; for on the 30th of November, in the same year, as he was reading a new publication by M. Clairaut, on the theory of the moon, and on which he had been intently engaged for several hours, he was seized with apoplexy, which rendered him immediately speechless, and occasioned his death in a few hours afterwards.

Besides Mr. Peter Dollond, whom we have had occasion to mention in the course of this memoir, his family, at his death, consisted of three daughters and a son, who, possessing the name of his father, and, we may add, a portion of the family abilities, carries on the optical business, in partnership with his elder brother. See also the articles ACHROMATIC and TELESCOPE.

DOME, is a round, vaulted, or arched roof, of a church, hall, pavilion, vestibule, stair-case, &c., by way of crowning, or acroter.—In plate 7, is represented the plan and elevation of a dome constructed without centring, by Mr. S. Bunce; viz, fig. 1 the plan, and fig. 2 the elevation. The first course consists of the stones marked 1, 1, 1, &c., of different sizes, the large ones exactly twice the height of the small ones, placed alternately, and forming intervals to receive the stones marked 2, 2, 2. The other courses are continued in the same manner, according to the order of the figures to the top.

It is evident, from the converging or wedge-like form of the intervals, that the stones they receive can only be inserted from the outside, and cannot fall through: therefore the whole dome may be built without centring or temporary support. To break the upright joints, the stones may be cut of the form marked in fig. 3; and those marked 16, 17, &c., near the key-stones, may be enlarged as at fig. 4.

For the mathematical theory of Domes, see my new Tracts, vol. 1, pa. 63, &c.

DOMINICAL Letter, otherwise called the **SUNDAY Letter**, is one of these first seven letters of the alphabet, ABCDEFG, used in almanacs; &c, to mark or denote the Sundays throughout the year. The reason for using seven letters, is because that is the number of days in a week; and the method of using them is this: the first letter A is set opposite the 1st day of the year, the 2d letter B opposite the 2d day of the year, the 3d letter C opposite the 3d day of the year, and so on through the seven letters; after which they are repeated over and over again, all the way to the end of the year, the letter A denoting the 8th day, the letter B the 9th, &c. Then, whichever of the letters so placed, falls opposite the first Sunday in the year, the same letter, it is evident, will fall opposite every future Sunday throughout the year, because the number of the letters is the same as the number of days in the week, being both 7 in number; that is, in common years; but in leap-years, an interruption of the order takes place in them. For, on account of the intercalary day, either the letters must be thrust out of their places for the whole year afterwards, so as that the letter, for example, which answers to the 1st of March, shall likewise answer to the 2d, &c; or else the intercalary day must be denoted by the same letter as the preceding one. This latter expedient was judged to be the best, and accordingly all the Sundays in the year after the intercalary day have another Dominical letter.

The Dominical letters were introduced into the calendar by the primitive Christians, instead of the nundinal letters in the Roman calendar; and in this manner were those seven letters set opposite the days of the year, to denote the days in the week, in most of our common almanacs, till the year 1771, when the initial letters of the days of the week were generally introduced instead of them, excepting the Sunday letter itself, which is still retained.

From the foregoing account it follows, that,

1st, As the common year consists of 365 days, or 52 weeks, and one day over; the letters go one day backwards every common year: so that in such a year, if the beginning or first day fall on a Sunday, the next year it will fall on a Saturday, the next on a Friday, and so on. Consequently, if G be the Dominical letter for the present year, F will be that for the next year; and so on in a retrograde order.

2d, As the bissextile or leap-year consists of 366 days, or 52 weeks, and 2 days over, the beginning of the year next after bissextile goes back 2 days. Whence, if in the beginning of the bissextile year the Dominical letter were G, that of the following year will be E.

3d, Since in leap-years the intercalary day falls on the 24th of February, in which case the 24th and 25th days are considered as one day, and denoted by the same letter; after the 24th day of February the Dominical letter goes back one place: thus, if in the beginning of the year the Dominical letter be E, it will afterwards change to the letter F for the remaining Sundays of the year. With us, however, this day is now added at the end of February, and from thence it is that the change takes place.

4th, As every fourth year is bissextile, or leap-year, and as the number of letters is 7; the same order of Dominical letters only returns in 4 times 7, or 28 years; which, without the interruption of bissextiles, would return in 7 years.

5th, Hence the invention of the solar cycle of 28 years; on the expiration of which the Dominical letters are restored successively to the same days of the month, or the same order of the letters returns.

To find the **DOMINICAL Letter** of any given year. Find the cycle of the sun for that year, as directed under Cycle; and the Dominical letter is found corresponding to it. When there are two letters, the proposed year is bissextile; the former of them serving till the end of February, and the latter for the rest of the year.

The Dominical letter for any year of the present century may be found thus:

To the number of years since the date 1800, add their fourth part, plus 2; and divide the sum by 7, then subtract the remainder from 7, and the last number will be that answering to the Dominical letter; that is, if the remainder be 1, it answers to A, 2 to B, &c, and 0 to G.

Suppose, for example, we wanted the Dominical letter for the year 1833.

Here $33 + 8 + 2 = 43$, being divided by 7, leaves a remainder 1, which taken from 7, gives 6; answering to F, which therefore is the Dominical letter for that year.

When the year is bissextile, that is, when the date of it is divisible by 4, then the letter obtained from this rule is that used from February to the end of the year, and the Sunday letter from the beginning of the year, to the end of February, will be that, next in order in the alphabet, unless the former is G, in which case the latter will be A.

By the reformation of the calendar under Pope Gregory the 13th, the order of the Dominical letters was again disturbed in the Gregorian year; for the year 1582, which had G for its letter at the beginning, by retrenching 10 days after the 4th of October, came to have C: by which means the Dominical letter of the ancient Julian calendar is 4 places before that of the Gregorian, the letter A in the former answering to D in the latter.

DONJON. See DUNGEON.

DONN (BENJAMIN), a respectable mathematician, was born at Bideford, in Devonshire, in 1729. He kept a school in that town for some years, and while there, made a complete survey and map of the county, for which he received a premium of 100*l.* from the society for promoting arts and commerce. He also published his Mathematical Essays in 8vo, which had a favourable reception, and procured him the office of keeper of the library at Bristol; where he also kept a flourishing academy for some years. In 1771 he printed an Epitome of Natural and Experimental Philosophy, 12mo; and in 1774, a work, entitled, The British Mariner's Assistant, being a collection of tables for nautical purposes. In 1796 he was appointed to the sinecure office of master of mechanics to the king. Besides the books above mentioned, he published also treatises on Arithmetic, Book-keeping, Geometry, and Trigonometry. Mr. Donn died in 1798, leaving behind him the character of an ingenious and worthy man.

DORADO, a southern constellation, not visible in our latitude; called also Xiphias, or the Sword-fish. Its stars, in Sharp's catalogue, are 6.

DORIC Order of Architecture, is the second of the five orders, being placed between the Tuscan and the Ionic. The Doric seems the most natural, and best proportioned, of all the orders; all its parts being founded on the natural position of solid bodies; for which reason it is most proper to be used in great and massive buildings,

as the outside of churches and public places. The Doric order has no ornaments on its base nor its capital. Its column is 8 diameters high, and its frieze is divided between triglyphs and metopes.

DORMER, or **DORMANT**, in Architecture, denotes a window made in the roof of a building, or above the entablature; being raised upon the rafters.

DOUBLE Horizontal Dial, one with a double gnomon, the one pointing out the hour on the outer circle, the other, on the stereographic projection drawn upon it. This dial finds the meridian, the hour, the sun's place, rising, setting, &c., and many other problems of the globe.

DOUBLE Point, in the Higher Geometry, is a point which is common to two parts or legs, or branches of some curve of the 2d or higher order: such as, an infinitely small oval, or a cusp, or the cruciform intersection, &c., of such curves. See Newton's *Enumeration Linearum, &c., de Curvarum Punctis Duplicibus.*

DOUBLE Stars. See **STAR**.

DOUBLER of Electricity, is an instrument capable of augmenting a very small quantity of electricity, so as to render it more than sufficiently manifest, by means of an electrometer, or even capable of affording sparks.

The invention of this instrument is due to the Rev. Abraham Bennet; the description of which is contained in the second part of the 77th volume of the Philosophical Transactions; and in the same Transactions, for the year 1788, Mr. Cavallo has given an account, at considerable length, of his experiments and observations on this instrument, as improved by himself, and also in its original form; from which he concludes, "that the invention of the doubler is very ingenious, but its use cannot be depended on;" that is to say, for ascertaining small quantities of electricity, because though no electricity be communicated to the plates of the instruments, yet by the usual process of doubling, a certain quantity of it will be produced. For the description of a very ingenious instrument for this purpose, by Mr. Nicholson, see Philosophical Transactions for the year 1788.

DOUBLING a Cape, or **Point of Land**, in Navigation, signifies the coming up with it, passing by it, and leaving it behind the ship. The Portuguese pretend that they first doubled the Cape of Good Hope, under their admiral Vasquez de Gama; but there are accounts in history, particularly in Herodotus, that the Egyptians, Carthaginians, &c., had done the same long before them.

DOUCINE, in Architecture, is an ornament on the highest part of the cornice, or a moulding cut in the figure of a wave, half convex, and half concave.

DRACHM, or **DRAM**, is the name of a small weight used with us, and is of two kinds, viz, the 8th part of an ounce in Apothecaries' weight, and the 16th part of an ounce in Avoirdupois weight.

DRACO, the **Dragon**, a constellation of the northern hemisphere, whose origin is variously fabled by the Greeks; some of them representing it as the Dragon which guarded the Hesperian fruit, or golden apples, but being killed by Hercules, Juno, as a reward for its faithful services, took it up to heaven, and so formed this constellation: while others say, that in the war of the giants, this Dragon was brought into the combat, and opposed to Minerva, when the goddess taking the Dragon in her hand, threw him, twisted as he was, up to the skies, and fixed him to the axis of the heavens, before he had time to unwind his contortions.

The stars in this constellation are, according to Ptolemy, 31; according to Tycho, 32; Hevelius, 40; Bayer, 33; and Flamsteed, 80.

DRAGON, in Astronomy. See **DRACO**.

DRAGON's Head, and **Tail**, are the nodes of the planets, but more particularly of the moon, being the points in which the ecliptic is intersected by her orbit, in an angle of about $5^{\circ} 18'$. One of these points is northward, the moon then beginning to have north latitude; and the other southward, where she commences south latitude; the former point being represented by the knot Θ for the head, and the other by the same reversed, or Θ for the tail. And near these points it is that all eclipses of the sun and moon happen. These intersections are not always in the same two points of the ecliptic, but shift by a retrograde motion, at the rate of $3^{\circ} 11''$ per day, and completing their circle in 18 years 225 days.

DRAGON-Beams, in Architecture, are two strong braces or struts, standing under a breast-summer, and meeting in an angle on the shoulder of the king-piece.

DRAM. See **DRACHM**.

DRAUGHT-Compasses, those provided with several moveable points, to draw fine draughts in architecture, &c. See **COMPASS**.

DRAUGHT-Hooks, are large hooks of iron, fixed on the cheeks of a gun-carriage, two on each side, one near the trunnion hole, and the other at the train.

DRAW-Bridge, a bridge made after the manner of a floor, to be drawn up, or let down, as occasion requires, before the gate of a town or castle.

DRIFT, SHOOT, or THRUST of an Arch, is the push or force it exerts.

DRIFT, in Navigation, denotes the angle which the line of a ship's motion makes with the nearest meridian, when she drives with her side to the wind and waves, and is not governed by the power of the helm; and also the distance which the ship drives on that line, so called only in a storm.

DRIP, in Architecture. See **LARMIER**.

DUCTILITY, a property of certain bodies, by which they are capable of being beaten, pressed, drawn, or stretched forth, without breaking; or by which they are capable of great alterations in their figure and dimensions, and of gaining in one way as they lose in another.

Such are metals, which, being urged by the hammer, gain in length and breadth what they lose in thickness; or, being drawn into wire through holes in iron, become longer as they are made more slender. Such also are gums, glues, resins, and some other bodies; which, though not malleable, may yet be denominated ductile, in as much as, when softened by water, fire, or some other menstruum, they may be drawn into threads.

Some bodies are ductile both when they are hot and cold, and in all circumstances: such are metals, and especially gold and silver; other bodies are ductile only when they have a certain degree of heat; such as glass, and wax, and such like substances: others again are ductile only when cold, and brittle when hot; as some kinds of iron, viz, those called by workmen redshort, as also brass, and some metallic alloys.

The cause of ductility is very obscure; as depending much on hardness, a quality whose nature we know very little about. It is true, it is usual to account for hardness from the force of attraction between the particles of the hard body; and for ductility, from the particles of the

ductile body being as it were jointed, and entangled with each other. But without dwelling on any fanciful hypotheses about ductility, we may amuse ourselves with some truly amazing circumstances and phenomena of it, in the instances of gold, glass, and spiders' webs. Observing, however, that the ductility of metals decreases in the following order: gold, silver, copper, iron, tin, lead.

Ductility of Gold. One of the properties of gold is, to be the most ductile of all bodies; of which the gold-beaters and gold-wire-drawers, furnish us with abundant proof. Fa. Mersenne, M. Rohault, Dr. Halley, &c, have made computations of it: but they trusted to the reports of the workmen. M. Reaumur, in the *Mémoires de l'Academie Royale des Sciences*, an. 1713, took a surer way; he made the experiment himself. A single grain of gold, he found, even in the common gold leaf, used in most of our gildings, is extended into 36 and a half square inches; and an ounce of gold, which, in form of a cube, has not half an inch for its side, is beaten under the hammer into a surface of 146 and a half square feet; an extent almost double to what could be done in former times. In Fa. Mersenne's time, it was deemed prodigious, that an ounce of gold should form 1600 leaves; which, together, only made a surface of 103 square feet.

But the distension of gold under the hammer (however considerable), is nothing to that which it undergoes in the drawing-iron. There are gold leaves, in some parts scarce the $\frac{1}{35000}$ part of an inch thick; but $\frac{1}{50000}$ part of an inch is a considerable thickness, in comparison of that of the gold spun-on silk in our gold thread. To conceive this prodigious ductility, it is necessary to have some idea of the manner in which the wire-drawers proceed. The wire, and thread that we commonly call gold thread, &c, (which is only silver wire gilt, or covered over with gold) is drawn from a large ingot of silver, usually about thirty pounds weight. This they form into a cylinder, or roll, about an inch and a half in diameter, and twenty-two inches long, and cover it with the leaves prepared by the gold-beater, laying one over another, till the cover is a deal thicker than that in our ordinary gilding; and yet, even then, it is very thin; as will be easily conceived from the quantity of gold that is used for gilding the thirty pounds of silver, which seldom exceeds two ounces; and, frequently, little more than one. In effect, the full thickness of the gold on the ingot rarely exceeds $\frac{1}{400}$ or $\frac{1}{500}$ part; and sometimes not $\frac{1}{600}$ part of an inch.

The ingot is then successively drawn through the holes of several irons, each smaller than the other, till it be as fine as, or finer than, a hair. Every new hole lessens its diameter; but it gains in length what it loses in thickness; and of course increases in surface: yet the gold still covers it; it follows the silver in all its extension, and never leaves the minutest part bare, not even to the microscope. How inconceivably therefore must it be attenuated while the ingot is drawn into a thread, whose diameter is 9000 times less than that of the ingot. M. Reaumur, by exact weighing, and rigorous calculation, found, that one ounce of the thread was 3232 feet long; and the whole ingot 1163520 feet. Paris measure, or 96 French leagues; equal to 1264400 English feet, or 240 miles English; an extent which far surpasses what Fa. Mersenne, Furetière, Dr. Halley, &c, ever thought of.

Mersenne says, that half an ounce of the thread is 100 toises or fathoms long; on which calculation, an ounce

would only be 1200 feet: whereas M. Reaumur finds it 3232. Dr. Halley makes 6 feet of the wire one grain in weight, and one grain of the gold 98 yards; and consequently the ten-thousandth part of a grain, above one third of an inch. The diameter of the wire he found one-156th part of an inch; and the thickness of the gold one-154500th part of an inch. But this too comes short of M. Reaumur; for, on this principle, the ounce of wire would only be 2680 feet.

But the ingot is not even in this case extended to its full length. The greatest part of our gold thread is spun, or wound on silk; and, before it is spun, they flat it, by passing it between two rolls, or wheels of exceedingly well polished steel; which wheels, in flattening it, lengthen it by above one-seventh. So that our 240 miles are thus extended to 274. Now, the breadth of these laminae, or plates, M. Reaumur finds, is only one-8th of a line, or one-96th of an inch; and their thickness one-3072d. The ounce of gold, then, is here extended to a surface of 1190 square feet; whereas, the utmost the gold-beaters can do, we have observed, is to extend it to 146 square feet. From M. Reaumur's calculus, it is found to be one-175000th of a line, or one-2100000th of an inch; which is scarce one-13th of the thickness that Dr. Halley supposed.

But he adds, that, from this supposition the thickness of the gold is every where equal, which is no ways probable; for in beating the gold leaves, whatever care they can bestow, it is impossible to extend them equally. This we easily find, by the greater opacity of some parts than others; for, where the leaf is thickest, it will gild the wire the thickest; and Reaumur, by computing what the thickness of the gold must be where it is thinnest, finds it only one-3150000th part of an inch. Yet even this is not the utmost ductility of gold; for, instead of two ounces of gold to the ingot, which we have here computed upon, a single one might have been used; and then the thickness of the gold, in the thinnest places, would only have been the $\frac{1}{6300000}$ part of an inch.

And still by only pressing them more between the flatter's wheels, they are extended to double the breadth and proportionately in length. So that their thickness, at last, will be reduced to one-thirteen or fourteen millionth part of an inch.

Yet, with this amazing thinness of the gold, it is still a perfect cover for the silver: the best eye, or even the best microscope, cannot discover the least chasm, or discontinuity. There is not an aperture to admit alcohol of wine, the subtlest fluid in nature, or even light itself, unless it be owing to cracks occasioned by repeated strokes of the hammer. To which we may add, that if a piece of this gold thread, or gold plate, be laid to dissolve in aquafortis, the silver will be all excavated, or eaten out, and the gold left entire, in little tubules.

It should be observed, that gold, when it has been struck for some time by a hammer, or violently compressed, as by gold wire-drawers, becomes more hard, elastic and stiff, and less ductile, so that it is apt to be cracked or torn: the same thing happens to the other metals by percussion and compression; but ductility and tractability may be restored to metals in that state, by annealing them, or making them red hot. Gold, however, seems to be more affected by percussion and annealing, than any other metals.

As to the **Ductility of soft bodies**, it is not yet carried.

to that pitch. We must not be surprised that, among the ductile bodies of this class, the first place is given to the most brittle of all others,—glass.

Ductility of Glass. It is known that, when well penetrated with the heat of the fire, the workmen can figure and manage glass like soft wax; but what is most remarkable, it may be drawn or spun out into threads exceedingly fine and long. Our ordinary spinners do not form their threads of silk, flax, or the like, with half the ease and expedition, as the glass-spinners do threads of this brittle matter. Some of them that are used in plumes for children's heads, and divers other works, are much finer than any hair, and which bend and wave like it with every wind.

Nothing is more simple and easy than the method of making them: there are two workmen employed; the first holds one end of a piece of glass over the flame of a lamp; and, when the heat has softened it, a second operator applies a glass hook to the metal thus in fusion; and, withdrawing the hook again, it brings with it a thread of glass, which still adheres to the mass: then, fitting his hook on the circumference of a wheel about two feet and a half in diameter, he turns the wheel as fast as he pleases; which, drawing out the thread, winds it on its rim; till, after a certain number of revolutions, it is covered with a skein of glass thread.

The mass in fusion over the lamp diminishes insensibly: being wound out, as it were, like a poloion, or clue of silk, upon the wheel; and the parts, as they recede from the flame, cooling, become more coherent to those next to them; and this by degrees: the parts nearest the fire are always the least coherent, and of course must give way to the effort the rest make to draw them towards the wheel. The circumference of these threads is usually a flat oval, being 3 or 4 times as broad as thick: some of them seem scarce larger than the thread of a silk-worm, and are surprisingly flexible. If the two ends of such threads be knotted together, they may be drawn and bent, till the aperture, or space in the middle of the knot, doth not exceed one-4th of a line, or one-48th of an inch diameter.

Hence M. Reaumur advances, that the flexibility of glass increases in proportion to the fineness of the threads; and that, probably, had we but the art of drawing threads as fine as a spider's web, we might weave stiffs and cloths of them for wear. Accordingly, he made some experiments this way, and found he could make threads fine enough, viz; as fine, in his judgment, as spiders' thread, but he could never make them long enough to do any thing with them.

Ductility of Spiders' Webs. See WEB.

DUNGEON, DONJON, in Fortification, the highest part of a castle built after the ancient mode; serving as a watch-tower, or place of observation; and also for the retreat of a garrison, in case of necessity, so that they may capitulate with greater advantage.

DUNN (SAMUEL), was a native of Crediton, in Devonshire, where he kept a mathematical school for several years; but afterwards removed to Chelsea, where he long kept an academy. He was a person well skilled in nautical calculations, and was a good practical astronomer, being employed as mathematical examiner for the East-India service. Besides several papers of his inserted in the Philos. Trans. he was also the author of some separate

works on practical branches of mathematics; and he published a folio Atlas, which has been held in some estimation. Mr. Dunn died in good circumstances, and bequeathed an estate of about 30*l.* a year, to support a mathematical school in his native town, the first master to which was appointed in 1793.

DUODECIMALS, a kind of multiplication in arithmetic, by which artificers square their dimensions, that is, multiply them together, to obtain the contents of their works, in square feet, inches, and parts. The method is, to multiply the feet and inches in the one dimension, by each of those in the other separately, in so many lines, the like names set under each other, feet under feet, and inches under inches, and then adding their like parts together, as here annexed; first multiplying 14*f.* 9*inc.* by the 4*f.* and then by the 6*inc.* observing to carry 1 for every 12, from one denomination to the other. Or, instead of multiplying by the 6 inches, or half a foot, it is better to take half the upper line, or divide 14*f.* 9*inc.* by 2. The sum of the products is 66*f.* 4*½ inc.* for the content. But it is to be noted, that though the 66 are square feet, yet the 4*½ inc.* are not square inches, but 4*½ inc.* parts in 12, of a square foot, or 4*½* twelfth-parts of a foot, that is, 4*½* parallelograms, each of 1 foot long and 1 inch broad. See the article *Duodecimal Arithmetic*; as also *Cross Multiplication*, and most books on Arithmetic and Mensuration.

$$\begin{array}{r} 14\text{f. } 9\text{inc.} \\ \times 4\text{ f. } \\ \hline 59\text{ } 0 \\ 7\text{ } 4\frac{1}{2} \\ \hline 66\text{ } 4\frac{1}{2} \end{array}$$

DUPLE, or DOUBLE Ratio, is that in which the antecedent is double the consequent; or where the exponent of the ratio is 2. Thus, 6 to 3 is in a duple ratio.

Sub-Duple Ratio, is that in which the consequent is double the antecedent; or in which the exponent of the ratio is $\frac{1}{2}$. As in 3 to 6, which is in subduple ratio.

Duplicate Ratio, is the square of a ratio, or the ratio of the squares of two quantities. Thus, the duplicate ratio of a to b , is the ratio of a^2 to b^2 , or of the square of a to the square of b .—In a series of geometrical proportions, the 1st term is to the 3d, in a duplicate ratio of the 1st to the 2d, or as the square of the first to the square of the 2d: Thus, in the geometricals 2, 4, 8, 16, &c, the ratio of 2 to 8, is the duplicate of that of 2 to 4, or as the square of 2 to the square of 4, that is, as 4 to 16. So that duplicate ratio is the ratio of the squares, as triplicate ratio is the ratio of the cubes, &c.

DUPLICATION, is the doubling of a quantity, or multiplying it by 2, or adding it to itself.

DUPLICATION of a Cube, is finding out the side of a cube that shall be double in solidity to a given cube: which is a celebrated problem, much cultivated by the ancient geometers, about 2000 years ago.

It was first proposed by the oracle of Apollo at Delphos; which, being consulted about the manner of stopping a plague then raging at Athens, returned for answer, that the plague should cease when Apollo's altar, which was cubical, should be doubled. Upon this, they applied themselves in good earnest, to seek the duplicature of the cube, which from thence was called the Delian problem.

This problem cannot be effected geometrically, as it requires the solution of a cubic equation, or requires the finding of two mean proportionals, viz; between the side of the given cube and the double of the same, the first of which two mean proportionals is the side of the double cube, as was first observed by Hippocrates of Chios. For,

let a be the side of the given cube, and z the side of the double cube sought; then it is $z^2=2a^2$, or $a^2 : z^2 :: z : 2a$; so that, if a and z be the 1st and 2d terms of a set of continued proportionals, then $a^2 : z^2$ is the ratio of the square of the 1st to the square of the 2d, which, it is known, is the same as the ratio of the 1st term to the 3d, or of the 2d to the 4th, that is of z to $2a$; therefore, z being the 2d term, $2a$ will be the 4th. So that z , the side of the cube sought, is the 2d of four terms in continued proportion, the 1st and 4th being a and $2a$, that is, the side of the double cube is the first of two mean proportionals between a and $2a$.

Eutocius, in his Commentaries on Archimedes, gives several ways of performing this by the mesolabé. In Pappus too are found three different ways; the first according to Archimedes, the second according to Hero, and the 3d by an instrument invented by Pappus, which gives all the proportions required. The Sieur de Comiers has also published a demonstration of the same problem, by means of a compass with three legs. But all these methods are only mechanical. See Valerius Maximus, lib. 8; also Eutocius's Comm. on lib. 2. Archimedes de Sphaera et Cylindro; and Pappus, lib. 3, prop. 5, and lib. 4, prop. 22.

DURER (ALBERT), descended of an Hungarian family, but born at Nuremberg, in 1471, was one of the best engravers, painters, and practical geometers of his age. He was at the same time a man of letters and a philosopher; and he was an intimate friend of Erasmus, who revised some of the pieces which he published. He was also a man of business, and for many years the leading magistrate of Nuremberg.

Though not the inventor, he was one of the first and greatest improvers of the art of engraving. He was however the inventor of cutting in wood, which he devised and practised in great perfection, using this way for expedition, as he had a multitude of designs to execute; and as his work was usually done in the most exquisite manner, his pieces took him up much time. For in many of those prints which he executed on copper, the engraving is elegant to a high degree. His Hell-Scene in particular, engraved in the year 1513, is as highly finished a print as ever was engraved, and as happily executed. In his wooden prints too it is surprising to see so much meaning in so early a master. In fact, Durer was a man of a very extensive genius. His pictures were excellent; as well as his prints, which were very numerous. They were much admired, from the first, and soon bought up; which put his wife, who was another Xantippe, on urging him to spend more time upon engraving than he was inclined to do: for he was rich; and chose rather to practise his art as an amusement, than as a business. He died at Nuremberg, in 1528, at 57 years of age.

Albert Durer wrote several books, in the German language, which were translated into Latin by other persons, and published after his death: viz,

1. His book upon the rules of painting, entitled, *De Symmetria Partium in rectis formis Humanoruin Corporum*, is one of them; printed in folio, at Nuremberg, in 1532, and at Paris in 1557. An Italian version also was published at Venice, in 1591.

2. *Institutiones Geometricæ*; Paris 1532.

3. *De Urbibus, Arcibus, Castellisque condendis et munientibus*; Paris 1531.

4. *De Varietate Figurarum, et Flexuris Partium, et Gestibus Imaginum*; Nuremberg 1534.

The figures in these books, which are from wooden plates, are very numerous, and most admirably well executed, indeed far beyond any thing of the kind done in our own days. Some of them also are of a very large size, as much as 16 inches in length, and of a proportional breadth, which being exquisitely worked, must have cost great labour. His geometry is chiefly of the practical kind, consisting of the most curious descriptions, inscriptions, and circumscriptions of geometrical lines, planes, and solids. We here meet, for the first time, with the plane figures, which folded up make the five regular or platonick bodies, as well as that curious construction of a pentagon, being the last method in prob. 23 of my Mensuration.

DYPTERE, in Architecture, the trunk of the pedestal, or that part between the base and the cornice, being so called, because it is often made in the form of a dye or cube.

DYNAMICS, is the science of moving powers; more particularly of the motion of bodies that mutually act on each other. See MECHANICS, MOTION, COMMUNICATION of Motion, OSCILLATION, PERCUSSION, &c; also my Course of Mathematics, vol. 2; besides the Mecanique Philosophique of Prony, the Mecanique Analytique of Lagrange, and the Mecanique Celeste of Laplace.

DYNOMETER is the name of an instrument intended for measuring the muscular strength of men and other animals. Mr. Graham, many years ago, invented an instrument for this purpose, which was afterwards improved by Dr. Desaguliers; but it was still too bulky and limited in its operations, to be of much use. The defect of this machine induced M. Leroy, of the Academy of Sciences at Paris, to construct another on more simple principles, and which was certainly more useful for the purpose it was designed for, than Mr. Graham's. The principle of this instrument was not much unlike that of the common spring steelyard, and perhaps it would have been still better, had its principles been exactly the same; for with this last-mentioned instrument, it is evident that the power of an animal may be as accurately ascertained as the weight of a body, and nothing more simple can well be devised.

DYPTERE, or DIPTERE, was a kind of temple, encompassed round with a double row of columns; and the pseudo-diptere, or false diptere, was the same, only this was encompassed with a single row of columns, instead of a double one.

E.

E A R

EAGLE, *Aquila*, is a constellation of the northern hemisphere, having its right wing contiguous to the equinoctial. For the stars in this constellation, see *AQUILA*.

EARTH, *Terra*, in Natural Philosophy, one of the four elements of the ancients; for, according to their system, all bodies were considered as resolvable into four simple elements, or constituent parts, namely, air, fire, water, and earth. The two former were avowedly almost unknown; most liquids were supposed to be modifications of the third, and the solid particles of bodies were attributed to the last. Earth in this extended sense was defined, a simple, dry, and cold substance; and as such, an ingredient that entered into the composition of all natural bodies. Modern chemists, though they have retained the term in a much more restricted sense, have yet included under it a sufficiently heterogeneous assemblage of bodies, many of which may be more properly considered as belonging to the class of alkalies.

The earths at present known, are nine in number; namely, Silex, Zircon, Alumine, Glycine, Ytria, Barites, Strontian, Lime, and Magnesia. And when they are purified by art from all foreign mixture, they agree in the following properties: 1. They are of a snow-white colour. 2. They are infusible by a very intense heat. 3. They are not reducible to the metallic state by being heated in contact with combustible matter. Of those nine earths, however, the last four have all the properties of alkalies; whence they are sometimes called alkaline earths; and many chemists are of opinion that the term earth ought only to be applied to the five former, by which arrangement the two classes of earths and alkalies would admit of distinct chemical definitions, which at present is wanted.

EARTH, in Geography, the terraqueous globe or ball which we inhabit, consisting of land and sea.

Figure of the EARTH. The ancients had various opinions as to the figure of the earth; some, as Anaximander and Leucippus, held it cylindrical, or in form of a drum; but the principal opinion was, that it was flat; that the visible horizon was the bounds of the earth, and the ocean the bounds of the horizon; that the heavens and earth above this ocean constituted the universe; and that all beneath the ocean was Hades: and of this same opinion were also some of the Christian fathers; as Lactantius, St. Augustine, &c. See Lactan. lib. 3, cap. 24; St. Aug. lib. 16, de Civitate Dei; Aristot. de Cœlo, lib. 2, cap. 13.

Such of the ancients however as understood any thing of astronomy, and especially the doctrine of eclipses, must have been acquainted with the round figure of the earth; as the ancient Babylonian astronomers, who had calculated eclipses long before the time of Alexander, and Thales the Grecian, who predicted an eclipse of the sun.

That the exterior of the earth is round, or rotund, is manifest to the most common perception, in the case of a ship sailing either from the land, or towards it; for when a person stands upon the shore, and sees a ship sail from the land, out to sea; at first he loses sight of the hull and lower parts of the ship, next the rigging and middle parts, and lastly of the tops of the masts themselves, in every

case the rotundity of the sea between the ship and the eye being very visible: the contrary happens when a ship sails towards us; we first see the tops of the masts appear just over the rotundity of the sea; next we perceive the rigging, and lastly the hull of the ship itself: all which is well illustrated by the following figure.

The round figure of the earth is also evident from the eclipses of the sun and moon; for in all eclipses of the moon, which are caused by the moon passing through the earth's shadow, that shadow always appears circular upon the face of the moon, whatever way it be projected, whether east, west, north, or south, and however its diameter vary, according to the greater or less distance from the earth. Hence it follows, that the shadow of the earth, in all situations, is really conical; and consequently the body that projects it, i. e. the earth, is at least nearly spherical.

The spherical figure of the earth is also evinced from the rising and setting of the sun, moon, and stars; all which happen sooner to those who live to the east, and later to those living westwardly; and that more or less so, according to the distance.

So also, in sailing to the northward, the north pole and northern stars become more elevated, and the south pole and southern stars more depressed; the elevation northerly increasing equally with the depression southerly; and each of them proportionably to the distance; and that is, in this case the south pole is elevated, and the north pole depressed. Besides, the oblique ascensions, descensions, emersions, and amplitudes of the rising and setting of the sun and stars in every latitude, are agreeable to the supposition of the earth's being of a spherical form: all which could not happen if it was of any other figure.

But the most convincing proof of the spherical figure of the earth, and which bids defiance to every objection, is, that many celebrated navigators have sailed round it, proceeding in a certain direction, and by constantly pursuing the same course, have finally arrived at the por-

whence they departed. The first who succeeded in this daring attempt, was Ferd. Magellan, a Portuguese, in the year 1519, and who completed his tour in 1124 days. In the year 1557 Francis Drake performed the same in 1056 days: in the year 1586, Sir Tho. Cavendish made the same voyage in 777 days; Simon Cordes, of Rotterdam, in the year 1590; and in the year 1598, Oliver Noort, a Hollander, in 1077 days; Van Schouten, in the year 1615, in 749 days; Jac. Heremites and Joh. Huygens, in the year 1623, in 802 days: and many others have since performed the same navigation, particularly Anson, Bougainville, and Cook; sometimes sailing round by the eastward, sometimes to the westward, till at length they arrived again in Europe, whence they set out; and in the course of their voyage, observed that all the phenomena, both of the heavens and earth, corresponded to, and evinced this spherical figure.

The globular figure of the earth is also inferred from the operation of levelling, in which it is found necessary to make an allowance for the difference between the apparent and the true level.

The natural cause of this sphericity of the globe is, according to Sir Isaac Newton, the great principle of attraction, which the Creator has stamped on all the matter in the universe; and by which all bodies, and all the parts of bodies, mutually attract one another.—And the same is the cause of the sphericity of the drops of rain, quicksilver, &c.

What the earth loses of its sphericity by mountains and valleys, is nothing considerable; the highest eminence being scarce equivalent to the minutest protuberance on the surface of an orange. Its difference from a perfect sphere, however, is more considerable in another respect, by which it approaches nearly to the shape of an orange, or to an oblate spheroid, being a little flattened at the poles, and raised about the equatorial parts, so that the axis from pole to pole is less than the equatorial diameter. What gave the first occasion to the discovery of this figure of the earth, was the observations of some French and English philosophers in the East Indies, and other parts, who found that pendulums performed their vibrations slower, the nearer they came to the equator; whence it follows, that the velocity of the descent of bodies by gravity, is less in countries nearer to the equator; and consequently that those parts are farther removed from the centre of the earth, or from the common centre of gravity. See the History of the Royal Academy of Sciences, by Du Hamel, p. 110, 156, 206; and Hist. de l'Acad. Roy. 1700 and 1701. This circumstance put Huygens and Newton upon finding out the cause, which they attributed to the revolution of the earth about its axis. If the earth were in a fluid state, its rotation round its axis would necessarily make it put on such a figure, because the centrifugal force being greatest towards the equator, the fluid would there rise and swell most; and that its figure really should be so now, seems necessary, to keep the sea in the equinoctial regions from overflowing the earth about those parts. See this curious subject well handled by Huygens, in his discourse De Causa Gravitatis, pa. 154, where he states the ratio of the polar diameter to that of the equator, as 577 to 578. And Newton, in his Principia, first published in 1686, demonstrates, from the theory of gravity, that the figure of the earth must be that of an oblate spheroid generated by the rotation of an ellipse about its shortest diameter, provided

all the parts of the earth were of an uniform density throughout, and that the proportion of the polar to the equatorial diameter of the earth, would be that of 689 to 692, or nearly that of 229 to 230, or as .9956522 to 1.

This proportion of the two diameters was calculated by Newton in the following manner. Having found that the centrifugal force at the equator is $\frac{1}{285}$ th of gravity, he assumes, as an hypothesis, that the axis of the earth is to the diameter of the equator as 100 to 101, and thence determines what must be the centrifugal force at the equator to give the earth such a form, and finds it to be $\frac{1}{303}$ ths of gravity: then, by the rule of proportion, if a centrifugal force equal to $\frac{1}{303}$ ths of gravity would make the earth higher at the equator than at the poles by $\frac{1}{303}$ th of the whole height at the poles, a centrifugal force that is the $\frac{1}{285}$ th of gravity will make it higher by a proportional excess, which by calculation is $\frac{1}{229}$ th of the height at the poles; and thus he discovered that the diameter at the equator is to the diameter at the poles, or the axis, as 230 to 229. But this computation supposes the earth to be every where of a uniform density; whereas if the earth is more dense near the centre, then bodies at the poles will be more attracted by this additional matter being nearer; and therefore the excess of the semi-diameter of the equator above the semi-axis, will be different. According to this proportion between the two diameters, Newton farther computes, from the different measures of a degree, that the equatorial diameter will exceed the polar, by $34\frac{1}{2}$ miles.

Nevertheless, Messrs. Cassini, both father and son, the one in 1701, and the other in 1713, attempted to prove, in the Memoirs of the Royal Academy of Sciences, that the earth was an oblong spheroid; and in 1718, M. Cassini again undertook, from observations, to show that, on the contrary, the longest diameter passes through the poles; which gave occasion for John Bernoulli, in his *Essai d'une Nouvelle Physique Celeste*, printed at Paris in 1735, to triumph over the British philosopher, apprehending that these observations would invalidate what Newton had demonstrated. And in 1720, M. De Mairan advanced arguments, supposed to be strengthened by geometrical demonstrations, further to confirm the assertions of Cassini. But in 1735 two companies of mathematicians were employed, one for a northern, and another for a southern expedition, the result of whose observations and measurement plainly proved that the earth was flattened at the poles; and so it has been considered ever since. See DEGREE.

The proportion of the equatorial diameter to the polar, as stated by the gentlemen employed on the northern expedition for measuring a degree of the meridian, is as 1 to 0.9891; by the Spanish mathematicians as 266 to 265, or as 1 to 0.99624; by M. Bouguer as 179 to 178, or as 1 to 0.99441.

As to all conclusions however deduced from the length of pendulums in different places, it is to be observed that they proceed upon the supposition of the uniform density of the earth, which is a very improbable circumstance; as justly observed by Dr. Horsley in his letter to Captain Phipps: "You finish your article," he concludes, "relating to the pendulum with saying, 'that these observations give a figure of the earth nearer to Sir Isaac Newton's computation, than any others that have hitherto been made'; and then you state the several figures given, as you imagine, by former observations, and by your own. Now it is very true, that if the meridians be ellipses, or if the figure of the earth be that of a spheroid generated

by the revolution of an ellipsis, turning on its shorter axis, the particular figure, or the ellipticity of the generating ellipsis, which your observations give, is nearer to what Sir Isaac Newton says it should be, if the globe were homogeneous, than any that can be derived from former observations. But yet it is not what you imagine. Taking the gain of the pendulum in latitude $79^{\circ} 50'$ exactly as you state it, the difference between the equatorial and the polar diameter, is about as much less than the Newtonian computation makes it, and the hypothesis of homogeneity would require, as you reckon it to be greater. The proportion of 212 to 211 should indeed, according to your observations, be the proportion of the force that acts upon the pendulum at the poles, to the force acting upon it at the equator. But this is by no means the same with the proportion of the equatorial diameter to the polar. If the globe were homogeneous, the equatorial diameter would exceed the polar by $\frac{1}{235}$ of the length of the latter: and the polar force would also exceed the equatorial by the like part. But if the difference between the polar and equatorial force be greater than $\frac{1}{235}$, (which may be the case in an heterogeneous globe, and seems to be the case in ours,) then the difference of the diameters should, according to theory, be less than $\frac{1}{235}$, and vice versa.

" I confess this is by no means obvious at first sight; so far otherwise, that the mistake, which you have fallen into, was once very general. Many of the best mathematicians were misled by too implicit a reliance upon the authority of Newton, who had certainly confined his investigations to the homogeneous spheroid, and had thought about the heterogeneous only in a loose and general way. The late Mr. Clairaut was the first who set the matter right, in his elegant and subtle treatise on the figure of the earth. That work has now been many years in the hands of mathematicians, among whom I imagine there are none, who have considered the subject attentively, that do not acquiesce in the author's conclusions.

" In the second part of that treatise, it is proved, that putting P for the polar force, Π for the equatorial, δ for the true ellipticity of the earth's figure, and ε for the ellipticity of the homogeneous spheroid, then

$$\frac{P - \Pi}{\Pi} = 2\varepsilon - \delta: \text{ therefore } \delta = 2\varepsilon - \frac{P - \Pi}{\Pi};$$

and therefore, according to your observation, $\delta = \frac{1}{235}$. This is the just conclusion from your observations of the pendulum, taking it for granted, that the meridians are ellipses: which is an hypothesis, upon which all the reasonings of theory have hitherto proceeded. But plausible as it may seem, I must say, that there is much reason from experiment to call it in question. If it were true, the increment of the force which actuates the pendulum, as we approach the poles, should be as the square of the sine of the latitude: or, which is the same thing, the decrement, as we approach the equator, should be as the square of the cosine of the latitude. But whoever takes the pains to compare together such of the observations of the pendulum in different latitudes, as seem to have been made with the greatest care, will find that the increments and decrements do by no means follow these proportions; and in those which I have examined, I find a regularity in the deviation which little resembles the mere error of observation. The unavoidable conclusion is, that the true figure of the meridians is not elliptical. If the meridians are not ellipses, the difference of the diameters may indeed, or it may not, be proportional to the difference between the polar and the equatorial force; but it is quite an un-

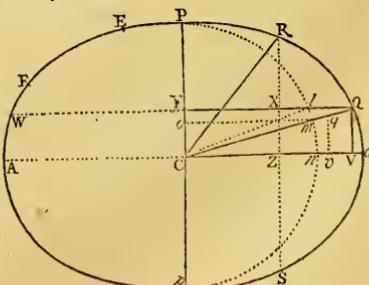

certainty, what relation subsists between the one quantity and the other; our whole theory, except so far as it relates to the homogeneous spheroid, is built upon false assumptions, and there is no saying what figure of the earth any observations of the pendulum give."

He then lays down the following table, which shows the different results of observations made in different latitudes; in which the first three columns contain the names of the several observers, the places of observation, and the latitude of each; the 4th column shows the quantity of $P - \Pi$ in such parts as Π is 100000, as deduced from comparing the length of the pendulum at each place of observation, with the length of the equatorial pendulum as determined by M. Bouguer, upon the supposition that the increments and decrements of force, as the latitude is increased or lowered, observe the proportion which theory assigns. Only the 2d and the last value of $P - \Pi$ are concluded from comparisons with the pendulum at Greenwich and at London, not at the equator. The 5th column shows the value of δ corresponding to every value of $P - \Pi$, according to Clairaut's theorem:

Observers.	Places.	Latitudes.	$P - \Pi$.	δ .
Bouguer	Equator	$0^{\circ} 0'$		
Bouguer	Porto Bello	$9 34$	741·8	$\frac{1}{235}$
Green	Otaheitee	$17 29$	563·2	$\frac{1}{235}$
Bouguer	San Domingo	$18 27$	591·0	$\frac{1}{235}$
Abbe de la Caille	Cape of Good Hope	$33 55$	731·5	
- - - - -	Paris	$48 50$	585·1	$\frac{1}{235}$
The Academicians	Pello	$66 48$	565·9	$\frac{1}{235}$
Capt. Phipps	- - - - -	$79 50$	471·2	$\frac{1}{235}$

" By this table it appears, that the observations in the middle parts of the globe, setting aside the single one at the Cape, are as consistent as could reasonably be expected; and they represent the ellipticity of the earth at about $\frac{1}{235}$. But when we come within 10 degrees of the equator, it should seem that the force of gravity suddenly becomes much less, and within the like distance of the poles much greater than it could be in such a spheroid."

The following problem, communicated by Dr. Leatherland to Dr. Pemberton, and published by Mr. Robertson, serves for finding the proportion between the axis and the equatorial diameter, from measures taken of a degree of the meridian in two different latitudes, supposing the earth an oblate spheroid.

Let rap be an ellipse, representing a section of the earth through the axis rp ; the equatorial diameter, or

the greater axis of the ellipse, being αa ; let E and F be two places where the measure of a degree has been taken; these measures are proportional to the radii of curvature in the ellipse at those places; and if c_Q , c_R be conjugates to the diameters whose vertices are E and F , c_Q will be to c_R in the subtriplicate ratio of the radius of curvature at E , to that at F , by Cor. I, prop. 4. part 6 of Milnes's Conic Sections, and therefore in a given ratio to one another; also the angles QCP , RCP are the latitudes of E and F ; so that, drawing QV parallel to RP , and $QWVW$ to AA , these angles being given, as well as the ratio of c_Q to c_R , the rectilinear figure $CQWVYX$ is given in species; and the ratio of $vc^2 - zc^2 (= QX \times XW)$ to $rz^2 - QV^2 (= RX \times XS)$ is given, which is the ratio of ca^2 to cp^2 ; therefore the ratio of ca to cp is given.

Hence, if the sine and cosine of the greater latitude, be each augmented in the subtriplicate ratio of the measure of the degree in the greater latitude, to that in the lesser, then the difference of the squares of the augmented sine, and the sine of the lesser latitude, will be to the difference of the squares of the cosine of the lesser latitude and the augmented cosine, in the duplicate ratio of the equatorial to the polar diameter. For c_Q , being taken in c_Q equal to c_R , and qv drawn parallel to QV , cv and vq , cZ and ZR will be the signs and cosines of the respective latitudes, to the same radius; and cv , vq will be the augmentations of cv and c_Q , in the ratio named.

Hence, to find the ratio between the two axes of the earth, let E denote the greater, and F the lesser of the two latitudes, M and N the respective measures taken in each; and let P denote

$$\sqrt[3]{\frac{M}{N}}: \text{ then } \sqrt{\frac{\cos^2 F - F^2 \times \cos^2 E}{P^2 + \sin^2 E - \sin^2 F}} \text{ is } \frac{\text{lesser axis}}{\text{greater axis}}.$$

It also appears by the above problem, that when one of the degrees measured, is at the equator, the cosine of the latitude of the other being augmented in the subtriplicate ratio of the degrees, the tangent of the latitude will be to the tangent answering to the augmented cosine, in the ratio of the greater axis to the less. For supposing e the place out of the equator; then if the semi-circle $elmp$ be described, and lc joined, and mo drawn parallel to ac : co is the cosine of the latitude to the radius cp , and cv that cosine augmented in the ratio before-named; yc being to yl , that is ca to cn or cr , as the tangent of the angle QCo , the latitude of the point E , to the tangent of the angle YCl , belonging to the augmented cosine. Thus, if m represent the measure in a latitude denoted by E , and n the measure at the equator, let α denote an angle whose measure is $\cos E \times \sqrt[3]{\frac{m}{n}}$. Then $\frac{\tan \alpha}{\tan E}$ is $\frac{\text{lesser axis}}{\text{greater axis}}$.

But m , or the length of a degree, obtained by actual mensuration in different latitudes, is known from the following table:

Names.	Latit.	Value of m .
		toises.
Swanberg and assoc.	66° 20'	$m = 57209$
Cassini and }	49 22	$m = 57074$
La Caille }	45 00	$m = 57050$
Boscovich	43 00	$m = 56972$
De la Caille	33 18	$m = 57037$
Bouguer and assoc.	00 0	$m = 56757$
measur. at equator		

Now, by comparing each of the first five with the 6th or last, there are obtained 5 results, each showing the

relation of the axes or diameters; the arithmetical means of all of which gives that ratio as 1 to 0.996747, which is the ratio of 308 to 307. But if the last of the four results be omitted, the medium among the other four gives the ratio of 1 to 0.996876, or of 320 to 319, which is probably nearest the truth.

Now the magnitude, as well as the figure of the earth, that is the polar and equatorial diameters, may be deduced from the foregoing problem. For, as half the latus rectum of the greater axis αa is the radius of curvature at α , it is given in magnitude from the degree measured there, and thence the axes themselves are given. Thus, the circular arc whose length is equal to the radius being 57°29578 degrees, if this number be multiplied by 56757 toises, the measure of a degree at the equator, the product, will be the radius of curvature there, or half the latus rectum of the greater axis; and this is to half the lesser axis in the ratio of the less axis to the greater, that is, as 319 to 320; whence the two axes are 6524252 and 6544704 toises, or 7901 and 7926 English miles; and the difference between the two axes about 25 miles. See Robertson's Navigation, vol. 2, pa. 206 &c. See also Suite des Mem. de l'Acad, 1718, pa. 247; and Maclaurin's Fluxions, vol. 2, book 1, ch. 14. Also the later measurements of the French Institute, of Swanberg, of Colonel Mudge, &c. &c.

And nearly the same ratio is deduced from the lengths of pendulums vibrating in the same time, in different latitudes; provided it be allowed that the meridians are real ellipses, or the earth a true spheroid, which however can only take place in the case of an uniform gravity in all parts of the earth.

Thus, in the new Petersburg Acts, for the years 1788 and 1789, are accounts and calculations of experiments relative to this subject, by M. Kraft. These experiments were made at different times, and in various parts of the Russian empire. This gentleman has collected and compared them, and drawn the proper conclusions from them: thus he infers that the length x of a pendulum that swings seconds in any given latitude λ , and in a temperature of 10 degrees of Réaumur's thermometer, may be determined by this equation: $x = 439178 + 2.321 \sin^2 \lambda$, lines of a French foot, or $x = 39.0045 + 0.206 \sin^2 \lambda$, in English inches, in the temperature of 53 of Fahrenheit's thermometer.

This expression nearly agrees, not only with all the experiments made on the pendulum in Russia, but also with those of Mr. Graham in England, and those of Mr. Lyons in 79° 50' north latitude, where he found its length to be 431.38 lines. It also shows the augmentation of gravity from the equator to the parallel of a given latitude λ : for, putting g for the gravity under the equator, g for that under the pole, and y for that under the latitude λ , M. Kraft finds $y = (1 + 0.0052848 \sin^2 \lambda)g$; and therefore $g = 1.0052848g$.

From this proportion of gravity under different latitudes, the same author infers that, in case the earth is a homogeneous ellipsoid, its oblateness must be $\frac{1}{191}$; instead of $\frac{1}{130}$, which ought to be the result of this hypothesis: but on the supposition that the earth is a heterogeneous ellipsoid, he finds its oblateness, as deduced from these experiments, to be $\frac{1}{177}$; which agrees with that resulting from the measurement of some of the degrees of the meridian nearly. This confirms an observation of M. Laplace, that, if the hypothesis of the earth's homogeneity be given

up, then theory, the measurement of degrees of latitude, and experiments with the pendulum, all agree in their result with respect to the oblateness of the earth. See Mémoires de l'Acad. 1753, pa. 17, and his later works.

In the Philos. Trans. for 1791, pa. 236, Mr. Dalby has given some calculations on measured degrees of the meridian; whence he infers, that those degrees measured in middle latitudes, will answer nearly to an ellipsoid whose axes are in the ratio assigned by Newton, viz, that of 230 to 229. And as to the deviations of some of the others, viz, towards the poles and equator, he thinks they are caused by the errors in the observed celestial arcs.

On the supposition that the earth's figure is that of an oblate spheroid, it has been shown, 1st, That a degree of the earth's équator is the first of two mean proportionals, between the last and first degrees of latitude. 2d, If the equatorial diameter be to the polar axis, as 180 to 179, the lat. in which the degree of lat. is equal to a degree of the equator, will be $54^{\circ} 48' 24''$. If the proportion be 230 to 229, the lat. comes out $54^{\circ} 45' 31''$. 3d, If the proportion be 180 to 179, the lat. where the degree of the meridian is equal to a degree of a circle whose diameter is equal to the earth's axis, will be $35^{\circ} 20' 30''$; assuming the proportion 230 to 229, that lat. will be $35^{\circ} 19' 25''$. (Horsley's Tracts, p. 394, &c.)

M. Swanberg observes, that occultations of the fixed stars by the moon is another method by which the figure of the earth may be determined: and M. Treisnecker, after comparing a great number of these occultations, concludes from them that the ellipticity of the earth is $\frac{1}{32}$.

The excellent mathematician and astronomer Laplace, in his Mécanique Céleste, has calculated the ellipticity of the earth, from the effect of precession and nutation, to be $\frac{1}{33\frac{1}{2}}$; which is nearly an arithmetical mean among those obtained from occultations of the stars, and the vibrations of the pendulum. The theory of the moon also gives $\frac{1}{33}$ for the ellipticity.

The preceding ellipticities of the earth, expressed in parts of its equatorial diameter, with their authors, and the principles from which they were derived, may be exhibited in one view, as follows:

Authors.	Ellipticities.	Principles.
Huygens - -	$\frac{1}{32\frac{9}{10}}$	
Newton - -	$\frac{1}{32\frac{9}{10}}$	Theory of gravity.
Maupertuis, &c.	$\left\{ \begin{array}{l} \frac{1}{32\frac{1}{4}} \\ \frac{1}{32\frac{1}{2}} \end{array} \right\}$	Mensuration of arcs.
Swanberg - -	$\frac{1}{32\frac{1}{2}}$	Rotatory motion.
Clairaut - -	$\left\{ \begin{array}{l} \frac{1}{32\frac{1}{2}} \\ \frac{1}{32\frac{1}{2}} \end{array} \right\}$	Vibration of pendulum.
Treisnecker - -	$\frac{1}{32\frac{9}{10}}$	Occult. of stars.
Laplace - -	$\left\{ \begin{array}{l} \frac{1}{32\frac{1}{4}} \\ \frac{1}{32\frac{1}{2}} \end{array} \right\}$	Precession and nutation. Theory of the moon.

The variety in the preceding results presents an interesting circumstance, as it indicates something in the figure and conformation of the earth, which is not yet understood, and naturally gives rise to the following important and intricate questions, to which all the accumulated knowledge of the present times has not been able to obtain complete solutions. Is the earth a spheroid of rotation? Are the northern and southern hemispheres equal and similar to each other? What is the ratio of an arc of the meridian, measured in a given latitude, to the whole

meridian? It is perhaps no improbable conjecture, that the effects of precession and nutation, with the vibrations of the pendulum, will be found among the most accurate means of determining, at least, the general outlines of our globe.

Tacquet draws some pleasing inferences, in the form of paradoxes, from the round figure of the earth; as, 1st, That if any part of the surface of the earth were quite plane, a man could no more walk upright upon it, than on the side of a mountain. 2d, That the traveller's head goes a greater space than his feet; and a horseman than a footman; as moving in a greater circle. 3d, That a vessel, full of water, being raised perpendicularly, some of the water will be continually flowing out, yet the vessel still remain full; and on the contrary, if a vessel of water be let perpendicularly down, though nothing flow out, yet it will cease to be full: consequently there is more water contained in the same vessel at the foot of a mountain, than on the top; because the surface of the water is formed into a segment of a smaller sphere below than above. Tacq. Astron. lib. 1, cap. 2.

Changes of the EARTH. Mr. Boyle suspects that there are great, though slow internal changes, in the mass of the earth. He draws his arguments from the varieties observed in the change of the magnetic needle, and from the observed changes in the temperature of climates. But as to the latter, there is reason to suspect that he could not have diaries of the weather sufficient to direct his judgement. Boyle's Works abr. vol. 1, pa. 292, &c.

Magnetism of the EARTH. The notion of the magnetism of the earth was started by Gilbert; and Boyle supposes magnetic effluvia moving from one pole to the other. See His Works abr. vol. 1, pa. 285, 290.

Dr. Knight also thinks that the earth may be considered as a great loadstone, whose magnetical parts are disposed in a very irregular manner; and that the south pole of the earth is analogous to the north pole in magnets, that is, the pole by which the magnetical stream enters. See MAGNET.

He observes also, that all the phenomena attending the direction of the needle, in different parts of the earth, in a great measure correspond with what happens to a needle, when placed on a large terrella; if we make allowances for the different dispositions of the magnetical parts, with respect to each other, and consider the south pole of the earth as a north pole with regard to magnetism. The earth might become magnetical by the iron ores it contains, for all iron ores are capable of magnetism; and that a great part of the earth consists of iron is rendered probable by its great medium specific gravity, being nearly 5 times that of water. It is true, the globe might notwithstanding have remained unmagnetic, unless some cause had existed capable of making that repellent matter producing magnetism move in a stream through the earth.

Now the doctor thinks that such a cause does exist. For if the earth revolves round the sun in an ellipse, and the south pole of the earth is directed towards the sun, at the time of its descent towards it, a stream of repellent matter will thence be made to enter at the south pole, and issue out at the north. And he suggests, that the earth being in its perihelion in winter may be one reason why magnetism is stronger in this season than in summer. The cause here assigned for the earth's magnetism must continue, and perhaps improve it, from year to year.

Hence the doctor thinks it probable, that the earth's magnetism has been improving ever since the creation, and that this may be one reason why the use of the compass was not discovered sooner. See Dr. Knight's attempt to demonstrate, that all the phenomena in nature may be explained by Attraction and Repulsion, prop. 87.

Magnitude and Constitution of the EARTH. This has been variously determined by different authors, both ancient and modern. The usual way has been, to measure the length of one degree of the meridian, and multiply it by 360, for the whole circumference. See DEGREE. Diogenes Laertius informs us, that Anaximander, a scholar of Thales, who lived about 550 years before the birth of Christ, was the first who gave an account of the circumference of the sea and land; and it seems his measure was used by succeeding mathematicians, till the time of Eratosthenes. Aristotle, at the end of lib. 2 De Cœlo, says, the mathematicians who have attempted to measure the circuit of the earth, make it 40000 stadii; which it is thought is the number determined by Anaximander.

Eratosthenes, who lived about 200 years before Christ, was the next who undertook this business; which, as Cleomedes relates, he performed by taking the sun's zenith distances, and measuring the distance between two places under the same meridian; by which he deduced for the whole circuit about 250000 stadii, which Pliny states at 31500 Roman miles, reckoning each at 1000 paces. But this measure was considered to be false by many of the ancient mathematicians, and particularly by Hipparchus, who lived 100 years afterwards, and who added 25000 stadii to the circuit of Eratosthenes.

Posidonius, in the time of Cicero and Pompey the Great, next measured the earth, viz, by means of the altitudes of a star, and measuring a part of a meridian; from which he concluded that the circumference was 240000 stadii, according to Cleomedes, but only 180000 according to Strabo.

Ptolemy, in his Geography, says that Marinus, a celebrated geographer, attempted something of the same kind; and in lib. 1, cap. 3, he mentions that he himself had tried to perform the same thing in a manner different from any others before his time, which was by means of places under different meridians: but he does not say how much he made the number; for he still made use of the number 180000, which had been before employed.

Snellius relates, from the Arabian geographer Abel-feda, who lived about the year 1300, that about the year 800, Almaimon, an Arabian king, having collected together some skilful mathematicians, commanded them to find out the circumference of the earth. Accordingly they made choice of the fields of Mesopotamia, where they measured under the same meridian from north to south, till the pole was depressed one degree lower: which measure they found equal to 56 miles, or $56\frac{2}{3}$: so that according to them the circuit of the earth is 20160 or 20340 miles.

It was long time after this, before any more attempts of this kind were made. At length, however, Snell, above mentioned, professor of mathematics at Leyden, about the year 1620, with great skill and labour, by measuring large distances between two parallels, found one degree equal to 28500 perches, each of which is 12 Rhinland feet, amounting to 19 Dutch miles, and so the whole periphery 6840 miles; a mile being, according to him,

1500 perches, or 18000 Rhinland feet. See his treatise called Eratosthenes Batavus.

The next that undertook this measurement, was Richard Norwood, who in the year 1635, by measuring the distance from London to York with a chain, and taking the sun's meridian altitude, June 11th old style, with a sextant of about 5 feet radius, found a degree contained 367200 feet, or 69 miles and a half and 14 poles; and thence the circumference of a great circle of the earth is a little more than 25036 miles, and the diameter a little more than 7966 miles. See the particulars of this measurement in his Seaman's Practice.

The measurement of the earth by Snell, though very ingenious and troublesome, and much more accurate than any of the ancients, being still thought by some French mathematicians liable to certain small errors, the business was renewed, after Snell's manner, by Picard and other mathematicians, by the king's order; using a quadrant of $3\frac{1}{2}$ French feet radius; and thus found a degree contained 342360 French feet. See Picard's treatise, La Mesure de la Terre.

M. Cassini the younger, in the year 1700, by the king's command also, renewed the business with a quadrant of 10 feet radius, for taking the latitude, and another of $3\frac{1}{2}$ feet for taking the angles of the triangles; and found a degree, from his calculation, contained 57292 toises, or almost $69\frac{1}{2}$ English miles.

Several other measurements have been taken, the best of which are the following, with the corresponding mean semidiometer annexed, in English miles.

Ulloo and Condamine	-	-	3957.7 miles.
Cassini and Lacaille	-	-	3957.1
Lacaille	-	-	3954.7
Boscovich	-	-	3955.0
Liesganig	-	-	3958.2
General Roy	-	-	3956.8
Major Lambton	-	-	3956.5

The medium among all these is nearly 3957 miles, which may be taken for the mean semidiometer of the earth. And supposing the solar parallactic angle to be $8^{\circ}6'$, it will be, as sin. $8^{\circ}6'$: radius : : 3957 : 95 millions of miles nearly, the earth's distance from the sun.

Hence the mean circumference is 24862 miles, which gives $69\frac{1}{2}$ miles for the medium length of a degree of a great circle.

See the results of many other measurements under the article DEGREE, and from the preceding part of the present article. From the mean of all which, the following dimensions may be taken as near the truth:

the circumference	-	4862 miles,
the diameter	-	27914 miles,
the superficies	-	196757900 square miles,
the solidity	-	259523200000 cubic miles.

Also the seas and unknown parts of the earth, by a measurement of the best maps, contain 160522026 square miles, the inhabited parts 38922180; of which Europe contains 4456065; Asia, 10768823; Africa, 9654807; and America, 14110874.

The terraqueous globe has two motions, besides that on which the precession of the equinoxes depends; the one diurnal around its own axis in the space of 24 hours, which constitutes the natural day; the other annual, about the sun, in an elliptical orbit or track, in 365 days 6 hours, constituting the year. From the former arise the diversities of day and night; and from the latter,

the vicissitudes of seasons, spring, summer, autumn, and winter.

The terraqueous globe is distinguished into three parts or regions, viz, 1st, The external part or crust, being that from which vegetables spring and animals are nursed. 2d, The middle, or intermediate part, which is possessed by fossils, extending further than human labour ever yet penetrated. 3d, The internal or central part, which is utterly unknown to us, though by many authors supposed of a magnetic nature; by others, a mass or sphere of fire; by others, an abyss or collection of waters, surrounded by the strata of earth; and by others, a hollow, empty space, inhabited by animals, who have their sun, moon, planets, and other conveniences within the same. But others divide the body of the globe into two parts, viz, the external part, called the cortex, including the internal, which they call the nucleus, being of a different nature from the former, and possessed by fire, water, or more likely by a considerable portion of metals, and probably mostly iron, as it has been found, by my calculation, that the mean density of the whole earth is near double the density of common stone. See my determination of it, Philos. Trans. 1778, p. 781; or my Tracts, vol. I, tract 26.

The external part of the globe either exhibits inequalities, as mountains and valleys; or it is plane and level; or hollowed into channels, fissures, &c, where rivers, lakes, and seas, flow in all directions. These inequalities in the face of the earth most naturalists suppose have arisen from a rupture or subversion of it, by the force either of the subterraneous fires or waters. The earth, in its natural and original state, it has been supposed by Descartes, and after him, Burnet, Steno, Woodward, Whiston, and others, was perfectly round, smooth, and equable; and they account for its present rude and irregular form, principally from the great deluge. See DELUGE.

In the external, or cortical part of the earth, there appear various strata, supposed the sediments of several floods; the waters of which, being replete with matters of divers kinds, as they dried up, or oozed through, deposited these different matters, which in time hardened into strata of stone, sand, coal, clay, &c.

Dr. Woodward has considered the circumstances of these strata with great attention, viz, their order, number, and situation with respect to the horizon, depth, intersections, fissures, colour, consistence, &c. He ascribes the origin and formation of them all, to the great flood, &c. At that terrible revolution he supposes that all sorts of terrestrial bodies had been dissolved and mixed with the waters, forming all together a chaos or confused mass. This mass of terrestrial particles, intermixed with water, he conceives was at length precipitated to the bottom; and that generally according to the order of gravity, the heaviest sinking first, and the lightest afterwards; by which means the strata were formed of which the earth consists; which, attaining their solidity and hardness by degrees, have continued so ever since. These sediments, he further concludes, were at first all parallel and concentrical; and the surface of the earth formed of them, perfectly smooth and regular; but that in course of time, divers changes arising, from earthquakes, volcanoes, &c, the order and regularity of the strata was disturbed and broken, and the surface of the earth by such means brought to the irregular form in which it now appears.

M. De Buffon surmises that the earth, as well as the other planets, are parts struck off from the body of the

sun by the collision of comets; and that when the earth assumed its form, it was in a state of liquefaction by fire. But this cannot be granted; for if they were struck off from the body of the sun, they would move in orbits that would always pass through the sun, instead of having the sun for their focus, or centre, as they are now found to have; so that having been struck off they would fall down into the sun again, terminating their career as it were after one revolution only.

Besides these, various other hypotheses have been advanced, all of them however more or less liable to objections; as must always be the case with conclusions drawn from uncertain data. We may however particularize Dr. James Hutton's treatise, on this subject, as one deserving the most attention, and from which much useful information may be derived.

EARTH, in Astronomy, is one of the primary planets, according to the system of Copernicus, or Pythagoras; its astronomical character or mark being Θ : but according to the Ptolemaic hypothesis, it is the centre of the system. For, whether the earth move or remain at rest, that is, whether it be fixed in the centre, having the sun, the heavens and stars moving round it from east to west; or, these being at rest, whether the earth only moves from west to east, is the great article that distinguishes the Ptolemaic system from the Copernican.

Motion of the EARTH. It has already been observed that, besides the small motion of the earth which causes the precession of the equinoxes, the earth has two great and independent motions; viz, the one by which it turns round its own axis, in the space of 24 hours nearly, which causes the continual succession of day and night; and the other an absolute motion of its whole mass in a large orbit about the sun, having that luminary for its centre, so that its axis keeps always parallel to itself, inclined in the same angle to its path, and by that means causing the vicissitudes of seasons, spring, summer, autumn, and winter.

It is indeed true that, as to sense, the earth appears to be fixed in the centre, with the sun, stars and heavens moving round it every day; and such, doubtless would be considered as the true nature of the motions in the first early ages of mankind, as they are still by the rude and unlearned. But to a thinking and learned mind, the contrary will soon appear.

Indeed there are traces of the knowledge of these motions in the earliest age of the sciences. Cicero, in his Tusc. Quæst. says that Nicetas of Syracuse first discovered that the earth had a diurnal motion, by which it revolved round its axis every 24 hours; and Plutarch, de Placit. Philosoph. informs us that Philolaus discovered its annual motion round the sun; also Aristarchus, about 100 years after Philolaus, alludes to the motion of the earth in stronger and clearer terms, as we are assured by Archimedes, in his Arenarius. And the same, we are further assured, was the opinion and doctrine of Pythagoras.

But the religious opinions of the heathen world prevented this doctrine from being more cultivated. For, Aristarchus being accused of sacrilege by Cleanthes for moving Vesta and the tutelar deities of the universe out of their places, the philosophers were obliged to dissemble, and seem to relinquish so perilous a position.

Many ages afterwards, Nic. Cusanus revived the ancient system, in his Doct. de Pignorant, and asserted the motion of the earth: but the doctrine gained very little ground till the time of Copernicus, who showed its great

utility and advantages in astronomy; and who had immediately all the philosophers and astronomers on his side, that dared to differ from the crowd, and were not afraid of ecclesiastical censure, which was not less dangerous under the Christian dispensation, than if had been under that of the heathen. For, because certain parts of Scripture make mention of the stability of the earth, and of the motion of the sun, as the rising and setting, &c., the fathers of the church thought their religion required that they should defend, with all its power, what they conceived to be its doctrines, and to censure and punish every attempt at innovation on those points. There is now however no doubt that in such instances the expressions are only to be considered as accommodated to appearances, and the vulgar notions of things.

By the diurnal rotation of the earth on its axis, the same phenomena must take place as if it had no such motion, that is, as if the sun and stars revolved about it. For, turning round from west to east, causes the sun and all the visible heavens to have the appearance of moving the contrary way, or from east to west, as we daily see them. So that, when in its rotation it has brought the sun or a star to appear just in the horizon in the east, they are then said to be rising; and as the earth continues to revolve more and more towards the east, other stars seem to rise and advance westwards, passing the meridian of the observer, when they are due south from him, and at their greatest altitude above his horizon; after which, by a continuance of the same motions, viz. of the earth's rotation eastwards, and the luminaries' apparent counter motion westwards, these decline from the meridian, or south point, towards the west, where being arrived, they are said to set and descend below it; and so on continually from day to day; thus making it day while the sun is above the horizon, and night while he is below it.

While the earth is thus revolving on its axis, it is at the same time carried by its proper motion in its orbit round the sun, as one of the planets, namely, between the orbits of Venus and Mars, having the orbits of Venus and Mercury within its own, or between it and the sun, in the centre, and those of Mars, Jupiter, Saturn, &c., without or above it; which are therefore called superior planets, and the others the inferior ones; which is called the annual motion of the earth, because it is performed in a year, of 365 days 6 hours nearly; or rather 365 days 5 hours 49 minutes, from either equinox or solstice to the same again, which completes the tropical year; but from any fixed star to the same again, as seen from the sun, in 365 days 6 hours 9 minutes, which is called the sidereal year. The figure of this orbit is elliptical, having the sun in one focus, the mean distance being about 95 millions of miles, which is upon the supposition that the sun's parallax is about $8^{\circ} \frac{1}{2}$, or the angle under which the earth's semi-diameter would appear to an observer placed in the sun: and the eccentricity of the orbit, or distance of the sun, in the focus, from the centre of this elliptic orbit, is about $\frac{1}{60}$ th of the mean distance.

Now this annual motion is performed in such a manner, that the earth's axis is every where parallel, or in the same direction in every part of the orbit; by which means it happens, that at one time of the year the sun enlightens more of the north polar parts, and at the opposite season of the year more of the southern parts, thus showing all the varieties of seasons, spring, summer, autumn and winter; which may be illustrated in the following manner:

Let the candle 1 (fig. 1, plate x) represent the sun, about which the earth E, or F, &c., is moved in its elliptical orbit ABCD, or ecliptic, and cutting the equator abcd in the nodes E and G: then, suspending the terrella by its north pole, and moving it, so suspended, round the ecliptic, its axis will always be parallel to its first position, and the various seasons will be represented at the different parts of the path. Thus, when the earth is at ss or F, the enlightened half of it includes the south pole, and leaves the north pole in darkness, making our winter; at G it is spring, and the two poles are equally illuminated, and the days are every where of the same length; at H or K it is our summer, the north polar parts being in the illuminated hemisphere, and the southern in the dark one; lastly, at E it is autumn, the poles being equally illuminated again, and the days of equal length every where.

EARTH, its Quantity of Matter, Density, and Attractive Power. Though the relative densities of the earth and most of the other planets have been known a considerable time, it is but very lately that we have come to the knowledge of the absolute gravity or density of the whole mass of the earth. This I have calculated and deduced from the observations made by Dr. Maskelyne, (late Astronomer Royal,) at the mountain Schehallien, in the years 1774, -5, and -6. The attraction of that mountain on a plummet, being observed on both sides of it, and its mass being computed from a number of sections in all directions, and consisting of stone; these data being then compared with the known attraction and magnitude of the earth, gave by proportion its mean density, which is to that of water nearly as 5 to 1, and to common stone as 2 to 1: from which very considerable mean density, it may be presumed that the internal parts contain some great quantities of metals.

From the density, thus found, its quantity of matter becomes known, being equal to the product of its density by its magnitude. From various experiments too, we know that its attractive force, at the surface, is such, that bodies fall there through a space of $16\frac{1}{2}$ feet in the first second of time: whence the force at any other place, either within or without it, becomes known; for the force at any part within it (supposing it every where uniform) is directly as its distance from the centre; but the force of any part without it, reciprocally as the square of its distance from the centre.

EAST, one of the cardinal points of the horizon, or of the compass, being the middle point of it between north and south, on that side where the sun rises, or the point in which it is intersected on that side by the prime vertical.

EASTER, a feast of the church, held in memory of our Saviour's resurrection. This feast has been annually celebrated ever since the time of the apostles, and is one of the most considerable festivals in the Christian calendar; being that which regulates and determines the times of all the other moveable feasts.

The rule for the celebration of easter, fixed by the council of Nice, in the year 325, is, that it be held on the sunday which falls upon, or next after, the full moon which happens next after the 21st of March; that is, the sunday which falls upon, or next after the first full moon after the vernal equinox. The reason of which decree was, that the Christians might avoid celebrating their easter at the same time with the Jewish passover, which, according to the institution of Moses, was held the very day of the full moon.

To find EASTER according to the Old, or Julian Style.

In the annexed table, find the golden number, with the day of the paschal full moon, and the sunday letter annexed; compare this letter with the dominical letter of the given year, that it may appear how many days are to be added to the day of the paschal full moon, to give easter-day.

For Example. In the year 1715, the dominical letter is *b*, and the golden number is *6*, opposite to which stands April 10 for the day of the paschal full moon; opposite to which is the sunday letter *b*, which happening to be the same with that of the given year, that day is a sunday; and therefore easter will fall 7 days after, viz, on the 17th of April.

But in this computation, the vernal equinox is supposed fixed to the 21st of March; and the cycle of 19 years, or golden numbers, is supposed to point out the places of the new and full moons exactly; both which suppositions are erroneous: so that the Julian easter never happens at its due time, unless by accident. For instance, in the above example the vernal equinox falls on the 10th of March, eleven days before the rule supposes it; and the paschal full moon on the 7th of April, or 3 days earlier than was supposed: and therefore easter-day should be held on the 10th of April, instead of the 17th.

This error had grown to such a height, that Pope Gregory the 13th thought it necessary to correct it; and accordingly, in the year 1582, by the advice of Aloysius Lilius and others, he ordered 10 days to be thrown out of October, to bring the vernal equinox back again to the 21st of March: and hence arise the terms Gregorian calendar, Gregorian year, &c.

This correction however did not entirely remove the error; for the equinoxes and solstices still anticipate 28° 20' in every 100 Gregorian years; but the difference is so inconsiderable as not to amount to a whole day, or 24 hours, in less than 5082 Gregorian years.

The Gregorian, or New Style, was not introduced into England till the year 1752, when eleven days were thrown out, viz, between the 3d and 14th of September, the error amounting then to that quantity.

To find EASTER according to the New or Gregorian Style, till the Year 1900 exclusive.

Look for the golden number of the year in the first column of the table, against which stands the day of the paschal full moon; then look in the 3d column for the sunday letter, next after the day of the full moon, and the day of the month standing against that sunday letter is easter-day. When the full moon happens on a sunday, then the next sunday after is easter-day.

For Example. For the year 1813, the golden number is *9*; against which stands April the 15th, and the next sunday letter, which is *c*, below that, stands opposite April 18; which is therefore the easter-day for the year 1813.

Though the Gregorian calendar be much preferable to the Julian, it is yet not without its defects. It cannot, for instance, keep the equinox always fixed on the 21st of March, but it will vary between the 19th and the 23d. To which we may add, that the full moon happening on the 20th of March, might sometimes be paschal; yet it is not allowed as such in the Gregorian computation; as on the contrary, the full moon of the 22d of March may be allowed for paschal, which it is not. Scaliger and Calvisius have also pointed out other inaccuracies in this calendar. An excellent paper on this subject by the Earl of Macclesfield, may be seen in the Philos. Trans. vol. 40, pa. 417; or my Abridg. vol. x, pa. 33.

ECHO, a sound reflected, or reverberated from some body, and thence returned or repeated to the ear.—For an echo to be heard, the ear must be in the line of reflection; that the person who made the sound, may hear the echo, it is necessary he should be in a perpendicular to the place which reflects it; and for a multiple or tautological echo, it is necessary that there should be a number of walls and vaults, rocks and cavities, either placed behind each other, or fronting each other. Those murmurs in the air, that are occasioned by the discharge of great guns, &c, are a kind of indefinite echoes, and are produced from the vaporous particles suspended in the atmosphere, which resist the undulations of sound, and reverberate them to the ear.

There can be no echo, unless the direct and reflex sounds follow one another at a sufficient distance of time; for if the reflex sound arrive at the ear before the impression of the direct sound ceases, it will not be doubled, but only rendered more intense. Now if we allow that 9 or 10 syllables can be pronounced in a second, in order to preserve the sounds articulate and distinct, there should be about the 9th part of a second between the times of their appulse to the ear; or, as sound flies about 1142 feet in a second, the said difference should be $\frac{1}{9}$ of 1142, or 127 feet; and therefore every syllable will be reflected to the ear at the distance of about 70 feet from the reflecting body; but as, in the ordinary way of speaking, 3 or 4 syllables only are uttered in a second, the speaker, that he

may have the echo returned as soon as they are expressed, should stand about 500 feet from the reflecting body; and so in proportion for any other number of syllables. Mersenne allows for a monosyllable the distance of 69 feet; Morton, 90 feet; for a disyllable 105 feet, a trisyllable 160 feet, a tetrasyllable 182 feet, and a pentasyllable 204 feet. *Nat. Hist. Northampton*, cap. 5, pa. 358.

From what has been said, it follows that echoes may be applied for measuring inaccessible distances. Thus, Mr. Derham, standing on the banks of the Thames, opposite to Woolwich, observed that the echo of a single sound was reflected back from the houses in 3 seconds; consequently the sum of the direct and reflex rays must have been $142 \times 3 = 3420$ feet, and the half of it, 1713 feet, the breadth of the river in that place.

It also follows, that the echoing body being removed farther off, it reflects more of the sound than when nearer; which is the reason why some echoes repeat but one syllable, or one word, and some many. Of these, some are tonical, which only return a voice when modulated into some particular musical tone; and others polysyllabical. That fine echo in Woodstock park, Dr. Plot assures us, in the day-time will return very distinctly 17 syllables, and in the night 20. *Nat. Hist. Oxf. cap. 1, pa. 7.*

Echoing bodies may be so contrived, and placed, as that reflecting the sound from one to the other, a multiple echo, or many echoes, shall arise.—At Rosneath, near Glasgow, in Scotland, there is an echo that repeats a tune played with a trumpet three times completely and distinctly.—At the sepulchre of Metella, wife of Crassus, there was an echo, which repeated what a man said five times.—Some authors mention a tower at Cyzicus, where the echo is repeated seven times, and one at Brussels, that answers 15 times.

But the finest echo we read of, is that mentioned by Barthius, in his notes on Statius's *Thebais*, lib. 6, ver. 30, which repeated the words a man uttered 17 times. This was on the banks of the Naha, between Coblenz and Bingen. And whereas, in common echoes, the repetition is not heard till some time after hearing the words spoken, or the notes sung; in this, the person who speaks, or sings, is scarce heard at all; but the repetition very clearly, and always in surprising varieties; the echo seeming sometimes to approach nearer, and sometimes farther off; sometimes the voice is heard very distinctly, and sometimes scarce at all: one person hears only one voice, and another several; one hears the echo on the right, and the other on the left, &c.

Addison, and other travellers in Italy, mention an echo at Simonetta palace, near Milan, still more extraordinary, returning the sound of a pistol 56 times. The echo is heard behind the house, which has two wings; the pistol is discharged from a window in one of these wings, the sound is returned from a dead wall in the other wing, and heard from a window in the back-front. See Addis, *Travels*, pa. 32; Misson, *Voyag. d'Ital.* tom. 2, pa. 196; Philos. Trans. N° 480, pa. 220.

Again, a multiple echo may be made, by so placing the echoing bodies, at unequal distances, as that they may reflect all one way, and not one on the other; by which means, a manifold successive sound will be heard; one clap of the hands like many; one *ha* like a laughter; one single word like many of the same tone and accent; and so one musical instrument like many of the same kind, imitating each other.

VOL. I.

Lastly, Echoing bodies may be so contrived, that from any one given sound, they shall produce many echoes, different both as to tone and intension. By which means a musical room may be so contrived, that not only one instrument playing in it shall seem many of the same sort and size, but even a concert of different ones; this may be contrived by placing certain echoing bodies so, as that any note played, shall be returned by them in 3ds, 5ths, and 8ths.

ECHO is also used for the place where the repetition of the sound is produced, or heard. This is either natural or artificial. The place where the speaker stands is called the *centrum phonicum*; and the object or place that returns the voice, the *centrum phonocampicum*.

ECHO, in Architecture, is applied to certain vaults and arches, mostly of elliptical or parabolical figures; used to redouble sounds, and produce artificial echoes.—The method of making them is taught by F. Blancani, in his *Echometria*, at the end of his book on the Sphere.

One of the finest echoes in England, is that commonly called the whispering-gallery, in the dome of St. Paul's, London; and another in Gloucester cathedral. See WHISPERRING-Places.

Vitruvius tells us, that in divers parts of Greece and Italy there were brazen vessels, artfully ranged under the seats of the theatres, to render the sound of the actors' voices more clear, and make a kind of echo; by which means, every one of the prodigious multitude of persons, present at those spectacles, might hear with ease and pleasure.

ECLIPSAREON, an instrument invented by Mr. Ferguson for shewing the phenomena of eclipses; as to their time, quantity, duration, progress, &c. Ferguson's *Astron.*, or *Philos. Trans.* vol. 48, pa. 520.

ECLIPSE, a privation of the light of one of the luminaries, by the interposition of some opaque body, either between it and the eye, or between it and the sun. The ancients had terrible ideas of eclipses; supposing them presages of some dreadful events. Plutarch assures us, that at Rome it was not allowed to talk publicly of any natural causes of eclipses; the popular opinion running so strongly in favour of their supernatural production, at least those of the moon; for as to those of the sun, they had some idea that they were caused by the interposition of the moon between us and the sun; but were, at a loss for a body to interpose between us and the moon, which they thought must be the way, if the eclipses of the moon were produced by natural causes. They therefore made a great noise with brazen instruments, and set up loud shouts, during eclipses of the moon; thinking by that means to ease her in labour: whence Juvenal, speaking of a talkative woman, says, "Una laborant poterit succurre luna." Others attributed the eclipse of the moon to the arts of magicians, who, by their enchantments, plucked her out of heaven, and made her skim over the grass.

The natives of Mexico keep fast during the time of eclipses; and particularly their women, who beat and abuse themselves, drawing blood from their arms, &c; imagining the moon has been wounded by the sun, in some quarrel between them.

The Chinese have an idea that eclipses are occasioned by great dragons, who are ready to devour the sun and moon; and therefore when they perceive an eclipse, they rattle drums and brass kettles, till they think the monster, terrified by the noise, lets go his prey.

The superstitious notions entertained of eclipses, have

3 M

been sometimes of considerable advantage, as was the case with Christopher Columbus, the discoverer of America, who, being driven on the island of Jamaica in the year 1493, and distressed for want of provisions, was refused relief by the natives; but having threatened them with a plague, at the same time foretelling an eclipse as a token of it, which happened according to his prediction, the barbarians were so terrified, that they strove who should be the first in bringing him supplies, throwing them at his feet, and imploring his forgiveness. But the most striking circumstance of this kind was the prediction of an eclipse of the sun by Thales, the great father of astronomy, which happened, according to Mayer's calculation, on the 17th of May, 603 years before Christ, at the moment that Cyaxares king of the Medes, and Aliathos king of the Lydians, were preparing for battle; but alarmed at the appearance of the eclipse, they immediately laid down their arms, and negotiated a peace: and thus ignorance, which is often so injurious to the happiness of man, may, in this instance, be said to have largely contributed towards it.

Duration of an ECLIPSE, is the time of its continuance, or the time between the immersion and emersion.

Immersion, or Incidence, of an ECLIPSE, is the moment when the eclipse begins, or when part of the sun, moon, or planet first begins to be obscured.

Emersion, or Expurgation, of an ECLIPSE, is the time when the eclipsed luminary begins to re-appear, or emerge out of the shadow.

Quantity of an ECLIPSE, is the part of the luminary eclipsed. To determine this part, it is usual to divide the diameter of the luminary into 12 equal portions, called digits; whence the eclipse is said to be of so many digits, according to the number of them contained in that part of the diameter which is eclipsed or obscured.

Eclipses are divided, with respect to the luminary eclipsed, into *Eclipses of the sun, of the moon, and of the satellites*; and with respect to the circumstances, into *total, partial, annular, central, &c.*

Annular ECLIPSE, is when the whole is eclipsed, except a ring, or annulus, which appears round the border or edge.

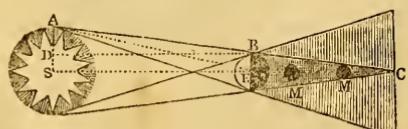

Central ECLIPSE, is one in which the centres of the two luminaries and the earth come into the same right line.

Partial ECLIPSE, is when only a part of the luminary is eclipsed. And a

Total ECLIPSE, is that in which the whole luminary is darkened.

ECLIPSE of the Moon, is a privation of the light of the moon, occasioned by the interposition of the body of the earth directly between the sun and moon, and so intercepting the sun's rays that they cannot arrive at the moon, to illuminate her. Or, the obscuration of the moon may be considered as a section of the earth's conical shadow, by the moon passing through some part of it.

The manner of this eclipse is represented in this figure, where *s* is the sun, *e* the earth, and *m* or *M* the moon.

Lunar eclipses only happen at the time of full moon; because it is only at that time the earth is between the sun

and moon: nor do they happen every full moon, because of the obliquity of the moon's path with respect to the sun's, or more properly the earth's; but only in such full moons as happen either at the intersection of those two paths, called the moon's nodes, or very near them; viz, when the moon's latitude, or distance between the centres of the earth and moon, is less than the sum of the apparent semi-diameters of the moon and the earth's shadow.

The chief Circumstances in *Lunar Eclipses* are the following:—1. All lunar eclipses are universal, or visible in all parts of the earth which have the moon above their horizon; and are every where of the same magnitude, with the same beginning and end.—2. In all lunar eclipses, the eastern side is what first immerges and emerges again, i.e. the left-hand side of the moon as we look towards her from the north; for the proper motion of the moon being swifter than that of the earth's shadow, the moon approaches it from the west, overtakes and passes through it with the moon's east side foremost, leaving the shadow behind, to the westward.—3. Total eclipses, and those of the longest duration, happen in the very nodes of the ecliptic; because the section of the earth's shadow, then falling on the moon, is considerably larger than her disc. There may, however, be total eclipses within a small distance of the nodes; but their duration is the less as they are farther from it; till they become only partial ones, and at last, none at all.—4. The moon, even in the middle of an eclipse, has usually a faint appearance of light, resembling tarnished copper; which Gassendus, Ricciolus, Kepler, &c, attribute to the light of the sun, refracted by the earth's atmosphere, and so transmitted thither.—Lastly. She becomes sensibly more dim and pale, before entering into the real shadow; owing to a penumbra which surrounds that shadow to some distance.

Astronomy of Lunar ECLIPSES, or the method of calculating their times, places, magnitudes, and other phenomena. The 1st preliminary is to find the length of the earth's conical shadow; which may be found either from the distance between the earth and sun, and the proportion of their diameters, or from the angle of the sun's apparent magnitude at the time. Thus, suppose the semiaxis of the earth's orbit 95,000,000 miles, and the eccentricity of the orbit 1,377,000 miles, making the greatest distance 96,377,000 miles, or 24194 semidiameters of the earth; and the sun's semidiameter being to the earth's, as 112 to 1; then as $AD : BE :: DB : EC$, that is, 111 : 1 :: 24194 : 218 semidiameters of the earth = EC the length of the earth's shadow. Otherwise, suppose the angle AES , or the sun's apparent semidiameter be $15^{\circ} 56''$, and the angle BAE , or the sun's parallax $8^{\circ} 6''$, then is their difference, or the angle $ACE = 15^{\circ} 47' 4''$; hence, as tang. $15^{\circ} 47' 4''$: radius :: BE or 1 : 218 nearly = CE , the same distance as before. Hence, as the moon's least distance from the earth is scarce 56 semidiameters, and the greatest not more than 64, the moon, when in opposition to the sun, in or near the nodes, will fall into the earth's shadow, and will be eclipsed, as the length of the shadow is almost 4 times the moon's distance.

2. To find the apparent semidiameter of the earth's shadow, in the place where the moon passes through it, at any given time. Add together the sun and moon's parallaxes, and from the sun subtract the apparent semidiameter of the sun; so shall the remainder be the apparent semidiameter of the shadow at the place of the moon's passage. For example, the 28th of April 1790, at midnight, the

moon's parallax is $61' 9''$, to which add $8' 6''$ or $9''$, for the sun's parallax; from the sum $61' 18''$ take $15' 56''$, the sun's apparent semidiameter, and the remainder $45' 22''$ is the semidiameter of the shadow at the place where the moon passes through at that time. But some omit the sun's parallax, as of no consequence; and increase the apparent semidiameter of the shadow by one whole minute, for the shadow of the atmosphere; which would give the semidiameter of the shadow, in the case above, $46' 13''$.

3. There must also be had, the true distance of the moon from the node, at the mean opposition; and the true time of the opposition, with the true place of the sun and moon, reduced to the ecliptic; also the moon's true latitude at the time of the true opposition; the angle of the moon's way with the ecliptic, and the true horary motions of the sun and moon: from which all the circumstances of her eclipse may be computed by common arithmetic and trigonometry.

To Construct an ECLIPSE of the Moon.—Let EW be a part of the ecliptic, and C the centre of the earth's shadow, through which draw perpendicular to EW , the line CX towards the north, if the moon have north latitude at the time of the eclipse, or Cs southward, if she have south latitude. Make the angle NCD equal to the angle of the moon's way with the ecliptic, which may be always taken at $5^{\circ} 35'$, on an average, without sensible error; and bisect this angle by the right line CF ; in which line it is that the true equal time of opposition of the sun and moon falls, as given by the tables.

From a convenient scale of equal parts, representing minutes of a degree, take the moon's latitude at the true time of full moon, and set it from C to G , on the line CF ; and through the point G , at right angles to CD , draw the right line $HKGLI$ for the path of the moon's centre. Then is L the point in the earth's shadow, where the moon's centre is at the middle of the eclipse; G the point where her centre is at the tabular time of her being full; and K the point where her centre is at the instant of her ecliptic opposition: also I the moon's centre at the moment of immersion, and H her centre at the end of the eclipse.

With the moon's semidiameter as a radius, and the points I , L , H , as centres, describe circles for the moon at the beginning, middle, and end of the eclipse.

Finally, the length of the line of path III , measured on the same scale, will serve to determine the duration of the eclipse, viz, by saying, As the moon's horary motion from the sun is to III :: 1 hour or 60 min. to the whole duration of the eclipse.

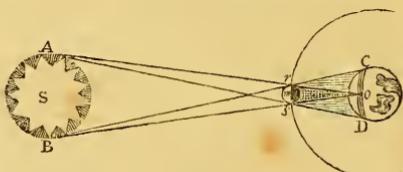

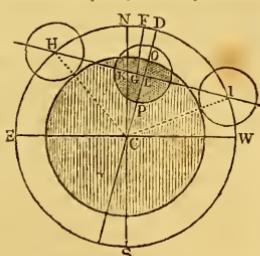

To Compute a Lunar ECLIPSE. This will be very easy from the foregoing construction. For, 1st, in the triangle CGL , right-angled at L , there are given the hypotenuse CG = the moon's latitude at the time of full moon, and the angle GCL = the half of $5^{\circ} 35'$; to find the legs CL and LG .—2d, in the right-angled triangle CNL or CIL , are given the leg CL , and hypotenuse CN or Ci , the sum of

the semidiameters of the moon and the earth's shadow; to find LH or Li , half the difference of the sun's and moon's motions during the time of the eclipse.—3d, As the difference of the horary motions of the luminaries is to one hour, or 60 min. :: HL to the semiduration of the eclipse, and :: CL to the difference between the opposition and middle of the eclipse; this last therefore taken from the time of full moon, gives the time of the middle of the eclipse; from which subtracting the time in Li , or semiduration before found, gives the beginning of the eclipse; or add the same, and it gives the end of it.—Lastly, from c the semidiameter of the shadow, take CL , and there remains Lo ; to which add LP , the moon's semidiameter, when necessary, the sum of which is op the quantity eclipsed.

Note. When the moon's distance from the node exceeds 12° , there can be no eclipse of the moon; or, more accurately, the limit is from $10\frac{1}{2}$ to $12\frac{1}{3}$ degrees, according to the distances of the sun, earth, and moon.

ECLIPSE of the Sun. is an occultation of the sun's body, occasioned by the interposition of the moon between the earth and sun. On which account it is by some considered as an eclipse of the earth, since the light of the sun is hid from it by the moon, whose shadow involves a part of the earth.

The manner of a solar eclipse is represented in this figure; where s is the sun, m the moon, and c the earth,

ross the moon's conical shadow, travelling over a part of the earth cod , and making a complete eclipse to all the inhabitants residing in that track, but no where else; excepting that for a large space around it there is a fainter shade, included within all the space rds , which is called the Penumbra.

Hence, solar eclipses happen when the moon is in conjunction with the sun, or at the new moon, and also in the nodes or near them, the limit being about 17 degrees on each side of it; and such eclipses only happen when the latitude of the moon, viewed from the earth, is less than the sum of the apparent semidiameters of the sun and moon; because the moon's way is oblique to the ecliptic, or sun's path, making an angle of nearly $5^{\circ} 35'$ with it.

In the nodes, when the moon has no visible latitude, the occultation is total; and with some continuance, when the disc of the moon in perige appears greater than that of the sun in apogee, and its shadow is extended beyond the surface of the earth; and without continuance at small distances when the cusp, or point of the moon's shadow, barely touches the earth. Lastly, out of the nodes, but near them, the eclipses are partial.

The other circumstances of solar eclipses are, 1. That none of them are universal; that is, none of them are seen throughout the whole hemisphere which the sun is then above; the moon's disc being too small and much too near the earth, to hide the sun from its whole disc. Commonly the moon's dark shadow covers only a spot on the earth's surface, about 180 miles broad when the sun's

distance is greatest, and the moon's least. But her partial shadow, or penumbra, may then cover a circular space of 4900 miles in diameter, within which the sun is more or less eclipsed, as the places are nearer to or farther from the centre of this shadow. In this case the axis of the shade passes through the centre of the earth, or the new moon happens exactly in the node, and then it is evident that the section of the shadow is circular; but in every other case the conical shadow is cut obliquely by the surface of the earth, and the section is an oval, and very nearly a true ellipse.

2. Nor does the eclipse appear the same in all parts of the earth, where it is seen; but when in one place it is total, in another it is only partial. Farther, when the moon appears much less than the sun, as is chiefly the case when she is in apogee and the sun in perige, the vertex of the lunar shadow is then too short to reach the earth; for though the moon be in a central conjunction with the sun at this time, yet she is not large enough to cover his whole disc, but lets his limb appear like a lucid ring or bracelet, and so causes an annular eclipse.

3. A solar eclipse does not happen at the same time, in all places where it is seen; but appears more early to the western parts, and later to the eastern; as the motion of the moon, and consequently of her shadow, is from west to east.

4. In most solar eclipses the moon's disc is covered with a faint light; which is attributed to the reflexion of the light from the illuminated part of the earth.

Lastly, In total eclipses of the sun, the moon's limb is seen surrounded by a pale circle of light; which some astronomers consider as an indication of a lunar atmosphere; but others as the atmosphere of the sun, because it has been observed to move equally with the sun, and not with the moon; and besides, it is generally believed that the moon is without any atmosphere, unless it be one that is very small, and very rare; which latter supposition may now be considered as a fact well established, being confirmed by a vast number of attentive observations.

To determine the Bounds of a Solar Eclipse. If the moon's parallax were inconsiderable, the bounds of a solar eclipse would be determined in the same manner as those of a lunar; but as it has a sensible parallax, the method of proceeding is a little different, viz.

1. Add together the apparent semidiamaeters of the luminaries, both in apogee and perige; which gives $33^{\circ} 6'$ for the greatest sum of them, and $30^{\circ} 31'$ for the least sum.

2. Since the parallax diminishes the northern latitude and augments the southern, therefore let the greatest parallax in latitude be added to the former sums, and also subtracted from them: thus in each case there will be had the true latitude, beyond which there can be no eclipse. This latitude being given, the moon's distance from the nodes, beyond which eclipses cannot happen, is found as for a lunar eclipse. This limit is nearly between $16\frac{1}{2}$ and $18\frac{1}{4}$ degrees distance from the nodes.

To find the Digits eclipsed. Add the apparent semidiamaeters of the luminaries into one sum; from which subtract the moon's apparent latitude; the remainder is the scruples, or parts of the diameter eclipsed. Then say, As the semidiamaeter of the sun is to the scruples eclipsed; so are 6 digits reduced into scruples, viz. 360 scruples or minutes, to the digits &c eclipsed.

To determine the Duration of a Solar Eclipse. Find the horary motion of the moon from the sun, for one hour

before the conjunction, and another hour after: then say, As the former horary motion is to the seconds in an hour, so are the scruples of half duration (found as in a lunar eclipse) to the time of immersion; and as the latter horary motion is to the same seconds, so are the same scruples of half duration to the time of emersion. Lastly, Adding the times of immersion and emersion together, the aggregate is the total duration.

The moon's apparent diameter when largest, exceeds the sun's when least, only by $2'$ of a degree; and in the greatest solar eclipse that can happen at any time and place, the total darkness cannot continue any longer than whilst the moon is moving through this $2'$ from the sun in her orbit, which is about 4 minutes of time: for the motion of the shadow on the earth's disc is equal to the moon's motion from the sun, which on account of the earth's rotation on its axis in the same direction, or eastward, is about $30\frac{1}{2}$ minutes of a degree every hour, at a mean rate; but so much of the moon's orbit is equal to $30\frac{1}{2}$ degrees of a great circle on the earth, because the circumference of the moon's orbit is about 60 times the circumference of the earth; and therefore the moon's shadow goes $30\frac{1}{2}$ degrees, or 1830 geographical miles in an hour, or $30\frac{1}{2}$ miles in a minute.

To determine the Beginning, Middle, and End, of a Solar Eclipse. From the moon's latitude, for the time of conjunction, find the arch $g\cdot l$ (last fig. but one), or the distance of the greatest obscurity. Then say, As the horary motion of the moon from the sun, before the conjunction, is to 1 hour; so is the distance of the greatest darkness, to the interval of time between the greatest darkness and the conjunction. Subtract this interval, in the 1st and 3d quarter of the anomaly, from the time of the conjunction; and in the other quarters, add it to the same; then the result will be the time of the greatest darkness. Lastly, from the time of the greatest darkness subtract the time of incidence, and add it to the time of emersion; the difference in the first case will be the beginning; and the sum, in the latter case, the end of the eclipse.

To Calculate ECLIPSES of the Sun. 1. Find the mean new moon, and thence the true one; with the place of the luminaries for the apparent time of the true one.—2. For the apparent time of the true new moon, compute the apparent time of the new moon observed.—3. For the apparent time of the new moon seen, compute the latitude seen.—4. Thence determine the digits eclipsed.—5. Find the times of the greatest darkness, immersion, and emersion.—6. Thence determine the beginning and ending of the eclipse.

From the foregoing problems, it is evident that all the trouble and fatigue of the calculus arises from the parallaxes of longitude and latitude, without which, the calculation of solar eclipses would be the same with that of lunar ones.

See the Construction and Calculation of Eclipses by Flamsteed, in Sir Jonas Moore's System of Mathematics, and in Ferguson's Astronomy, &c.

In the Philos. Trans. N° 461, is a contrivance to represent solar eclipses, by means of the terrestrial globe, by M. Seguer, professor of mathematics at Gottingen. And Mr. Ferguson fitted a terrestrial globe, so as to show the time, quantity, duration, and progress of solar eclipses, at any place of the earth where they are visible; which he calls the Eclipsoeon. He has also given a large catalogue of ancient and modern eclipses, including those re-

corded in history, from 721 years before Christ, to A. D. 1485; also computed eclipses from 1485 to 1700, and all the eclipses visible in Europe from 1700 to 1800. See his Astron.

The Number of ECLIPSES, of both luminaries, in any year, cannot be less than two, nor more than seven; the most usual number is 4, and it is rare to have more than 6. The reason of which limitation is obvious; because the sun passes by both the nodes but once in a year, unless he pass by one of them in the beginning of the year; in which case he will pass by the same again a little before the end of the year; because the nodes move backwards $19\frac{1}{2}$ degrees every year, so that the sun will come to either of them 173 days after the other: if either node be within 17° of the sun at the time of new moon, the sun will be eclipsed; and at the subsequent opposition, the moon will be eclipsed in the other node, and come round to the next conjunction before the former node be 17° beyond the sun, and eclipse him again. When three eclipses happen about either node, the like number commonly happens about the opposite one; as the sun comes to it in 173 days afterward, and 6 lunations contain only 4 days more. Thus there may be two eclipses of the sun, and one of the moon, about each of the nodes. But when the moon changes in either of the nodes, she cannot be near enough the other node, at the next full, to be eclipsed; and in 6 lunar months afterward she will change near the other node; in which case there cannot be more than two eclipses in a year, both of the sun.

Period of ECLIPSES, is the period of time in which the same eclipses return again; and as the nodes move backwards $19\frac{1}{2}$ degrees every year, they must shift through every point of the ecliptic in 18 years and 225 days; and this would be the regular period of their return, if any complete number of lunations were finished without a fraction; but this is not the case. However, in 223 mean lunations, after the sun, moon, and nodes have been once in a line of conjunction, they return so nearly to the same state again, as that the same node which was in conjunction with the sun and moon at the beginning of the first of these lunations, will be within $28' 12''$ of the line of conjunction with the sun and moon again, when the last of these lunations is completed; and in this period there will be a regular return of eclipses for many ages. To the mean time of any solar or lunar eclipse, by adding this period, or 18 Julian years 11 days 7 hours 43 minutes 20 seconds, when the last day of February in leap-years is 4 times included, or a day less when it occurs 5 times, we shall have the mean time of the return of the same eclipse. In an interval of 6890 mean lunations, containing 557 years 21 days 18 hours 30 minutes 11 seconds, the sun and node meet so nearly, as to be distant only 11 seconds.

The Use of ECLIPSES. In astronomy, eclipses of the moon determine the spherical figure of the earth; they also show that the sun is larger than the earth, and the earth than the moon. Eclipses also, that are similar in all circumstances, and that happen at considerable intervals of time, serve to ascertain the period of the moon's motion. In geography, eclipses discover the longitude of different places; for which purpose those of the moon are the more useful, because they are more often visible, and the same lunar eclipse is of equal magnitude and duration at all places where it is seen. In chronology, both solar and lunar eclipses serve to determine exactly the time of any past event.

The following is a list of all the solar eclipses visible in this country till the year 2000; the times adapted to Leicestershire, the middle of England.

A Table of all the SOLAR ECLIPSES that will be visible till the Year 2000.

ECLIPSES of the Satellites. See SATELLITES of Jupiter.—The principal circumstances here observed are, 1. That the satellites of Jupiter undergo two or three kinds of eclipses; the first of which are proper, being such as happen when Jupiter's body is directly interposed between them and the sun; which eclipses happen almost every day. Various authors have given tables for computing

eclipses of the satellites of Jupiter; as Flamsteed, Cassini, Wargentin, &c.

The second sort are occultations, rather than observations; when the satellites, coming too near the body of Jupiter, are lost in his light; which Riccioli calls occidere zeusiaci, setting jovially. In which case, the nearest or first satellite exhibits a third kind of eclipse; being observed like a round macula, or dark spot, transiting the disc of Jupiter, with a motion contrary to that of the satellite; like as the moon's shadow, projected on the earth, will appear to do, to the lunar inhabitants.

The eclipses of Jupiter's satellites furnish very good means of finding the longitude at sea. Those especially of the first satellite are much surer than the eclipses of the moon, and they also happen much oftener: the manner of applying them is also very easy. In the Philos. Trans. for 1786, Mr. Pigott gave a preferable method by the lunar transits. See LONGITUDE.

ECLIPTIC, in Astronomy, a great circle of the sphere conceived to pass through the middle of the zodiac. It is sometimes called the via solis, or sun's path, being the track which he appears to describe among the fixed stars; though more properly it is the apparent path of the earth, as viewed from the sun, and thence called the heliocentric circle of the earth. It is called the ecliptic, because all the eclipses of the sun or moon happen when the moon crosses it, or is nearly in one of those two parts of her orbit where it crosses the ecliptic, which points are called the moon's nodes.

Upon the ecliptic are marked and counted the 12 celestial signs, Aries, Taurus, Gemini, &c.; and also the longitude of the planets and stars. Its situation is oblique with respect to the equator, which it cuts in two opposite points, viz, the beginning of Aries and Libra, being directly opposite to each other, and called the equinoxes, making one half of the ecliptic to the north, and the other half on the south side of the equator; the two extreme points of it, to the north and south, which are opposite to each other, and at a quadrantal distance from the equinoctial points both ways, are called the solstices, or solstitial points, or also the two tropics, which are at the beginning of Cancer and Capricorn, being at the farthest distance of any points of it from the equator, which distance is the measure of the sun's greatest declination, and is the same with the obliquity of the ecliptic, or the angle it makes with the equator.

This obliquity of the ecliptic is not permanent, but is continually varying, by the ecliptic approaching nearer and nearer to a parallelism with the equator, at the rate at present of $42''$ per 100 years, as is deduced from ancient and modern observations compared together; and as the mean obliquity of the ecliptic was $23^{\circ} 28'$ about the end of the year 1788, or beginning of 1789, by adding $.426$ of a second for each preceding year, or subtracting the same for each following year, the mean obliquity will be found nearly, for any year either before or since that period. The quantity however of this change is variously stated by different authors. Hipparchus, almost two thousand years since, observed the obliquity of the ecliptic, and found it about $23^{\circ} 51'$; and all succeeding astronomers, to the present time, having observed the same, have found it always less and less; being now rather under $23^{\circ} 28'$; a difference of about $23'$ in 1950 years; which gives a medium of $70''$ in 100 years. There is no doubt, however, that the diminution is variable.

It is now well known that this change in the obliquity of the ecliptic, is wholly owing to the actions of the planets upon the earth, and especially the planets Venus and Jupiter, but chiefly the former. See Lagrange's excellent paper on this subject in the Memoirs of the French Academy for 1774; Cassini's in 1778; and Lalande's Astron. vol. 3, art. 2737. According to Lagrange, who proceeds upon theory, the annual change of obliquity is variable, and has its limits: about 2000 years ago, he thinks it was after the rate of "about $38''$ in 100 years; that it is now, and will be for 400 years to come, $50''$ per century; but 2000 years hence, $49''$ per century. According to Cassini, who computes from observations of the obliquity between the years 1739 and 1778, the annual change at present is $60''$ or $1'$ in 100 years. But according to Lalande, the diminution is at the rate of $42''$ per century; while Dr. Maskelyne makes it $50''$ in the same time. But later observations and the calculations of Laplace, give now $52''$ for the mean secular variation.

Besides the diminution of the obliquity of the ecliptic, at the above rate, which arises from a change of the ecliptic itself, it is subject to two periodical inequalities, the one produced by the unequal force of the sun in causing the precession of the equinoxes, and the other depending on the nutation of the earth's axis. See the Explanation and Use of Dr. Maskelyne's Tables and Observations, pa. vi, where he shows how to calculate those inequalities; and also, from his own observations, determines the mean obliquity of the ecliptic to the beginning of the year 1769, to be $23^{\circ} 28' 9''$.

To find the Obliquity of the Ecliptic, or the greatest declination of the sun:—About the time of the summer solstice observe very carefully the sun's zenith distance for several days together; then the difference between this distance and the latitude of the place, will be the obliquity sought, when the sun and equator are both on one side of the place of observation; but their sum will be the obliquity when they are on different sides of it. Or, it may be found by observing the meridian altitude, or zenith distance, of the sun's centre, on the days of the summer and winter solstice; then the difference of the two will be the distance between the tropics, the half of which will be the obliquity sought.

By the same method too, the declination of the sun from the equator for any other day may be found; and thus a table of his declination for every day in the year might be constructed. Thus also the declination of the stars might be found.

The observations of astronomers of all ages, on the obliquity of the ecliptic, have been collected together; and although some of them may not be quite accurate, yet they sufficiently show the gradual and continual decrease of the obliquity from the times of the earliest observations down to the present time. The chief of those observations may be seen in the following table; where the first column contains the name of the observer, or author; the 2d, the year before or after Christ; and the 3d, the obliquity of the ecliptic for the time.

See Ptolem. Alm. lib. 1, cap. 10; Riccioli Alm. vol. 1, lib. 3, cap. 27; Flamsteed, Proleg. Hist. Cœl. vol. 3; Philos. Trans. N° 163; ibid. vol. 63, pt. 1; Long's Astron. vol. 1, cap. 16; Memoirs of the Acad. an. 1716, 1734, 1762, 1767, 1774, 1778; Acta Erud. Lipsie, 1719; Naut. Alm. 1779; Maskelyne's Observ. Explan. pa. vi; &c. See LAPLACE.

	2900	23° 18' 23"3
	3000	23° 17' 31"3

According to an ancient tradition of the Egyptians, mentioned by Herodotus, the ecliptic had formerly been perpendicular to the equator: they were led into this notion by observing, for a long series of years, that the obliquity was continually diminishing; or, which amounts to the same thing, that the ecliptic was continually approaching to the equator. Hence they took occasion to suspect that those two circles, in the beginning, had been as far off each other as possible, that is, perpendicular to each other. Diiodorus Siculus relates, that the Chaldeans reckoned 403,000 years from their first observations to the time of Alexander's entering Babylon. This enormous account may have some foundation, on the supposition that the Chaldeans deduced it from the diminution of the obliquity of the ecliptic at the rate of a minute in 100 years. M. de Louville, taking the obliquity, such as it must have been at the time of Alexander's entrance into

Babylon, and going back to the time when the ecliptic, at that rate, must have been perpendicular to the equator, actually finds 402,942 Egyptian or Chaldean years; which is only 58 years short of that epocha. Indeed there is no way so probable of accounting for the fabulous antiquity of the Egyptians, Chaldeans, &c, as from the superposition of long periods of very slow celestial motions, a small part of which they had observed, and from which they calculated the beginning of the period, making the world and their own nation to commence together. Or perhaps they sometimes counted months or days for years.

ECLIPТИC, in Geography, a great circle on the terrestrial globe, in the plane of, or directly under, the celestial ecliptic.

ECLIPТИC, *Eclipticus*, something belonging to the ecliptic, or to eclipses; as *ecliptic conjunction*, *opposition*, &c.

ECLIPТИC Bounds, or *Limits*, are the greatest distances from the nodes at which the sun or moon can be eclipsed; namely, near 18 degrees for the sun, and 12 degrees for the moon.

ECLIPТИC Digits, *Digitii ecliptici*. See **DIGITS**.

Poles of the ECLIPТИC, are the two opposite points of the sphere which are each every where equally distant from the ecliptic, viz., 90°. The distance of the poles of the ecliptic from the poles of the equator, or of the world, is always equal to the varying distance of the obliquity of the ecliptic, which for the year 1800 was, according to Dr. Maskelyne, 23° 27' 56" 6.

Reduction to the ECLIPТИC. See **REDUCTION**.

EFFECT. The result or consequence of the application of a cause, or agent, on some subject. It is one of the great axioms in philosophy, that effects are always proportional to the powers of their adequate causes.

EFFECTION, denotes the geometrical construction of a proposition. The term is also used in reference to problems and practices; which, when they are deducible from, or founded on some general propositions, are called the *geometrical effect* of them.

EFFERVESCEENCE, is popularly used for a light ebullition, or a brisk intestine motion, produced in a liquor by the first action of heat, with any remarkable separation of its parts.

EFFICIENT Cause, is that which produces an effect. See **CAUSE** and **EFFECT**.

EFFICIENTS, in Arithmetic, are the numbers given for an operation of multiplication, and are otherwise called the factors. Hence the term coefficients in algebra, which are the numbers prefixed to, or that multiply the letters or algebraic quantities.

EFLUVIUM, a flux or exhalation of minute particles from any body; or an emanation of subtle corpuscles from a mixed, sensible body, by a kind of motion of transpiration.

ELASTIC, an appellation given to all bodies endowed with the property of elasticity or springiness.

ELASTIC Body, is that which changes its figure, and yields to any impulse or pressure, but endeavours by its own nature and force to restore the same again; or, it is a body of such a nature that, when compressed or condensed, it will make an effort to set itself at liberty, and to repel the body that constrained it: such, for instance, as a bow, or a sword-blade, &c, which are easily bent, but presently return to their former figure and extension. All bodies partake of this property in some degree, though

perhaps none are perfectly elastic, as none are found to restore themselves with a force equal to that with which they are compressed.

The principal phenomena observable in elastic bodies, are, 1. That an elastic body (i. e. a body perfectly elastic, if any such there be) endeavours to restore itself with the same force with which it is pressed or bent. 2. An elastic body exerts its force equally towards all sides; though the effect is chiefly found on that side where the resistance is weakest; as is evident in the case of a gun exploding a ball, a bow shooting out an arrow, &c.—3. Elastic bodies, in whatever manner they are struck or impelled, are inflected and rebound after the same manner: thus a bell yields the same musical sound, in whatever manner, or on whatever side it be struck; the same of a tense or musical chord; and a body rebounds from a plane in the same angle in which it meets or strikes it, making the angle of incidence equal to the angle of reflection, whether the intensity of the stroke be great or small.—4. A perfectly fluid body cannot be elastic, if it be allowed that its parts cannot be compressed.—5. A body perfectly solid, cannot be elastic; because, having no pores, it is incapable of being compressed.—6. The elastic properties of bodies seem to differ, according to their greater or less density or compactness, though not in an equal degree: thus, metals are rendered more compact and elastic by being hammered: tempered steel is much more elastic than soft steel; and the density of the former is to that of the latter as 7809 to 7738. Cold condenses solid bodies, and renders them more elastic; while heat, that relaxes them, has the opposite effect: but, on the contrary, air, and other elastic fluids, are expanded by heat, and rendered more elastic.—For the laws of motion and percussion in elastic bodies, see **MOTION**, and **PERCUSSION**.

ELASTIC Curve. See **CATENARIA**.

ELASTIC Fluids. See **AIR**, **ELECTRICITY**, **GAS**, **ELASTIC VAPOURS**, &c.

ELASTIC Gum. The same as **CAOUTCHOUC**, or Indian Rubber.

ELASTIC Vapours, or **Fluids**, are such as may be compressed mechanically into a less space, and which resume their former state when the compressing force is withdrawn; such as atmospheric air, and all the aerial fluids, with all kinds of fumes raised by means of heat, whether from solid or fluid bodies.

Of these, some remain elastic only while a considerable degree of heat is applied to them, or to the substance which produces them; while others continue elastic in every degree of cold that has yet been observed. Of the former kind, are the vapours of water, spirit of wine, mercury, sal-ammoniac, and all kinds of sublimable salts: of the latter, those of spirit of salt, mixtures of vitriolic acid and iron, nitrous acid, and various other metals, and in short the several species of aerial fluids indiscriminately.

The elastic force with which any one of these fluids is endowed, has not yet been calculated, as being ultimately greater than any obstacle we can put in its way. Thus, on compressing atmospheric air, we find that for some little time at first it easily yields to any force applied; but at every succeeding moment the resistance becomes stronger, and a greater and greater force must be applied, to compress it further. As the compression goes on, the vessel containing the air becomes hot; but no power whatever has yet been able in any degree to destroy the elasticity of

the contained fluid; for, upon removing the pressure, it is always found to occupy the very same space that it did before. The case is the same with the steam of water, to which a sufficient heat is applied to keep it from condensing into water again.

Elasticity, or Elastic Force, that property of bodies by which they restore themselves to their former figure, after any external pressure.

The cause or principle of this important property, elasticity, is variously accounted for. The Cartesians ascribe it to a subtle matter making an effort to pass through pores that are too narrow for it. Thus, say they, in bending or compressing a hard elastic body, as a bow, for instance, its parts recede from each other on the convex side, and approach on the concave one: consequently the pores are contracted or straitened on the concave side; and, if they were before round, are now perhaps oval: so that the *materia subtilis*, or matter of the second element, endeavouring to pass out of the pores thus straitened, must make an effort, at the same time, to restore the body to the state it was in when the pores were cylindrical, i.e. before the bow was bent: and in this consists its elasticity.

Other later philosophers account for elasticity much after the same manner as the Cartesians; with this difference only, that instead of the subtle matter of the Cartesians, these substitute ether, or a fine ethereal medium that pervades all bodies.

Others, setting aside the precarious notion of a *materia subtilis*, account for elasticity from the great law of nature, attraction, or the cause of the cohesion of the parts of solid and firm bodies. Thus, say they, when a hard body is struck or bent, so that the component parts are moved a little from each other, but not quite disjointed or broken off, or separated so far as to be out of the power of that attracting force by which they cohere; they must, on removing the external violence, spring back to their former natural state.

Others again resolve elasticity into the pressure of the atmosphere: for a violent tension, or compression, though not so great as to separate the constituent particles of bodies far enough to let in any foreign matter, must yet occasion many little vacuola between the separated surfaces; so that on the removal of the force they will close again by the pressure of the aerial fluid upon the external parts.

Lastly, Others attribute the elasticity of all hard bodies to the power of resiliency in the air included within them; and so make the elastic force of the air the principle of elasticity in all other bodies. See Desaguliers's Exper. Philos. vol. 2, pa. 38, &c.

The **Elasticity of Fluids** is accounted for from their particles being all endowed with a centrifugal force; whence Sir Isaac Newton demonstrates, prop. 23, lib. 2, that particles, which naturally avoid or fly off from one another by such forces as are reciprocally proportional to the distances of their centres, will compose an elastic fluid, whose density is proportional to its compression; and vice versa, if any fluid be composed of particles that fly off or avoid one another, and have its density proportional to its compression, then the centrifugal forces of those particles will be reciprocally proportional to the distances of their centres.

Elasticity of the Air is the force with which that element endeavours to expand, and with which it does actually dilate itself, on removing the force that compresses it. The elasticity or spring of the air was first

discovered by Lord Bacon, and farther established by Galileo. Its existence is thus proved by the latter philosopher: An extraordinary quantity of air being intruded, by means of a syringe, into a hollow ball or shell of glass or metal, till such time as the ball, with its accession of air, weigh considerably more in the balance than it did before; then, opening the mouth of the ball, the air rushes out, till the ball sink to its former weight. Hence he inferred, that just as much air had issued out, as compressed air had been compressed in. Air therefore returns to its former degree of expansion, on removing the force that compressed or resisted its expansion; and consequently it is endowed with an elastic force. It may be added, that as the air is found to rush out in every situation or direction of the orifice, the elastic force acts every way, or in every direction alike. See *Air*, and *Atmosphere*.

The cause of elasticity in air has been usually ascribed to a repulsion between its particles; but what is the cause of that repulsion? The term repulsion, like that of attraction, requires to be defined; and probably it will be found in most cases to be the effect of the action of some other fluid. Thus, it is found that the elasticity of the atmosphere is very considerably affected by heat. Supposing a quantity of air heated to such a degree as to raise Fahrenheit's thermometer to 212, it will then occupy a considerable space; but if it be cooled again to such a degree, as to sink the thermometer to 0, it will shrink up to less than half the former bulk. The quantity of repulsive power therefore acquired by the air, while passing from one of these states to the other, is evidently owing to the heat added to it, or taken away from it. Nor does there seem to be any reason to suppose, that the quantity of elasticity or repulsive power it still possesses, is owing to any other cause than the fire contained in it. The supposition that repulsion is a primary cause, independent of all others, has given rise to many erroneous theories, and very much embarrassed philosophers in accounting for the phenomena of elasticity.

The elasticity of the air is not only proportional to its density, but is always equal to the force which compresses it, because these two forces exactly balance each other. This elasticity, in the atmospheric air, is measured by the height of the barometer at any time, allowing for its heat or temperature, after this rate, viz, the 434th part for each degree of Fahrenheit's thermometer, above or below some mean temperature, as 55° ; for by that part of the whole it is that air expands or contracts, or else increases or decreases in its elasticity, for each degree of the thermometer. Sir Geo. Shuckburgh, in the Philos. Trans. for 1777, pa. 561.

ELECTIONS, or Choice, signify the several different ways of taking any number of things proposed, either separately, or as combined in pairs, in threes, in fours, &c; not as to the order, but only as to the number and variety of them. Thus, of the things a , b , c , d , e , &c, the elections of

one thing are (a) , $1 = 2^1 - 1$,

two things are (a, b) , $ab = 2^2 - 1$,

three things are (a, b, c) , $abc = 2^3 - 1$, &c;

and of any number, n , all the elections are $2^n - 1$; that is, one less than the power of 2 whose exponent is n , the number of single things to be chosen, either separately or in combination. See *Combination*.

ELECTRIC, in Physics, is a term applied to those sub-

stances in which the electric fluid can be excited, and accumulated, without transmitting it; and which are therefore called non-conductors. They are also called original Electrics, and Electrics per se. The word is derived from *γλεντρος*, amber, one of the most observable non-conductors, and the only one known to the ancients. To this class also belong glass, and all vitrifications, even of metals; all precious stones, of which the most transparent are the best; resins, and resinous compositions; sulphur, and baked wood; all bituminous substances, wax, silk, and cotton; all dry animal substances, as feathers, wool, hair, &c.; also paper, white sugar, and sugar-candy; likewise air, oils, chocolate, calces of metals and semi-metals, the ashes of animal and vegetable substances, the rust of metals, all dry vegetable substances, and stones, of which the hardest are the best.

Substances of this kind may be excited, so as to exhibit the electric appearances of attracting and repelling light bodies, emitting a spark of light, attended with a snapping noise, and yielding a current of air, the sensation of which resembles that of a spider's web drawn over the face, &c., and a smell like that of phosphorus; and this exciting may be either produced by friction, or by heating and cooling, or by melting, and pouring one melted substance into another.—The term is peculiarly applied to the electric, viz, the globe, or cylinder, &c., used in electrical machines, for collecting the fluid by friction.

ELECTRICAL Air Thermometer, an instrument contrived by Mr. Kinnersley of Philadelphia, and used in determining the effects of the electrical explosion upon air; a description of which may be seen in *Franklin's Letters, &c.*, pa. 389, 4to, 1769.

ELECTRICAL Apparatus, consists of glass tubes, about 3 feet long, and an inch and a half in diameter, one of which should be closed at one end, and furnished at the other end with a brass cap and stop-cock, to rarefy or condense the inclosed air; sticks of sealing-wax, or tubes of rough glass, or glass tubes covered with sealing-wax, or cylinders of baked wood for producing the negative electricity; with proper rubbers, as black oiled silk, with amalgam upon it for the former, and soft new flannel, or hare-skins, or cat-skins, tanned with the hair on, for the latter; coated jars, or plates of glass, either single, or combined in a battery, for accumulating electricity; metal rods, as dischargers; an electrical machine; electrometers, and insulated stools, supported by pillars of glass, covered with sealing-wax, or baked wood, varnished or boiled in linseed oil.

ELECTRICAL Atmosphere, is a stream or mass of the electric fluid which surrounds an excited or electrified body, to a certain distance.

ELECTRICAL Balls. See **BALLS**, and **ELECTROMETER**.

ELECTRICAL Battery, consists of a number of coated jars, placed near each other in a convenient manner. These being charged, or electrified, and connected with each other, are then suddenly exploded or discharged, with a prodigious effect. See **BATTERY**.

ELECTRICAL Bells, are a set of bells mounted in a peculiar manner, so as to be rung by means of the action of the electric fluid. Fig. 10, plate vii., represents a set of bells of this kind; when the clapper is suspended from the fly bed, the axis of which resin is in a small hole on the top of the glass pillar *ef*; the upper part of the axis moves freely on, and is supported by a hole in the brass piece *ge*, and bells of different tones are placed round the board

hik. This apparatus being placed near the cylinder, the prime conductor being removed, will, when the machine is in action, be put in motion, the clapper of which striking the bells in succession, produces an agreeable harmony.

ELECTRIC Experiments, are certain experiments made by means of an electric machine and apparatus; sometimes in order to discover the nature and properties of the electric fluid, and at others for the amusement of the operator or by-standers. But, in a work like the present, it is impossible to give any thing like a complete set of experiments: we have however selected the following; and must refer the reader, for others, to Adams's, Cavallio's, and Cuthbertson's works on this subject.

Experiment 1. Put the machine in action, connect the cushion by a chain with the ground, and those bodies which communicate with the positive conductor will be electrified positively. Connect the positive conductor with the earth by a chain, take off the chain from the cushion, and those bodies which communicate with the cushion, or negative conductor, will be electrified negatively.

Exper. 2. Connect the positive conductor by a chain with the table; turn the cylinder, and the cushion will be found to be negatively electrified. Take the chain off from the positive conductor, and both will exhibit signs of electricity; but any electrified body, which is attracted by the one, will be repelled by the other. If they are brought sufficiently near to each other, sparks will pass between them, and they will act on each other stronger than on any other bodies. If they are connected together, the electricity of the one will destroy that of the other; for though the fluid seems to proceed from the cushion to the conductor, the two, when thus conjoined, will exhibit no signs of electricity, because the fluid is continually circulating from one to the other, and is therefore kept always in the same state.

We see, by this experiment, that electric appearances are produced both in the electric which is excited, and the substance by which it is excited, provided that substance be insulated; but their electric powers are directly reverse of each other, and may be distinguished by opposite effects.

Exper. 3. If the cushion and the conductor are both insulated, it is observed, that the less electric fluid is obtained, the more perfect the insulation is made.

The moisture, which is at all times floating in the air, together with the small points, from which it is impossible totally to free the cushion, do not permit it to be perfectly insulated, so as to afford no supply of electric matter to the cushion. If the air, and other parts of the apparatus, are very dry, little or no electricity will be produced under the above-mentioned circumstances. From this experiment it is inferred, that the electric powers do not exist in the electrics themselves, but are produced from the earth by the excitation of electrics; or that the electric matter on the prime conductor is not produced by the friction of the cylinder against the cushion, but is collected by that operation from it, and from those bodies which are connected with it.

Exper. 4. Touch a pair of insulated pith balls with an excited glass tube, they will become electrified, and will separate from each other; the balls are electrified positively, and are therefore attracted by excited wax, and repelled by excited glass. As those light substances, which possess the same electric power, repel each other;

we can easily discover whether they are electrified positively or negatively, by presenting an excited stick of sealing-wax or glass to them. If they are attracted by the glass, they are negatively, if repelled by it, they are positively electrified; on the contrary, if repelled by the excited wax, they are negative, if attracted, positive.

In ascertaining the nature of the electric powers, we must avoid bringing the bodies to be tried near each other suddenly; or one with a strong electricity near another which is weakly so; as it may render the experiment doubtful, by attracting, and not repelling the light body.

Exper. 5. Insulate a long metallic rod, suspend a pair of pith balls from each end of it, place one of the ends at about two inches from the prime conductor, the other end as far from it as possible, electrify the conductor, and the electric fluid in the rod will be driven to that end which is furthest from the conductor; so that one end will be electrified negatively, the other end positively, as will be seen by the balls.

Exper. 6. Fix the end of a wire, having feathers attached to it, in the small hole which is at the end of the prime conductor; turn the cylinder, and the feathers, which are connected with the wire by linen threads, will separate from each other; the fibrous and downy parts will become turgid, and expand in a pleasing manner, and in a variety of directions.

Present a metallic point, or the finger, or any other conducting substance, to the feathers, the downy parts thereto will immediately collapse, the divergence of the feathers will cease, and they will approach each other, and cling round the non-electric body.

The feathers separate from each other, and tend towards unelectrified bodies, from the effort made by the electricity which is communicated to them to diffuse itself, and the resistance it meets with from the air.

Exper. 7. Fix the end of the wire into the hole at the end of the conductor, as before, having now two pith balls attached, instead of the feathers; put the machine in action, and the two small balls will recede from each other. Bring a conducting substance within the sphere of their action, and they will fly towards it; touch the conductor with a non-electric, and they will immediately come together.

The balls do not always diverge so much as might be expected, from the action of their atmospheres, because they are influenced by that of the conductor.

The balls, or feathers, will separate, &c, in the same manner, if they are annexed to a negative conductor.

Exper. 8. Present a fine thread towards an electrified conductor; when it is at a proper distance, it will fly towards, and stick to the conductor, and convey the electric fluid from it to the hand; remove the thread to a small distance from the conductor, and it will fly backwards and forwards with great velocity and in a very pleasing manner: present the same thread towards one that hangs from the conductor, they will attract and join each other. Bring a non-electric body, as a brass ball, near these threads, the ball will repel that held by the hand, and attract that which is fixed to the conductor: the upper thread renders the brass ball negative, and therefore goes towards it; while the under thread, which is also negative, is repelled. Let the ball be brought near the lower part of the under one, and it will be attracted by it. The junction of the threads arises from the effort the electric fluid makes to diffuse itself through them.

Exper. 9. Place a square piece of leaf brass or silver on the under plate, hold this parallel to the upper one, at about 5 or 6 inches from it; turn the machine, and the leaf will then rise up into a vertical situation, and remain between the two plates, without touching either of them. Present metal point towards the leaf, and it will immediately fall down. Place a brass ball at the end of the conductor, and when the leaf of brass is suspended between the plate and ball, move the plate round the ball, and the leaf will also move round without touching either plate or ball.

Exper. 10. Place two wires directly under, and parallel, to each other; suspend one from the conductor, let the other communicate with the table; then a light image placed between these, will, when the conductor is electrified, appear like a kind of electrical rope-dancer.

Exper. 11. Put a pointed wire into one of the holes which are at the end of the conductor, hold a glass tumbler over the point, covering it with your hands, which serve as a temporary coating; then electrify the conductor, and turn the tumbler round, that the whole interior surface may receive the fluid from the point; place a few pith balls on the table, and cover them with this glass tumbler, the balls will immediately begin to leap up and down as if they were animated, and will continue to move for a considerable time.

Exper. 12. Connect one end of a chain with the outside of a charged jar, and let the other end lie on the table, place the end of another piece of chain at about one quarter of an inch distant from the former; then set a decanter of water on these separated ends, and on making the discharge through the chain, the water will appear perfectly and beautifully luminous.

Exper. 13. Let any person stand on an insulated stool, and connect himself by a wire or chain with the prime conductor, and he will then exhibit the same appearances which are observed in the conductor, and will attract light bodies, give the spark, &c, and thus afford a pleasing mode of diversifying every experiment. It is however absolutely necessary, to the complete success of this experiment, that no part of the clothes touch the floor, table, &c, and that the glass feet be carefully dried; a sheet of dry brown paper placed under the stool will be found of considerable service, by rendering the insulation more complete.

If the insulated person lay his hands on the clothes of one that is not so, especially if they are woollen, they will both feel as it were many pins pricking them, as long as the cylinder is in motion.

Exper. 14. Place the brass ball of a coated jar in contact with the prime conductor, while the outside communicates with the table, turn the cylinder, and the bottle will in little time be charged. Now to discharge the jar, that is to restore it to its natural state, bring one end of a conducting substance in contact with the outside coating, and let the other be brought near the knob of the jar which communicates with the inside coating, and a strong explosion will take place, the electric light will be visible, and the report very loud. Charge the jar again, then touch the outside coating with one hand, and the knob with the other, by which means the bottle will be discharged, and a sudden peculiar sensation will be perceived, which is called the electric shock. The shock, when it is taken in this manner, generally affects the wrists, elbows, and breast; and when it is strong it re-

sembles a universal blow. This peculiar sensation is probably owing to the two-fold and instantaneous action of the electric fluid, which enters and goes out of the body, and the various parts through which it passes, at one and the same instant. It has been also observed, that nature has appointed a certain modification of the electric fluid in all terrestrial bodies, which we violate in our experiments; when this violation is small, the powers of nature operate in a gentle manner, to rectify the disorder we have introduced; but when the deviation is considerable, the natural powers restore the original constitution with extreme violence.

If several persons join hands, and the first touches the outside of a charged jar, and the last the knob, the bottle will be discharged, and they will all feel the shock at the same instant; but the greater the number of persons are that take a shock, the weaker are its effects.

The force of the shock is in proportion to the quantity of coated surfaces, the thinness of the glass, and the power of the machine; or the effect of the Leyden phial is increased in proportion as we destroy the equilibrium on the surfaces.

Exper. 15. A cork ball, or an artificial spider, made of burnt cork with legs of linen thread, suspended by silk, will play between the knobs of two bottles, one of which is charged positively, the other negatively, and will in a little time discharge them.

Exper. 16. A ball suspended on silk, and placed between two brass balls, one proceeding from the outside, and the other from the inside of a Leyden jar, when the bottle is charged, will fly from one knob to the other; and by thus conveying the fluid from the inside to the outside of the bottle, will soon discharge it.

Exper. 17. Take a glass tube, round which, at small, but equal distances from each other, pieces of tin-foil are pasted in a spiral form from end to end; this tube is inclosed in a larger one, fitted with brass caps at each end, which are connected with the tin-foil of the inner tube. Hold one end in the hand, and apply the other near enough to the prime conductor to take sparks from it, a beautiful and lucid spot will then be seen at each separation of the tin-foil; which multiply, as it were, the spark taken from the conductor; for if there was no break in the tin-foil, the electric fluid would pass off unperceived.

Exper. 18. To take the electric spark with a metal point, screw a pointed brass wire into one end of a spiral tube, and present it to the conductor while the machine is in action; then a strong spark will pass between the conductor and the point.

Exper. 19. Take a clean dry glass tube, of about a quarter of an inch bore, and insert a pointed wire in this tube, keep the pointed end at some distance from the end of the tube, at the same time let the other end be connected with the ground, bring the former towards the prime conductor, and strong zig-zag sparks, attended with a peculiar noise, will pass between the conductor and the point.

Exper. 20. The Luminous Word. This experiment is exactly on the same principles as Experiment 17. The word is formed by the small separations made in the tin-foil, which is pasted on a piece of glass, that is fixed in a frame of baked wood, having a brass ball at one end. To make the experiment, hold the frame in the hand, and present the ball to the conductor, the spark received on this will be communicated to the tin-foil, and follow

it in all its windings, till it arrives at the hook, whence it is conveyed to the ground by a chain: and thus the lucid appearance at each break exhibits a word in characters of fire.

ELECTRICAL Fluid, is a fine rare fluid which issues from, and surrounds, electrified bodies.

ELECTRICAL Kite, an instrument contrived by Dr. Franklin, to verify his hypothesis of the identity of electricity and lightning. It consisted of a large thin silk handkerchief, extended and fastened at the four corners to two slender strips of cedar, and accommodated with a tail, loop, and string, so as to rise in the air like a paper kite. To the top of the upright stick of the cross was fixed a very sharp-pointed wire, rising a foot or more above the wood; and to the end of the twine, next the hand, a silk ribbon was tied. From a key suspended at the junction of the twine and silk, when the kite is raised during a thunder-storm, a phial may be charged, and electric fire collected, as is usually done by means of an excited glass tube or globe. *Philos. Trans.* vol. 47, pa. 565, or *Franklin's Letters*, pa. 111 and 112.—Kites made of paper, covered with varnish, or with well boiled linseed oil, to preserve them from the rain, with a stick and cane bow, like the common ones used by boys, will answer the purpose extremely well, and are very useful in determining the electricity of the atmosphere. See *Cox-Dexter*.

ELECTRICAL Machine, a piece of mechanism in which an electric body, such as glass, sulphur, resin, &c., is subjected to friction, in order to excite in it that power which is commonly known under the name of electricity.

It would be useless to trace this machine through all its various forms and improvements, which the ingenuity and industry of philosophers have given to it; we shall therefore limit ourselves to describing and exhibiting some of the most approved constructions, which may be enumerated as follows.

Description of the most useful Electrical Machines.

Fig. 1, plate xi, represents Dr. Priestley's machine, which is a very extensively useful one, described in his *History of Electricity*; in which *g* is the globe, or electric; *f* the rubber; in the two pillars *d*, *d*, of baked wood, are several holes to receive the spindles of different globes or cylinders, several of which may be put on together, to increase the electricity: *klm* is the prime conductor, being a copper tube, supported on a stand of glass or baked wood.

Dr. Watson's machine, for using several globes at once, to accumulate a great quantity of electricity, is represented fig. 2.

Fig. 3 represents a very portable electrical machine invented by Mr. Read, and improved by Mr. Lane. A is the glass cylinder, moved vertically by means of the pulley at the lower end of the axis, the pulley being turned by the large wheel *b* parallel to the table: there are also several pulleys, of different sizes, either of which may be used, according as the motion is required to be quicker or slower. The conductor *c* is furnished with points to collect the fluid, and is screwed to the wire of a coated jar *d*. The figure shows also the manner of applying Mr. Lane's electrometer to this machine.

Electrical machines have of late years undergone some very essential alterations and improvements; both from the suggestions of private electricians, and the inventions of Messrs. Adams, Bairne, and Jones, instrument-makers in London; some of which are as follow:

Fig. 4 represents a very convenient machine for practice. The frame of this machine consists of the bottom board **A B C D**; which, when the machine is used, must be fastened to the table by two metal cramps. **E F** are two round pillars, of baked wood, which support the cylinder **G** by the axles of the brass or wooden caps **H**, turned sometimes by a simple winch **I**, and sometimes by a pulley and wheel, as in the next fig. The rubber is fixed to a glass pillar **K**, which is fastened to a wooden basis **L** at the bottom. The conductor **X** is usually made of brass or tin japanned, and is insulated by a glass pillar, screwed into a wooden basis or foot, most conveniently placed parallel to the cylinder.

Fig. 5 represents an electrical machine, with a conductor in the shape of a τ ; and an improved medical apparatus, where it is necessary to give the shock in the arms, or any other particular part of the body.

Fig. 6 shows Mr. Nairne's patent machine for medical purposes. Its glass cylinder is about 7 inches in diameter, and 12 long, with two conductors parallel to it. The rubber is fastened to the conductor **K**; and consists of a cushion of leather stuffed, having a piece of silk glued to its under part. The conductors are made of tin, and covered with black lacquer, each of them containing a large coated glass jar, and likewise a smaller one, or a coated tube, which are visible when the caps **N N** are removed. To each conductor is fixed a knob **O**, for the occasional suspension of a chain to produce positive or negative electricity. That part of the winch **C** which acts as a lever in turning the cylinder, is of glass. Thus every part of the machine is insulated, the cylinder itself and its brass caps not excepted; by which means very little of the electricity is dissipated, and hence of course the effects are likely to be the more powerful: the inventor has also adapted to this machine some flexible conducting joints, a discharging electroineter, &c., for the practice of medical electricity.

The large electrical machine placed in Teyler's Museum at Harlem, was constructed by Mr. John Cuthbertson, an English instrument-maker; and it has, for the electric, two glass plates of 65 inches diameter, made of French glass, as this is found to produce the most electricity next to English flint glass, which could not be made of a sufficient size: these plates are set on the same horizontal axis, at the distance of $7\frac{1}{2}$ inches, and are excited by 8 rubbers, each $15\frac{1}{2}$ inches long; and both sides of the plates are covered with a resinous substance to the distance of $10\frac{1}{2}$ inches from the centre, both to strengthen the plates, and to prevent any electricity from being carried off by the axis. Its battery of jars contains 225 square feet of coated surface, and its effects are astonishingly great; as a proof of which we mention the following particulars: The sensation commonly called the spider's web, when this machine is in action, is felt by the by-standers at the distance of 8 feet from the prime conductor. A thread 6 feet long, suspended perpendicularly, was sensibly attracted by the prime conductor at the distance of 38 feet, and a pointed wire presented to the prime conductor appeared luminous even at the distance of 28 feet. A single spark from the prime conductor melted a considerable length of gold leaf. And a Leyden phial, containing about a square foot of coated surface, was fully charged by about half a revolution of the plates, so as to discharge itself; and by repeated trials it was found that, in one minute's time, this phial discharged itself 76, 78, and frequently even 80 times in a minute. Having thus described the electrical machines of the most approved construction, it only remains to add

some general and practical directions necessary to be observed for the preservation and proper management of them, in making experiments.

Moisture and dust, but particularly the former, being detrimental to the power of an electrical machine, it becomes necessary to guard against both, as much as may be practicable; hence when not actually in use, the machine should be kept in a dry and clean place, and at least the glass part of it should not be suffered to remain dirty and soiled. If it has been long neglected, the operator, in order to render it ready for use, must, in the first place, remove the rubber; he must then place the machine at a moderate distance from the fire, so as to render every part of it perfectly dry, but not too warm. This done, and the dust removed, the glass part must be repeatedly rubbed with a clean and warm handkerchief, or towel; the rubber likewise must be cleaned, removing all the old amalgam that may have adhered to it. The glass plate, or cylinder, in its rotation frequently contracts some dark spots or concretions on its surface, which tend to diminish its power, and which must therefore be removed. Previously to replacing the rubber, the following operation generally contributes towards increasing the excitation. It consists in touching the cylinder with the bottom of a tallow candle, in streaks parallel to the axis of the cylinder, then rub the cylinder again with a dry warm linen cloth, taking care that this cloth be not very old, for in that case it is apt to leave filaments about the glass and about the rest of the machine. This done, the rubber is fixed in its place, and its supporter being properly adjusted as to pressure, as also a chain suspended from the rubber, connecting it with the floor of the room, then the machine is ready for operation, except the application of the amalgam, in which the following directions must be observed.

Formerly the amalgam was spread upon the rubber; but experience has shown that it is much better for it to be fixed clean in its place, and then to apply the amalgam upon a piece of leather, to the surface of the cylinder, while this is revolving in its usual direction; for by this means the revolution of the plate or cylinder will carry from the leather a sufficient quantity of the amalgam, and will deposit it upon the rubber. The leather with the amalgam need not be applied longer than the cylinder makes 10 or 12 revolutions, moving the leather at the same time, backward and forward, from one end of the cylinder to the other, in order that the amalgam may be equally distributed. Now if the cylinder be turned, and a hand or the ends of the fingers be presented to it, a crackling noise, which is accompanied with luminous brushes and dense sparks of the electric fire, will be observed, particularly in a dark room, which appearances indicate that the machine is in good action; then, the prime conductor being situated in its proper place, you may proceed to perform the experiments. During the performance of which, the electrified part of the machine is apt to attract dust from all quarters, which the operator must guard against as much as possible, by frequently wiping those parts with a clean and perfectly dry cloth, or silk handkerchief.

The amalgam which we have mentioned above is generally composed of 1 part of zinc, and 4 or 5 parts of quicksilver, which are amalgamated in the following manner.

Let the quicksilver be heated to about the degree of boiling water; then, the zinc being already melted in a crucible, pour the quicksilver first into a wooden box, and immediately after the melted zinc. Then shut the box,

and shake it for about half a minute. After this you must wait till the amalgam is quite cold, or nearly so, when you may mix some grease with it by trituration. If the melted zinc be poured into the quicksilver when cold, a very small portion of the former will be amalgamated, the rest remaining in lumps of different sizes.

The above is the method recommended by M. Cavallo, but Mr. Cuthbertson gives the following directions for preparing amalgam. Take one part of tin and zinc, melt them in a crucible, and pour them on two parts of mercury, which put into a wooden box made for the purpose; and shake the box till the metals are cold. The amalgam is then to be pulverised in a metal mortar to a very fine powder, and afterwards mixed with a sufficient quantity of hogs-lard, to make it into a paste.

ELECTRICAL Phial. See **LEYDEN Phial.**

ELECTRICAL Rubber. See **ELECTRICAL Apparatus**, and **ELECTRICAL Machine**.

ELECTRICAL Shock, is the sudden explosion between the opposite sides of a charged electric; so called because if the discharge be made through the body of an animal, it occasions a sudden motion by the contraction of the muscles through which it passes, accompanied with a disagreeable sensation. The force of this shock is proportioned to the quantity of coated surface, the thinness of the glass, and the power of the machine by which it is charged. Its velocity is almost instantaneous, and it has not been found to take up the least sensible time in passing to the greatest distances.

It has however been observed that the electrical shock is weakened by being communicated through several persons in contact with one another. Indeed it is obstructed in its passage, even through the best conductors, as it will prefer a short passage through the air to a long one through the most perfect conductors; and if the circuit be interrupted, either by electrics, or very imperfect conductors of a moderate thickness, the shock will rend them in its passage, disperse them in every direction, and exhibit the appearance of a sudden expansion of the air about the centre of the shock. A strong shock made to pass through or over the belly of a muscle, forces it to contract; and sent through a small animal body, deprives it instantly of life, and hastens putrefaction. It gives polarity to magnetic needles, reverses their poles, and produces effects precisely similar, though inferior in degree, to those of lightning.

ELECTRICAL Star. See **STAR**.

ELECTRICITY, or **ELECTRICAL Force**, is that power or property, which was first observed in amber, the lycneum, or tourmalin, and which sealing-wax, glass, and a variety of other substances, called electrics, are now known to possess, of attracting light bodies, when excited by heat or friction; and which is also capable of being communicated in particular circumstances to other bodies.

ELECTRICITY also denotes the science, or that part of natural philosophy, which proposes to investigate the nature and effects of this power. From *χειρός*, the Greek name for amber, is derived the term electricity, which is now very extensively applied, not only to the power of attracting light bodies inherent in amber, but to other similar powers, and their various effects, in whatever bodies they reside, or to whatever bodies they may be communicated. Muschenbroek and *Æpinus* have observed a considerable analogy, in a variety of particulars, between the powers of electricity and magnetism; and they have also pointed out many instances in which they differ.

History of ELECTRICITY.—The property which amber possesses of attracting light bodies, was observed by Thales of Miletus, 600 years before Christ, who concluded from hence that it was animated. But the first person who expressly mentioned this substance, was Theophrastus, about 300 years before Christ. The attractive property of amber is also occasionally noticed by Pliny, and other naturalists, particularly Gassendus, Sir Kenelm Digby, and Sir Thos. Brown. But it was generally apprehended that this quality was peculiar to amber and jet, and perhaps agate, till Dr. Gilbert, a native of Colchester, and a physician in London, published his treatise *De Magnete*, in the year 1600. Dr. Gilbert made many considerable experiments and discoveries, considering the then infant state of the science. He enlarged the list both of electrics, and of the bodies on which they act; and remarked, that a dry air was most favourable to electrical appearances, while a moist air almost annihilates the electric virtue: he also observed the conical figure assumed by electrified drops of water. He considered electrical attraction separately from repulsion, which he thought had no place in electricity, as a phenomenon similar to the attraction of cohesion, and he imagined, that electrics were brought into contact with the bodies on which they act by their effluvia, excited by friction.

The ingenious Mr. Boyle added to the catalogue of electric substances; but he thought that glass possessed this power in a very low degree: he found, that the electricity of all bodies, in which it might be excited, was increased by wiping and warming them before they were rubbed; that an excited electric was acted on by other bodies as strongly as it acted upon them: that diamonds rubbed against any kind of stuff, emitted light in the dark; and that feathers would cling to the fingers, and to other substances, after they had been attracted by electrics. He accounted for electrical attraction, by supposing a glutinous effluvia emitted from electrics, which laid hold of small bodies, in its way, and carried them back to the body from which it proceeded.

Otto Guericke, the celebrated inventor of the air-pump, lived about the same time. This ingenious philosopher discovered, by means of a globe of sulphur, that a body once attracted by an electric, was next repelled, and that it continued in this state of repulsion till it was touched by some other body; he also observed the sound and light produced by the excitation of his globe; and that bodies immersed in electrical atmospheres are themselves electrified, with an electricity opposite to that of the atmosphere.

The light emitted by electrical bodies was, soon after, observed to much greater advantage by Dr. Wall, who ascribes the light to the electrical property which they possess; and he suggests a similarity between the effects of electricity and lightning.

Sir Isaac Newton was not inattentive to this subject: he observed that excited glass attracted light bodies on the side opposite to that on which it was rubbed; and he ascribed the action of electric bodies to an elastic fluid, which freely penetrates glass, and the emission of it to the vibratory motions of the parts of excited bodies.

Mr. Hawksbee wrote on this subject in the year 1709, when a new era commenced in the history of this science. He first took notice of the great electrical power of glass, and the light proceeding from it; though others had before observed the light proceeding from other electrified

substances : he also noted the noise occasioned by it, with a variety of phenomena relating to electrical attraction and repulsion. He first introduced a glass globe into the electrical apparatus, to which circumstance many of his important discoveries may be attributed.

After this time there was an interval of near 20 years in the progress of this science, till Mr. Stephen Grey established a new æra in the history of electricity. To him we owe the important discovery of communicating the power of native electrics to other bodies, in which it cannot be excited, by supporting them on silken lines, hair lines, cakes of resin or glass ; and also a more accurate distinction than had hitherto been made between electrics and non-electrics : he likewise showed the effect of electricity on water much more obviously than Gilbert had done in the infancy of this science.

The experiments of Mr. Grey were repeated by M. du Fay, member of the Academy of Sciences at Paris, to which he added many new experiments and discoveries of his own. He observed, that electrical operations are obstructed by great heat, as well as by a moist air ; that all bodies, both solid and fluid, would receive electricity, when placed on warm or dry glass, or sealing-wax ; that those bodies which are naturally the least electric, have the greatest degree of electricity communicated to them by the approach of the excited tube. He transmitted the electric virtue through a distance of 1256 feet ; and first observed the electric spark from a living body, suspended on silken lines, and noted several circumstances attending it. M. du Fay also established a principle, first suggested by Otto Guericke, that electric bodies attract all those that are not so, and repel them as soon as they are become electric, by the vicinity or contact of the electric body. He likewise inferred from other experiments, that there were two kinds of electricity ; one of which he called the vitreous, belonging to glass, rock crystal, &c. ; and the other resinous, as that of amber, gum-lac, &c., which are distinguished by their repelling those of the same kind, and attracting each other. He farther observed, that communicated electricity had the same property as the excited ; and that electric substances attract the dew more than conductors.

Mr. Grey, resuming his experiments in 1734, suspended several pieces of metal on silken lines, and found that by electrifying them they gave sparks ; which was the origin of metallic conductors : and on this occasion he discovered a cone or pencil of electric light, such as is now known to issue from an electrified point. And from other experiments he concluded that the electric power seems to be of the same nature with that of thunder and lightning.

Dr. Desaguliers succeeded Mr. Grey in the prosecution of this branch of philosophy. The account of his first experiments is dated in 1739, and to him we owe those technical terms of conductors or non-electrics, and electrics per se ; he also first ranked pure air among the electrics per se, and supposed its electricity to be of the vitreous kind.

After the year 1742, in which Dr. Desaguliers concluded his experiments, the subject was taken up and pursued in Germany : the globe was substituted for the tube, which had been used ever since the time of Hawksbee, and a cushion was soon after used as a rubber, instead of the hand ; it was also about this time that cylinders began to be used, instead of the globes ; and some of the German electricians made use of many globes at the same time. By thus increasing the electrical power, they were the first who succeeded in setting fire to inflammable sub-

stances : which was first done by Dr. Ludolf, in the beginning of the year 1744, who, with sparks excited by the friction of a glass tube, kindled the ethereal spirit of Frobenius. Winkler did the same by a spark from his own finger, by which he kindled French brandy, and other spirits, after previously heating them. Mr. Gratalf fired the smoke of a candle just blown out, and so lighted it again ; and Mr. Boze fired gun-powder, by means of its inflammable vapour. It was also at this time Ludolf the younger demonstrated, that the luminous barometer was made perfectly electrical by the motion of the quicksilver. The electrical star and electrical bells were also of German invention.

From this period Dr. Watson considerably distinguished himself in the pursuit of this science ; he fired a variety of substances by the electrical spark, and first discovered that they are capable of being fired by the repulsive power of electricity. In the year 1745, the accumulation of the electrical power in glass, by means of the Leyden phial, was first discovered. See *LEYDEN PHIAL* : and for the method practised about this time, of measuring the distance to which the electrical shock may be conveyed, see *ELECTRICAL CIRCUIT*. Dr. Watson discovered that the glass tubes and globes do not contain the electric matter in themselves, but only serve as first-movers or determiners, as he expresses it, of that power ; which was also confirmed towards the end of 1746, by Mr. Benjamin Wilson, who made the same discovery, that the electric fluid does not come from the globe, but from the earth, and other non-electric bodies about the apparatus. Dr. Watson also discovered what Dr. Franklin observed about the same time in America, and called the plus and minus electricity. He likewise showed that the electric matter passed through the substance of the metal of communication, and not merely over the surface. The history of medical electricity commenced in the year 1747 ; but we are under the necessity of omitting many experiments, and conclusions drawn from them, by Mr. Wilson, Mr. Smeaton, and Dr. Miles in England, and by the Abbé Nollet, with regard to the effect of electricity on the evaporation of fluids, on solids, and on animal and other organized bodies, in France.

While the philosophers of Europe were busily employed in electrical experiments and pursuits, those of America, and Dr. Franklin in particular, were equally industrious, and no less successful. His discoveries and observations in electricity were communicated in several letters to a friend ; the first of which is dated in 1747, and the last in 1754 ; the particulars of his system may be seen under the articles, *THEORY OF ELECTRICITY*, *LEYDEN PHIAL*, *POINTS*, *CHARGING*, *CONDUCTORS*, *ELECTRICS*, &c.

The similarity between electricity and lightning had been suggested by several writers : and Dr. Franklin first proposed a method of bringing the matter to the test of experiment, by raising an electrical kite ; by which means he succeeded in collecting electrical fire from the clouds, in 1752, one month after the same theory had been verified in France, and without knowing what had been done there : and to him we owe the practical application of this discovery, in securing buildings from the damage of lightning, by erecting metallic conductors. See *CONDUCTORS*, and *LIGHTNING*.

In the subsequent period of the history of electricity, Mr. Canton in England, and Signor Beccaria in Italy, acquired distinguished reputation. They both discovered,

independently of each other, that air is capable of receiving electricity by communication, and of retaining it when received. Mr. Canton also, towards the latter end of the year 1753, pursued a series of experiments, which proved that the appearances of positive and negative electricity, which had hitherto been deemed essential and unchangeable properties of different substances, as of glass and sealing-wax for instance, depend on the surface of the electrics, and that of the rubber. This hypothesis, verified by numerous experiments, occasioned a controversy between Mr. Canton and Mr. Delaval, who still maintained that these different powers depended entirely on the substances themselves. About this time also some curious experiments were performed by four of the principal electricians of that period, viz. Dr. Franklin, and Messrs. Canton, Wilcke, and *Æpinus*, to ascertain the nature of electric atmospheres; the result of which see under that article. The theory of two electric fluids, always co-existent and counteracting each other, though not absolutely independent, was maintained by a course of experiments on silk stockings of different colours, communicated to the Royal Society by Mr. Symmer, in the year 1759, and which were farther pursued by Mr. Cigna of Turin, who published an account of them in the Memoirs of the Academy at Turin for the year 1765.

Many instances occur in the history of the science about this time, of the astonishing force of the electric shock, in melting wires, and producing other similar effects: but the most remarkable is an experiment of S. Beccaria, in which he thus revived metals. Several experiments were also made by Dr. Watson, Mr. Smeaton, Mr. Canton, and others, on the passage of the electric fluid through a vacuum, and its luminous appearance, and on the power possessed by certain substances of retaining the light communicated to them by an electric explosion. Mr. Canton, S. Beccaria, and others, made many experiments to identify electricity and lightning, to ascertain the state of the atmosphere at different times, and to explain the various phenomena of the aurora borealis, water-sprouts, hurricanes, &c. on the principles of this science.

Those who are desirous of farther information with respect to the history of electrical experiments and discoveries, may consult Dr. Priestley's History and Present State of Electricity. This author however, is not merely an historian: his work contains many original experiments and discoveries made by himself. He ascertained the conducting power of charcoal and of hot glass, the electricity of fixed and inflammable air, and of oil; the difference between new and old glass, with respect to the diffusion of electricity over its surface; the lateral explosion in electrical discharges; a new method of fixing circular-coloured spots on the surfaces of metals, and the most probable difference between electrics and conductors, &c. The science is also greatly indebted to many other persons, either for their experiments and improvements in it, or for treatises and other writings upon it; as Mr. Henley, to whom we owe several curious experiments and observations on the electrical and conducting quality of different substances, as chocolate, vapour, &c., with the reason of the difference between them; the fusion of platinum; the nature of the electric fluid, and its course in a discharge; the method of estimating the quantity of it in electrical bodies by an electrometer; the influence of points; &c., &c. Also Messrs. Van Marum, Van Swinden, Ferguson, Cavallo, Lord Mahon, Nairne, &c., &c., for

their several treatises on the subject of electricity, any of which may be consulted with advantage for the experiments and principles of the science.

Medical ELECTRICITY. It is natural to imagine that a power of such efficacy as that of electricity would soon be applied to medical purposes; especially, since it has been found invariably to increase the sensible perspiration, to quicken the circulation of the blood, and to promote the glandular secretion: accordingly, many instances occur in the latter period of the history of this science, in which it has been applied with considerable advantage and success. And among the variety of cases in which it has been tried, there are none where it has been found prejudicial, except those of pregnancy and the venereal disease. In most disorders, in which it has been used with perseverance, it has given at least a temporary and partial relief, and in many it has effected a complete cure. Numerous instances of this kind may be seen in the Philos. Trans., and the writings on this science by Messrs. Lovet, Westley, Ferguson, Cavallo, &c., &c.

Theory of ELECTRICITY. It is hardly necessary to recite the ancient hypotheses on this subject; such as that of the sympathetic powder of the Puripatetics; that of unctuous effluvia emitted by excited bodies, and returning to them again, adopted by Gilbert, Gassendus, Sir Kenelm Digby, &c.; or that of the Cartesians, who ascribed electricity to the globules of the first elements, discharged through the pores of the rubbed substance, and in their return carrying with them those light bodies, in whose pores they were entangled: these hypotheses were framed in the infancy, not only of this science, but of philosophy in general, and have long since been deservedly exploded. In the more advanced state of electricity there have been two principal theories, each of which has had its advocates. The one, is that of two distinct electric fluids, repulsive with respect to themselves, and attractive of one another, adopted by M. du Fay, on discovering the two opposite species of electricity, viz. the vitreous and resinous, and since new-modelled by Mr. Symmer. It is supposed that these two fluids are equally attracted by all bodies, and exist in intimate union in their pores; and that in this state they exhibit no mark of their existence. But that the friction of an electric by a rubber separates these fluids, and causes the vitreous electricity of the rubber to pass to the electric, and then to the prime conductor of a machine, while the resinous electricity of the conductor and electric is conveyed to the rubber: and thus the quality of the electric fluid, possessed by the conductor and the rubber, is changed, while the quantity remains the same in each. In this state of separation, the two electric fluids will exert their respective powers; and any number of bodies charged with either of them will repel each other, attract those bodies that have less of each particular fluid than themselves, and be still more attracted by bodies that are wholly destitute of it, or that are overcharged with the contrary. According to this theory, the electric spark makes a double current; one fluid passing to an electrified conductor from any substance presented to it, while the same quantity of the other fluid passes from it; and when each body receives its natural quantity of both fluids, the balance of the two powers is restored, and both bodies are unelectrified. For a farther account of the explication of some of the principal phenomena of electricity by this theory, see Dr. Priestley's History, vol. 2, § 3.

The other theory is commonly distinguished under the denomination of *positive and negative electricity*, being first suggested by Dr. Watson, but digested, illustrated, and confirmed by Dr. Franklin; and since that it has been known by the appellation of the Franklinian hypothesis. It is here supposed that all the phenomena of electricity depend on one fluid, *sui generis*, extremely subtle and elastic, dispersed through the pores of all bodies, by which the particles of it are as strongly attracted as they are repelled by one another. When bodies possess their natural share of this fluid, or such a quantity as they can retain by their non-attraction, it is then said they are in an unelectrified state; but when the equilibrium is disturbed, and they either acquire an additional quantity *from* other bodies, or lose part of their own natural share by communication *to* other bodies, they exhibit electrical appearances. In the former case it is said they are electrified positively, or plus; and in the other negatively, or minus. This electric fluid, it is supposed, moves with great ease in those bodies that are called conductors, but with extreme difficulty and slowness in the pores of electrics; whence it happens, that all electrics are impermeable to it. It is further supposed that electrics contain always an equal quantity of this fluid, so that there can be no surcharge or increase on one side, without a proportionate decrease or loss on the other, and vice versa; and as the electric does not admit the passage of the fluid through its pores, there will be an accumulation on one side, and a corresponding deficiency on the other. Thus when both sides are connected together by proper conductors, the equilibrium will be restored by the rushing of the redundant fluid from the overcharged surface to the exhausted one. Thus also, if an electric be rubbed by a conducting substance, the electricity is only conveyed from one to the other, the one giving what the other receives; and if one be electrified positively, the other will be electrified negatively, unless the loss be supplied by other bodies connected with it, as in the case of the electric and insulated rubber of a machine. This theory serves likewise to illustrate the other phenomena and operations in the science of electricity. Thus, bodies differently electrified will naturally attract each other, till they mutually give and receive an equal quantity of the electric fluid, and the equilibrium is restored between them. Beccaria supposes, that this effect is produced by the electric matter making a vacuum in its passage, and the contiguous air afterwards collapsing, and so pushing the bodies together.

The influence of points, in drawing or throwing off the electric fluid, depends on the less resistance it finds to enter or pass off through fewer particles than through a greater number, whose resistance is united in flat or round surfaces. The electric light is supposed to be part of the electric fluid, which appears when it is properly agitated; and the sound of an explosion is produced by vibrations, occasioned by the air's being displaced by the electric fluid, and again suddenly collapsing.

As to the nature of the electric fluid, philosophers have entertained very different sentiments: some, and among them Mr. Wilson, have supposed that it is the same with the ether of Sir Isaac Newton, to which the phenomena of attraction and repulsion are ascribed; while the light, smell, and other sensible qualities of it, are referred to the grosser particles of bodies, driven from them by the forcible action of this ether; and other appearances are ex-

plained by means of a subtle medium diffused over the surfaces of all bodies, and resisting the entrance and exit of the ether; which medium, it is supposed, is the same with the electric fluid, and is more rare on the surfaces of conductors, and more dense and resisting on those of electrics: but Dr. Priestley remarks that, though they may possess some common properties, they have others essentially distinct; the ether is repelled by all other matter, whereas the electric fluid is strongly attracted by it. Others have had recourse to the element of fire; and from the supposed identity of fire and the electric fluid, as well as from the similarity of some of their effects, the latter has been usually called the electric fire: but most electricians have supposed that it is a fluid *sui generis*. Mr. Cavendish has published an attempt to deduce and explain some of the principal phenomena of electricity in a mathematical and systematic manner, from the nature of this fluid, considered as composed of particles that repel each other, and attract the particles of all other matter, with a force inversely as some less power of the distance than the cube, while the particles of all other matter repel each other, and attract those of the electric fluid, according to the same law. Philos. Trans. vol. 61, pa. 584—607. And a similar hypothesis and method of reasoning was also proposed by M. Æpinus, in his *Tentamen Theoriae Electricityæ et Magnetismi*.

Dr. Priestley concludes, from experiments which he made, that the electric matter either is phlogiston, or contains it, since he found that both produced similar effects. And Mr. Henley also apprehends, that the electric fluid is a modification of that element, which, in its quiescent state, is called phlogiston; in its first active state, electricity; and when violently agitated, fire. Perhaps we may be allowed to enlarge our views, and consider the sun as the fountain of the electric fluid, and the zodiacal light, the tails of comets, the aurora borealis, lightning, and artificial electricity; as its various and not very dissimilar modifications. On this subject, see Priestley's Hist. of Electr. vol. 2, part 3, § 1, 2, 3; Wilson's Essay towards an Explication of the Phenomena of Electricity, &c.; Wilson and Hoadley's Obs. &c., pa. 55, 1759; Freke's Essay on the Cause of Electricity, 1746; Priestley on Air, vol. I, pa. 186, 274, &c.; Philos. Trans. vol. 67, pa. 129; Eales's Letters, on the same subject; and Cavallo's Electricity.

ELECTROMETER, is an instrument that measures the quantity, and determines the quality of electricity, in any electrified body. Previous to the invention of instruments of this kind, Mr. Canton estimated the quantity of electricity in a charged phial, by presenting the phial with one hand to an insulated conductor, and giving it a spark, which he took off with the other; proceeding in this manner till the phial was discharged, when he determined the height of the charge by the number of sparks. Electrometers are of various kinds: as 1, the single thread; 2, the cork or pith balls; 3, the quadrant; and 4, the discharging electrometer, &c.

The 1st, or most simple electrometer, is a linen thread, called by Dr. Desaguliers, the *thread of trial*; which, being brought near an electrified body, is attracted by it: but this does little more than determine whether the body is in any degree electrified or not; without determining with any precision its quantity, much less the quality of it. The Abbé Nollet used two threads, showing the degree of electricity by the angle of their divergency exhibited in their shadow on a board placed behind them.

Mr. Canton's electrometer consisted of two balls of cork, or pith of elder, about the size of a small pea, suspended by fine linen threads, about 6 inches long, which may be wetted in a weak solution of salt. (See fig. 7.) If the box containing these balls be insulated, by placing it on a drinking-glass, &c, and an excited smooth glass tube be brought near them, they will first be attracted by it, and then be both repelled, from the glass, and from each other; but if excited wax be applied to them, they will gradually approach and come together; and vice versa. This apparatus will also serve to determine the electricity of the clouds and air, by holding them at a sufficient distance from buildings, trees, &c; for if the electricity of the clouds or air be positive, their mutual repulsion will increase by the approach of excited glass, or decrease by the approach of amber or sealing-wax; and on the contrary, if it be negative, their repulsion will be diminished by the former, and increased by the latter. See Philos. Transact. vol. 48, part 1 and 2, for an account of Mr. Canton's curious experiments with this apparatus. If two balls of this kind be annexed to a prime conductor, they will serve to determine both the degree and quality of its electrification, by their mutual repulsion and divergency.

The Discharging Electrometer (fig. 3, plate xi.) was invented by Mr. Lane. It consists of brass work σ , the lower part of which is enclosed in the pillar τ , made of baked wood, and boiled in linseed oil, and bored cylindrically about two-thirds of its length; the brass work is fixed to the pillar by the screw π , moveable in the groove ι ; and through the same is made to pass a steel screw λ , to the end of which, and opposite to κ , which is a polished hemispherical piece of brass, attached to the prime conductor, is fixed a ball of brass η , well polished; and to this screw is annexed a circular plate α , divided into 12 equal parts. The use of this electrometer is to discharge a jar δ , or any battery connected with the conductor, without a discharging rod, and to give shocks successively of the same degree of strength; on which account it is very fit for medical purposes. Now, if a person holds a wire fastened to the screw π in one hand, and another wire fixed to ε , which is a loop of brass wire passing from the frame of the machine to a tin-plate, on which the phial σ stands, he will perceive no shock, while κ and α are in contact; and the degree of the explosion, as well as the quantity of electricity accumulated in the phial, will be regulated by the distance between κ and α . Philos. Trans. vol. 57, pa. 451.—Mr. Henley much improved Mr. Lane's electrometer, by taking away the screw, the double-milled nut, and the sharp-edged graduated plate, and adding other things in their stead. Mr. Henley's discharger of this kind has two tubes, one sliding within the other, to lengthen and accommodate it to larger apparatus.

The Quadrant Electrometer of Mr. Henley, consists of a stem, terminating at its lower end with a brass ferrule and screw, for fastening it on any occasion; and its upper part ends in a ball. Near the top is fixed a graduated semicircle of ivory, on the centre of which the index, being a very light rod with a cork ball at its extremity, reaching to the brass ferrule of the stem, is made to turn on a pin in the brass piece, so as to keep near the graduated limb of the semicircle. When the electrometer is not electrified, the index hangs parallel to the stem; but as soon as it begins to be electrified, the index, repelled by the stem, begins to move along the graduated edge of

the semicircle, and so mark the degree to which the conductor is electrified, or the height to which the charge of any jar or battery is advanced. (See fig. 8.)

M. Cavallo also contrived several ingenious electrometers, for different uses; as may be seen in his Treatise on Electricity, pa. 370, &c, and in the Philos. Trans. vol. 67, pa. 48 and 399.

ELECTROPHOR, or ELECTROPHORUS, an instrument for showing perpetual electricity; which was invented by M. Volta, of Como, near Milan, in Italy. The machine consists of two plates, fig. 9, one of which B is a circular plate of glass, covered on either side with some resinous electric, and the other A is a plate of brass, or a circular board, coated with tin-foil, and furnished with a glass handle i , which may be screwed into its centre by means of a socket. Now, if the plate B be excited by rubbing it with new white flannel, and the plate A be applied to its coated side, a finger, or any other conductor, will receive a spark on touching this plate; and if the plate A be then separated, by means of the handle i , it will be found strongly electrified, with an electricity contrary to that of the plate B . Then replacing the plate A , touching it with the finger, and separating it again, it will be found electrified as before, and give a spark to any conductor, attended with a snapping noise; and by this means a coated phial may be charged. The same phenomena may repeatedly be exhibited, without any renewed excitation of the electric plate B ; the electric power of B having continued for several days, and even weeks, after excitation; though there is no reason to imagine that it is perpetual.

M. Cavallo prepares this machine by coating the glass plate with sealing-wax; and the late Mr. Adams, philosophical-instrument-maker, prepared them with plates formed from a composition of two parts of shell-lac, and one of Venetian turpentine, without any glass. The action of this plate depends on a principle discovered and illustrated by the experiments of Franklin, Canton, Wilcke, and Epinus, viz, that an excited electric repels the electricity of another body, brought within its sphere of action, and gives it a contrary electricity. Thus the plate A , touched by a conductor, while in contact with the plate B , which is negatively electrified, it will acquire an additional quantity of the electric fluid from the conductor; but if it were in contact with a plate electrified positively, it would part with its electricity to the conductor connected with it. See an account of several curious experiments with this machine, by Mr. Henley, M. Cavallo, and Dr. Ingenhousz, in the Philos. Trans. vol. 66, pa. 513; vol. 67, pa. 116 and 389; and vol. 68, pa. 1027 and 1049.

ELEMENTARY, something that relates to the principles or elements of bodies, or sciences; as Elementary Air, Fire, Geometry, Music, &c.

ELEMENTS, the first principles of which all bodies and things are composed. These are supposed few in number, unchangeable, and by their combinations producing that extensive variety of objects to be met with in the works of nature. Democritus stands at the head of the elementary philosophers, in which he is followed by Epicurus, and many others after them, of the Epicurean and corpuscular philosophers.

Among those who consider matter, or the elements, as corruptible, some assert that there is only one element in nature, while others maintain that there are several. Of the former, the principal are Heraclitus, who considers fire

as this element; Anaximenes asserts that it is air; Thales Milesius says water, and Hesiod earth. Hesiod is followed by Bernardin, Telesius; and Thales by many of the chemists.

Among those who admit several corruptible elements, the principal are the Peripatetics; who, after their leader Aristotle, contend for four elements, viz, fire, air, water, and earth. Aristotle took the notion from Hippocrates; Hippocrates from Pythagoras; and Pythagoras from Ocellus Lucanus, who it seems was the first author of it, or from the orientals.

The modern chemists, however, do not acknowledge any particular number of elements, but freely admit into this class all substances that have not been decomposed. An element is therefore merely one of the last results of chemical analysis; and in denominating substances elementary or simple, we consider them as such only with regard to the present state of chemical science. It is not probable any one of the simplest bodies with which we are acquainted, is really and essentially elementary, and it is at best needless to enter into an enquiry in which there are no facts to rest on for support.

ELEMENTS, a term also used for the first grounds and principles of arts and sciences; as the Elements of geometry, Elements of mathematics, &c. So Euclid's Elements, or simply the Elements, as they were anciently and peculiarly named, denotes the treatise on the chief properties of geometrical figures by that author.

The ELEMENTS of mathematics have been delivered by several authors in their courses, systems, &c. The first work of this kind is that of Herigon, in Latin and French, and published in 1634, in 5 tomes; which contains Euclid's Elements and Data, Apollonius, Theodosius, &c.; with the modern elements of arithmetic, algebra, trigonometry, architecture, geography, navigation, optics, spherics, astronomy, music, perspective, &c. The work is remarkable for this, that a kind of real and universal characters are used throughout; so that the demonstrations may be understood by such as only remember the characters, without any dependence on language or words at all.

Since Herigon, the elements of the several parts of mathematics have been also delivered by many others; particularly the Jesuit Schottus, in his Cursus Mathematicus, in 1674; De Chales, in his Cursus, 1674; Sir Jonas Moore, in his New System of Mathematics, in 1681; Ozanam, in his Cours de Mathematique, in 1699; Jones, in his Synopsis Palmariorum Mathesos, in 1706; and many others, but above all, Christ. Wolfius, or Wolf, in his Elementa Matheseos Universe, in 2 vols 4to, the 1st published in 1713, and the 2d in 1715; a very excellent work of the kind. Another edition of the work was published at Geneva, in 5 vols 4to, of the several dates 1732, 1733, 1735, 1738, and 1741.

The ELEMENTS of Euclid, as they were the first, so they still continue to be the best system of geometry yet extant. They are contained in 15 books, of which numerous editions and commentaries have been published. Proclus wrote a commentary on this work, and Oronotius Fineus gave a printed edition of the first 6 books, in 1530, with notes, to explain Euclid's sense. Peletarius did the same in 1557. Nic. Tartaglia also, about the same time, made a comment on all the 15 books, with the addition of many things of his own. And the same was also done by Billingsley in 1570; and by Flussates Candalla, a

French nobleman, in the year 1578, with considerable additions as to the comparison and inscriptions of solid bodies; which work was afterwards republished with a prolix commentary, by Clavius. But the first who translated them into Latin, while they were yet unknown to the European nations, was Adhelard, or Adelard, a learned Englishman, who performed this task in the 12th century. Commandine also gave a good edition of this work, and in 1703 Dr. Gregory published an edition of the whole works of Euclid, in Greek and Latin. But it would be endless to notice all the editions of this celebrated performance that have been given; some of the best of these however are those of Tacquet, Ozanam, Whiston, Stone, Playfair, Ingram, and more particularly that of Dr. Rob. Simson, of Glasgow.

Beside these there are several other writers on geometry, who have not followed Euclid strictly either in form or arrangement; as it is thought by some, that in the present state of mathematical knowledge, a system of geometry less tedious and prolix than Euclid's would be a considerable acquisition.

ELEMENTS, in the Higher or Sublime Geometry, are the infinitely small parts, or differentials, of a right line, curve, surface, or solid.

ELEMENTS, in Astronomy, are those principles deduced from astronomical observations and calculations, and such fundamental numbers, as are employed in the construction of tables exhibiting the planetary motions. Thus, the elements of the theory of the sun, or rather of the earth, show its mean motion and eccentricity, with the motion of the apelia. And the elements of the theory of the moon, relate to her mean motion, that of the node and apogee, the eccentricity, the inclination of her orbit to the plane of the ecliptic; &c. For the particulars of which see the respective names above mentioned.

ELEVATION, the height or altitude of any object.

ELEVATION, in Architecture, denotes a draught or description of the principal front or side of a building; called also its upright or orthography.

ELEVATION, in Astronomy and Geography, is various; as elevation of the equator, of the pole, of a star, &c.

ELEVATION of the Equator, is the height of the equator above the horizon; or an arc of the meridian intercepted between the equator and the horizon of the place.—The elevation of the equator and of the pole together always make up a quadrant; the one being the complement of the other. Therefore, the elevation of the pole being found, and subtracted from 90°, leaves the elevation of the equator.

ELEVATION of the Pole, is its height above the horizon; or that arc of the meridian which is comprehended between the equator and the horizon of the place. The elevation of the pole is always equal to the latitude of the place; that is, the arc of the meridian intercepted between the pole and the horizon, is every where equal to the arc of the same meridian intercepted between the equator and the zenith. Thus the north pole is elevated 51° 31' above the horizon of London; and the distance, or number of degrees, is the same between London and the equator; so that London is also in 51° 31' of north latitude.

ELEVATION of a Star, or of any other point in the sphere, is the angular height above the horizon; or an arc of the vertical circle intercepted between the star and

the horizon. The meridian altitude of any such point, or its altitude when in the meridian, is the greatest possible.

ELEVATION of a Cannon, or Mortar, is the angle which the bore or the axis of the piece makes with the horizontal plane.

Angle of ELEVATION, is the angle which any line of direction makes above a horizontal line.

ELEVATION is also used by some writers on Perspective, for the scenography, or perspective representation of the whole body or building.

ELIMINATION, in Algebra, is that operation by which any number n of equations, containing n unknown quantities, being given, we find one equation which involves only one unknown quantity; so that by resolving this equation, we obtain the value of that unknown quantity, and retracing our steps back again, we obtain also the values of all the other quantities, which, in the course of the operation, are found to have certain relations with, or dependence on each other. See EXTERMINATION.

ELLIPSE, or *ELLIPSIS*, is one of the conic sections, popularly called an oval: it was first called an Ellipse or Ellipsis by Apollonius, the first and principal author on the conic sections, because in this figure the squares of the ordinates are less than, or defective of, the rectangles under the parameters and abscissæ.

This figure is differently defined by different authors; either from some of its properties, or from mechanical construction, or from the section of a cone, which is the best and most natural way. Thus;

Fig. 1.

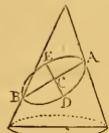

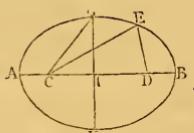

Fig. 2.

1. An ellipse is a plane figure made by cutting a cone by a plane obliquely through the opposite sides of it; or so as that the plane makes a less angle with the base than the side of the cone makes with it; as ABD fig. 1. The line AB connecting the upper and lower points of the section, is the transverse axis; the middle of it C , is the centre; and the perpendicular to it DC , through the centre, is the conjugate axis. The parameter, or latus rectum, is a $3d$ proportional to the transverse and conjugate axes; and the foci are two points in the transverse axis, at such equal distances from the centre, that the double ordinates passing through those points, and perpendicular to the transverse, are equal to the parameter.

2. The ellipse is also variously described from some of its properties; the principal of which are as follow: That if two lines be drawn from two certain points c and d in the axis, fig. 2, to any point e in the circumference, the sum of those two lines ce and de will be every where equal to the same constant quantity, viz., to the axis AB .

Fig. 3.

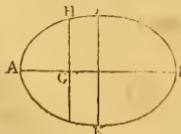

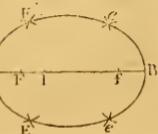

Fig. 4.

And, secondly, that the rectangle $AG \times GB$ (fig. 3) of the abscissæ, tending contrary ways, is to GH^2 the square of the ordinate, as AB^2 to IK^2 , the square of the transverse axis to the square of the conjugate, or, which is the same thing, as the transverse axis is to the parameter; beside various other properties.

3. The ellipse is also variously described from mechanical constructions, which also depend on some of its peculiar properties. 1st, If in the axis AB , there be taken any point i (fig. 4); and with the radii AI , Bi , and centres r and f , the two foci, arcs be described, these arcs will intersect in certain points e , F , e , e , which will be in the curve or circumference of the figure: and thus several points i being taken in the axis AB , as many more points, e , e , &c., will be found; then the curve line drawn through all these points e ; e , will be an ellipse. And if there be taken a thread of the exact length of the transverse axis AB , and the ends of the thread be fixed by pins in the two foci r and f (fig. 5); then moving a pen or pencil within the thread, so as to keep it always stretched, it will describe an ellipse. Or it may be described from the property of the directrix.

Fig. 5.

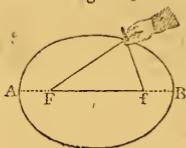

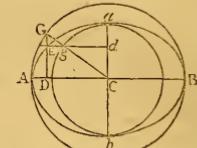

Fig. 6.

To construct an ELLIPSE. There are many other ways of describing or constructing an ellipse, besides those already mentioned.

1st. If upon the given transverse axis there be described a circle AGB (fig. 6), to which there be drawn any ordinate DG , and DE be taken a 4th proportional to the transverse, the conjugate, and the ordinate DG ; then E will be a point in the curve. Or if the circle AGB be described on the conjugate axis ab , to which any ordinate DG is drawn, in which taking dg in like manner a 4th proportional to the conjugate, the transverse, and ordinate DG , then shall E be a point in the curve. Or, having described the two circles, and drawn the common radius cg , cutting them in g and g ; and then dge being drawn parallel to the transverse, and dge parallel to the conjugate, the intersection E of these two lines will be in the curve of the ellipse. And thus several points E being found, the curve may be drawn through them all with a steady hand.

Fig. 7.

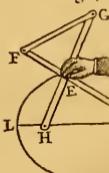

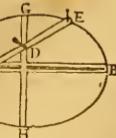

Fig. 8.

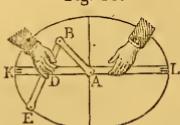

2. Or take three rulers, of which the two gu and ri (fig. 7) are of the length of the transverse axis lk , and the third rg equal to ii the distance between the foci; then connecting these rulers so as to be moveable about the foci r and i , and about the points g and u , their in-

Intersection E will always be in the curve of the ellipse; so that by moving the rulers about the joints, with a pencil passed through the slits made in them, it will trace out the ellipse LK.

Fig. 9.

Fig. 10.

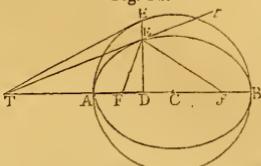

3. If one end A of any two equal rulers AB, DB, (fig. 9 and 10), which are moveable about the point B, like a carpenter's joint-rule, be fastened to the ruler LK, so as to be moveable about the point A; and if the end D of the ruler DB be drawn along the side of the ruler LK, then any point E, taken in the side of the ruler DB, will describe an ellipse, whose centre is A, conjugate axis 2DE, and transverse axis $2AB + 2BE$.

Another method of description is by the elliptical compass. See that article, below.

The most *Remarkable Properties of the Ellipse*, are as follow:—1. The rectangles under the abscisses are proportional to the squares of their ordinates; or as the square of any axis, or any diameter, is to the square of its conjugate, so is the rectangle under two abscisses of the former, to the square of their ordinate parallel to the latter; or again, as any diameter is to its parameter, so is the said rectangle under two abscisses of that diameter, to the square of their ordinate. So that if d be any diameter, c its conjugate, p its parameter, so that $p = c^2 \div d$, x the one absciss, $d - x$ the other, and y the ordinate; then, as $d^2 : c^2 :: x(d-x) : y^2$, or $d^2y^2 = c^2x(d-x)$; or as $d : p :: x(d-x) : y^2$, or $dy^2 = px(d-x)$; From either of which equations, called the equation of the curve, any one of the quantities may be found, when the other three are given.

2. The sum of two lines drawn from the foci to meet in any point of the curve, is always equal to the transverse axis; that is, $CE + DE = AB$, in the 2d fig. Consequently the line CG drawn from the focus to the end of the conjugate axis, is equal to the semi-transverse.

Fig. 11.

3. If from any point of the curve, there be drawn an ordinate to either axis, and also a tangent meeting the axis produced; then half that axis will be a mean proportional between the distances from the centre to the two points of intersection; viz, CA a mean proportional between CD and CT; and consequently all the tangents TE, TE, meet in the same point of the axis produced, which are drawn from the extremities E, E, of the common ordinates DE, DE, of all ellipses described on the same axis AB.

4. Two lines drawn from the foci to any point of the curve, make equal angles with the tangent at that point: that is, the $\angle FET = \angle fgt$. And hence a line drawn to bisect the angle fff, will be perpendicular to the tangent and curve at the point E.

5. All parallelograms that are formed by tangents drawn

through the extremities of any diameter and its conjugate, and thus circumscribed about an ellipse, are equal to each other; and every such parallelogram is equal to the rectangle of the two axes.

6. The sum of the squares of every pair of conjugate diameters, is equal to the same constant quantity, viz, the sum of the squares of the two axes.

7. If a circle be described upon either axis, and from any point in that axis an ordinate be drawn both to the circle and to the ellipse; then will the ordinate of the circle be to the ordinate of the ellipse, as that axis is to the other axis: viz,

$$AB : ab :: DG : DE, \text{ (in the 6th fig.)}$$

$$\text{and } ab : AB :: dg : de.$$

And in the same proportion is the area of the circle to the area of the ellipse, or any corresponding segments ADG, ADE. Also the area of the ellipse is a mean proportional between the areas of the inscribed and circumscribed circles. Hence therefore,

8. *To find the area of an Ellipse.* Multiply the two axes together, and that product by 7854, for the area. Or,

9. *To find the area of any segment ADE.* Find the area of the corresponding segment ADG of a circle on the same diameter AB; then say, as the axis AB: its conj. ab :: circ. seg. ADG : elliptic seg. ADE.

10. *To find the length of the whole circumference of the Ellipse.* Multiply the circumference of the circumscribing circle by the sum of the series

$$1 - \frac{d^2}{2^2} - \frac{3d^2}{2^2 \cdot 4^2} - \frac{8d^2}{2^2 \cdot 4^2 \cdot 6^2} - \frac{3d^2 \cdot 7d^4}{2^2 \cdot 4^2 \cdot 6^2 \cdot 8^2} \text{ &c, for the circumference; where } d \text{ is the difference between an unit and the square of the less axis divided by the square of the greater.}$$

See another series, p. 178, vol. 4, Edinb. Philos. Trans.

Or, for a near approximation, take the circumference of the circle whose diameter is an arithmetical mean between the two axes, or half their sum: that is, $\frac{1}{2}(t + c) \times 3'1416$ = the perimeter nearly; being about the 200th part too little; where t denotes the transverse, and c the conjugate axis.

Or, again, take the circumference of the circle, the square of whose diameter is half the sum of, or an arithmetical mean between, the squares of the two axes: that is, $\sqrt{\frac{1}{2}(t^2 + c^2)} \times 3'1416$ = the perimeter nearly; being about the 200th part too great.

Hence combining these two approximating rules together, the periphery of the ellipse will be very nearly equal to half their sum, or equal to $\frac{1}{2}[\frac{1}{2}(t + c) + \sqrt{\frac{1}{2}(t^2 + c^2)}] \times 3'1416$, within about the 3000th part of the truth.

For the length of any particular arc, and many other parts about the ellipse, see my Mensuration, pa. 212, &c, 4th edit. See also my Conic Sections, for many other properties of the ellipse, especially such as are common to the hyperbola also, or to the conic sections in general.

Infinite Ellipses. See ELLIPTOID.

ELLIPOSID, is an elliptical spheroid, being the solid generated by the revolution of an ellipse about either axis. See SPHEROID.

ELLIPTIC or ELLIPTICAL, something relating to an ellipse.

ELLIPTIC Compasses, or ELLIPTICAL Compass, is an instrument for describing ellipses at one revolution of the index. It consists of a cross ABGJ (fig. 8.) with grooves in it, and an index CE, sliding in dovetail grooves; by which motion the end E describes the curve of an ellipse.

ELLiptical Conoid, is sometimes used for the spheroid, or ellipsoid.

ELLiptical Dial, an instrument usually made of brass, with a joint to fold together, and the gnomon to fall flat, for the convenience of the pocket. By this instrument are found the meridian, the hour of the day, the rising and setting of the sun, &c.

ELLipticity, of the terrestrial spheroid, is the ratio, or the difference, between the two semiaxes. It is usually expressed in terms of the greater, or radius of the equator, that is, by what fractional part this exceeds the axis or polar diameter. The quantity of this ellipticity has been variously assigned by different mathematicians. Sir Isaac Newton, supposing the earth of uniform density, gave $\frac{1}{235}$ for the ellipticity; Boscowich, from a mean of several add-measurements, stated it at $\frac{1}{245}$; Lalande at $\frac{1}{237}$; Laplace, $\frac{1}{217}$; Sajour, $\frac{1}{215}$; Carouge, $\frac{1}{205}$; Kraft, $\frac{1}{207}$; and Playfair, from a theorem of Clairaut, applied to the heterogeneous spheroid, states it at $\frac{1}{212}$. Setting aside those which are deduced from the hypothesis of uniform density, $\frac{1}{235}$ may be admitted as the most probable value of the ellipticity. Under the article **EARTH**, see other proportions, and the manner of deducing them.

ELLIPTOID, an infinite or indefinite ellipse, defined by the indefinite equation $ay^m + n = bx^m(a - x)^n$, where m or n are greater than 1; for when they are each 1, it denotes the common ellipse. There are several kinds or degrees of elliptoids, which receive their denominations from the exponent $m + n$ of the ordinate y . As the cubical ellipsoid, expressed by $ay^3 = bx^2(a - x)$; the biquadratic, or sursolid $ay^4 = bx^2(a - x)^2$; &c.

ELONGATION, in Astronomy, the distance of a planet from the sun, with respect to the earth; or the angle formed by two lines drawn from the earth, the one to the sun, and the other to the planet; or the arc measuring that angle: or it is the difference between the sun's place and the geocentric place of the planet.

The greatest elongation, is the greatest distance to which the planets recede from the sun, on either side. This is chiefly considered in the inferior planets, Venus and Mercury; the greatest elongation of Venus being about $47\frac{1}{2}$ degrees, and of Mercury only about $27\frac{1}{2}$ degrees; which is the reason that this planet is so rarely seen, being usually lost in the sun's beams.

EMBER-Days, are certain days observed by the church at four different seasons of the year; viz, the wednesday, friday, and saturday next after Quadragesima sunday, or the 1st sunday in Lent; after Whit-sunday; after Holyrood, or Holycross, the 14th day of September; and after St. Lucy, the 13th day of December. The name, it seems, is derived from embers, or ashes, which it is supposed the primitive Christians strewed on their heads at these solemn fasts.

EMBER-Weeks, are those weeks in which the ember-days fall. These ember-weeks are now chiefly noticed on account of the ordination of priests and deacons; because the canon appoints the sundays next after the ember-weeks for the solemn times of ordination; though the bishops, if they please, may ordain on any sunday or holiday.

EMBOLIUM, and **EMBOLISMIC**, *Intercalary*, is chiefly used in speaking of the additional months inserted by chronologists to form the lunar cycle of 19 years. The 19 solar years, consist of 6939 days and 18 hours, and the 19 lunar years of only 6726 days, so that it was found necessary to intercalate or insert 7 lunar months, contain-

ing 209 days; which, with the 4 bissextile days happening in the lunar cycle, make 213 days, and the whole 6939 days, the same as the 19 solar years, which make the lunar cycle.

In the course of 19 years there are 228 common moons, and 7 embolismic moons, which are distributed in this manner, viz, the 3d, 6th, 9th, 11th, 14th, 17th, and 19th years, are embolismic, and so contain 384 days each. And this was the method of computing time among the Greeks; though they did not strictly observe it, as it seems the Jews did. And the method of the Greeks was followed by the Romans till the time of Julius Caesar. The embolismic months, like other lunar months, sometimes contain 30 days, and sometimes only 29 days.

The **Embolismic Epacts** are those between 19 and 29; which are so called, because, with the addition of the epact 11, they exceed the number 30: or rather, because the years which have these epacts, are embolismic; having 13 moons each, the 13th being the embolismic.

EMBOLISMUS, in Chronology, signifies intercalation. As the Greeks used the lunar year, which contains only 354 days; in order that they might bring it to the solar year, of 365 days, they had an embolism every two or three years, when they added a 13th lunar month.

EMBRASURE, in Architecture, an enlargement of the aperture or opening of a door, or window, within-side the wall, sloping back inwards, to give the greater play for the opening of the door, casement, &c, or to take in the more light.

EMBRASURES, in Fortification, are the apertures or holes through which the cannon are pointed, whether in cascades, batteries, or in the parapets of walls. In the navy, these are called port-holes. The embrasures are placed 12 or 15 feet apart from each other; being made sloping or opening outwards, from 6 to 9 feet wide on the outside of the wall, and from 2 to 3 within, to allow the gun to traverse from side to side. Their base is about $2\frac{1}{2}$ or 3 feet above the platform on the inside of the wall, but sloping down outwards, so as to be only about $1\frac{1}{2}$ above it on the outside; in order that the muzzle may be occasionally depressed, when it is necessary to point the gun in that direction.

EMERGENT Year, in Chronology, is the epoch, from which any people begin to compute their time or dates. So, our emergent year is sometimes the year of the creation, but more usually the year of the birth of Christ. The Jews used that of the Deluge, or the Exodus, &c. The emergent year of the Greeks, was the beginning of the Olympic games; while that of the Romans was the date of the Building of their City.

EMERSION, in Astronomy, is the re-appearance of the sun, moon, or other planet, after having been eclipsed, or hid by the interposition of the moon, earth, or other body.

The immersions and emersions of Jupiter's first satellite, are particularly useful for finding the longitudes of places; the immersions being observed from Jupiter's conjunction with the sun, till his opposition; and the emersions from the opposition till the conjunction. But within 15 days of the conjunction, both before and after it, they cannot be observed, the planet and his satellites being then lost in the sun's light.

EMERSION is also used when a star, after being hid by the sun, begins to re-appear, and emerges out of his rays.

Minutes or Scruples of EMERSION, an arc of the moon's orbit, which her centre passes over, from the time she

begins to emerge out of the earth's shadow, to the end of the eclipse.

EMERSION, in Physics, the rising of any solid above the surface of a fluid that is specifically heavier than the solid, into which it had been violently immersed, or pushed. It is one of the known laws of hydrostatics, that a lighter solid, being forced down into a heavier fluid, immediately endeavours to emerge; and that with a force equal to the excess of the weight of a quantity of the fluid above that of an equal bulk of the solid. Thus, if the body be immersed in a fluid of double its specific gravity, it will emerge again, till half its bulk be above the surface of the fluid.

EMERSON (WILLIAM), a late eminent mathematician, was born in June 1701, at Hurworth, a village about three miles south of Darlington, on the borders of the county of Durham; at least it is certain that he resided here from his childhood. His father Dudley Emerson was a schoolmaster, and a tolerable proficient in the mathematics; and without his books and instructions, probably his son's genius, though eminently fitted for mathematical studies, might never have been unfolded: but besides his father's instructions, our author was assisted in the learned languages by a young clergyman, then curate of Hurworth, who was boarded at his father's house. Being satisfied with a moderate competence left him by his parents, he devoted himself to a studious retirement, which he thus closely pursued, in the same place, through the course of a long life, being mostly very healthy, till towards the latter part of his days, when he was much afflicted with the stone. Towards the close of the year 1781, being sensible of his approaching dissolution, he disposed of the whole of his mathematical library to a bookseller at York; and on May the 20th, 1782, his lingering and painful disorder put an end to his life at his native village, being near 81 years of age.

Mr. Emerson, in his person, was rather short, but strong and well made, with an open countenance and ruddy complexion. He was of a singular turn in his behaviour, dress, and conversation; his manner and appearance being rather plain and uncouthly: he had strong natural mental parts, and could discourse sensibly on any subject, but was always positive and impatient of contradiction. He spent his whole life in close study, and writing books, from the profits of which, he redeemed his little patrimony from some original incumbrance. In his dress he was as singular as in every thing else. He possessed commonly but one suit of clothes at a time, and those very old in their appearance. He seldom used a waistcoat; and his coat he wore open before, except the lower button; and his shirt quite the reverse of one in common use, the hind side turned foremost, to cover his breast, -and buttoned close at the collar behind. He also had a kind of rusty-coloured wig, without a crooked hair in it, which probably had never been tortured with a comb from the time of its being made; and the hat he wore had served him the greater part of his life, of which he gradually lessened the flaps, bit by bit, as it lost its elasticity, till little or nothing but the crown remained.

He sometimes walked up to London when he had any book to be published, revising sheet by sheet himself:—for trusting no eye but his own, was always a favourite maxim with him. In mechanical subjects, he always tried the propositions practically, making all the different parts himself on a small scale; so that his house was filled with all kinds of mechanical instruments, together or disjointed,

He would frequently stand up to his middle in water while fishing; a diversion he was very fond of. He used to study incessantly for some time, and then for relaxation take a ramble to some pot-alehouse, where he could get any body to drink with and talk to. He was a married man, but without children; and his wife used to spin on an old-fashioned wheel, of his own making, a drawing of which is given in his Mechanics.

Mr. Emerson, from his strong vigorous mind and close application, had acquired a deep knowledge of all the branches of mathematics and physics, on every part of which he wrote good treatises, though in a rather antiquated style and manner. He was not remarkable, however, for genius or discoveries of his own, as his works show hardly any traces of original invention. He was well skilled in the science of music, the theory of sounds, and the various scales both ancient and modern; but he was a very poor performer, though he could make and repair some instruments, and sometimes went about the country tuning harpsichords, as well as cleaning clocks.

The following is a list of Mr. Emerson's works; all of them printed in 8vo, excepting his Mechanics and his Increments in 4to, and his Navigation in 12mo. 1. The Doctrine of Fluxions.—2. The Projection of the Sphere, orthographic, stereographic, and gnomonical.—3. The Elements of Trigonometry.—4. The Principles of Mechanics.—5. A Treatise of Navigation.—6. A Treatise on Arithmetic.—7. A Treatise on Geometry.—8. A Treatise of Algebra, in 2 books.—9. The Method of Increments.—10. Arithmetic of Infinites, and the Conic Sections, with other Curve Lines.—11. Elements of Optics and Perspective.—12. Astronomy.—13. Mechanics, with Centripetal and Centrifugal Forces.—14. Mathematical Principles of Geography, Navigation, and Dialling.—15. Commentary on the Principia, with the Defence of Newton.—16. Miscellanies.

Besides these, Mr. Emerson was a frequent mathematical correspondent in the Ladies' Diary, the Palladium, &c, in the fictitious names of Merones, Nichol Dixon, and other fanciful appellations. In the same works, sometimes a riddle or a question in rhyme, showed that he was not destitute of poetical talents.

EMINENTIAL Equation, a term used by some algebraists, in the investigation of the areas of curvilinear figures, for a kind of assumed equation that contains another equation eminently, the latter being a particular case of the former. Hayes's Flux. pa. 97.

ENCEINTE, a French term, in Fortification, signifying the whole inclosure, circumference, or compass, of a fortified place, whether built with stone or brick, or only made of earth, and whether with or without bastions, &c.

ENCYCLOPÆDIA, the circle or chain of arts and sciences; sometimes also written Cyclopædia.

Numerous are the encyclopedias, or general dictionaries that have been published; but our business is only with those which treat chiefly on the mathematical or philosophical sciences. The first dictionary of this kind, it appears, was that of Dasypodius, printed in 1573, under the title of *Aegeion*, seu Dictionarium mathematicarum, in quo definitiones et divisiones continentur scientiarum mathematicarum, arithmeticarum, &c, M. Courado Dasypodio authore; a very extraordinary work for the time of its publication, and of which a new edition was printed at Strasburg, in 1579.—In 1632 came out the work J. H. Alstedii Encyclopedia, in 2 vols. folio: an elaborate performance;

which was followed in 1657, by Erhardi Wegalii *Idea Encyclopaedie Mathematico-philosophicae*; a work not superlatively interesting, even for that period. Of a similar kind is the *Lexicon Math. Astron. Geomet.* of Vatalis, printed at Paris in 1668, 8vo; as also the *Dictionnaire Mathematique* of Ozanam, printed in 1 vol. 4to, 1691.

As to the works of Ger. J. Vossius (1650), and of Beughem (1694), they are little more than catalogues of mathematical books.

The next important step was made by Dr. Harris, in his *Lexicon Technicum*, published, the 1st vol. in 1704, the 2d in 1710. This is the earliest English work that assumes to good purpose the systematic form of a general dictionary, and attempts to allot to each article its comparative portion in the scale of science. The author possessed very considerable general knowledge; but his attainments as a mathematician and philosopher were most conspicuous. To the 5th edit. in 1736, a supplement was added by the booksellers, but of minor importance.—Various dictionaries, comprising more or less of scientific materials, were published between the times of Harris's *Lexicon* and Chambers's *Cyclopaedia*; such, for instance, as the Great Dictionary of the French Academy, the Dictionary of the Jesuits of Trevoux, the Chemical Dictionary of Johnson, the Medical ones of Blanchard and Castellas, the Mathematical Dictionaries of Stone and Wolfus, the Sea Dictionary of Mainwaring, the Dictionary of the Bible by Calmet, the *Lexicon Philosophicum* of Chauvin, a work of importance, especially in the mathematics and philosophy of the ancients; the *Lexicon* of J. Burkard Monkens, in, 1715; Jablonski's *Lexicon* in 1721; and Collier's great Historical Dictionary, begun in 1694, and finished in 1727.

The first edition of Chambers's *Cyclopaedia* came out in 1727, 2 vols. folio; of which the public demand occasioned a 2d edit. in 1738, a 3d in 1739, a 4th in 1741, and a 5th in 1746. This unprecedented success induced the proprietors, at a great expense, to engage G. L. Scott and Dr. Hill to prepare a Supplement to the 6th edition, which was accordingly published in 2 additional volumes. The 7th edition, completed in 1780 in four thick folio volumes, removed the disadvantage of the double alphabets, by incorporating them into one, by the labour and skill of that able editor Dr. Abr. Rees.

From this period, dictionaries devoted to arts and sciences, as well as general dictionaries, increased very rapidly, both in number and importance; of which a few of the chief may be noticed: as, the Medical Dictionaries of Metherby, Quincy, James, Turton, and the Edinburgh Dictionary; the Chemical Dictionaries of Macquer, Nicholson, and the Aikins; the Dictionaries of Gusseau and Rasches, on Numismatology; those of Miller, Martyn, and Dickson, on Gardening; those of Burn, Cunningham, and Jacob, on Law; the Marine Dictionaries of Chapman and Falconer; the Builder's Magazine, and Felibien's Dictionary of Architecture; Jombert's *Dictionnaire de l'Engeneur et de l'Artilleur*, and James's Military Dictionary; Pilkington's Dictionary of Painters; Mortimer's and Postlethwaite's Dictionaries of Trade and Commerce; Rousseau's, Hoyles', and Busby's Dictionaries of Music; our own Mathematical and Philosophical Dictionary; and the *Dictionnaire de Physique* of M. Libes. The diligence exerted by the authors of these, and a few other dictionaries appropriated to separate branches of science, and by the editors of encyclopedias, has operated reciprocally to improve both; and hence it has happened, that many of such dic-

tionaries, during the last 50 years, have greatly contributed to the improvement and diffusion of human knowledge.

The labours of the continental encyclopædist, during this period, are also of much importance. Among the works of the Germans may be noticed, the *Universal Lexicon* of Ludwig, in 1732—1750, in 64 volumes; *Oekonomische Encyclopädie*, by Krünitz, in 1773; the *Encyclopädie der Historischen, Philosophischen, und Mathematischen Wissenschaften*, by Büsch, in 1775 and 1795; Klügel's *Encyclopädie aller Mathematischen Wissenschaften ihre Geschichte und Litteratur*, by Rosenthal, in 1790. To these may be added, the Swedish *Encyclopædia*, by Giornell, in 1785; and the *Encyclopedie Italiana ovvero Biblioteca universale della umane cognizioni*, at Naples in 1788.

Our neighbours the French also have the *Dictionnaire universel de Mathématique et de Physique*, by M. Savérien, in 1753; the *Encyclopédie, ou Dictionnaire raisonné des Sciences, des Arts, et des Métiers*, by Diderot, Dalembert, &c, in 1754—1757; the *Dictionnaire Portatif*, in 1760; the *Dictionnaire de Physique Portatif*, in 1763; the new edition of the *Encyclopédie*, by Diderot, &c, in 39 vols. in 1778, 1779; and the *Encyclopédie Méthodique*, by Dalembert, Bossut, Condorcet, Lalande, &c, which commenced in 1785, and consists of separate alphabets, or dictionaries, for the several arts and sciences.

We must now glance rapidly at the labours of British encyclopædist since the time of Chambers; passing over the productions of Owen, Procter, Castiean, Hall, Howard, and Kendal, with a mere notice of their names; the only one of which that we do not feel desirous to forget is Owen. We must however mention, with commendation, the *Dictionary of Arts and Sciences*, published in 1766, by Crowder, in 3 vols. 4to; the editors of which were, the Rev. J. Scott, Trinity-college, Cambridge; Mr. Chas. Green, assistant at the royal observatory; Mr. J. Meades; and Mr. Falconer, the unfortunate author of the *Shipwreck*.

The work last mentioned, though respectable, is far inferior to Chambers, who has however now had some formidable rivals in Britain; viz. the *Encyclopædia Britannica*, published in Edinburgh, first we believe in 1768, in 4 vols. 4to, and afterwards in 10 vols. This work seems also to have been the first that attempted the innovation of incorporating systems or treatises, along with the usual articles in the alphabetical arrangement. The 3d edition of this *Encyclopædia*, superintended by Dr. Gleig, was finished in 1800; the whole with a supplement, making 20 large volumes. It contains, besides the general matters treated in Chambers's work, the additional subjects of biography, history, and geography. It is a work, in many respects, of considerable excellence: it commonly explains the principles and practices, in the various arts and sciences, with great correctness and perspicuity. Many of the treatises it contains, were drawn up by some of the most eminent Scotch professors, which do them great credit.—The English *Encyclopædia* was completed in 10 vols. 4to, in 1803. The names of its conductors are not mentioned; but they are commonly understood to have been Dr. Aikin and Mr. Houlston. Its general plan is much like that of the *Encyclopædia Britannica*, but much less imbued with original masterly compositions.

Such is the general diffusion of knowledge in this country, and so prevalent is the desire to possess a library as it were in one work, that besides two general dictionaries

just finished, no less than six others are now in course of publication, viz, The Encyclopædia Londinensis; a new edition of the Encyclopædia Perthesii; Brewster's Edinburgh Encyclopædia; the Pantologia, or New Cyclopædia, by Mr. Good, Dr. O. Gregory, and Mr. Bosworth, including all English words, besides all sciences and human knowledge, to be comprised in 10 or 12 volumes; also a new edition of the Encyclopædia Britannica, and Dr. Rees's New Cyclopædia, both to be extended to several more volumes.

ENDECAGON, a plane geometrical figure of eleven sides and angles, otherwise called undecagon. If each side of this figure be 1, its area will be $9\cdot3656399 = \frac{1}{2}$ of the tang, of $73\frac{3}{4}$ degrees, to the radius 1. See my Mensuration, pa. 85, &c, 4th edit. See also *REGULAR Figure*.

ENFILADE, a French term in Fortification, applied to those trenches, and other lines, that are ranged in a right line, and so may be scoured or swept by the cannon lengthways, or in the direction of the line.

To ENFILADE, is to sweep lengthways by the firing of cannon, &c.

A *Battery d'ENFILADE*, is that where the cannon sweep a right line.

A *Post*, or *Command d'ENFILADE*, is a height from which a whole line may be swept at once.

ENGINE, in Mechanics, a compound machine, consisting of several simple ones, as wheels, screws, levers, or the like, combined together, in order to lift, cast, or sustain a weight, or produce some other considerable effect, so as to save either force or time. There are numberless kinds of engines; of which some are for war, as the Balista, Catapulta, Scorpion, Aries or Ram, &c; others for the arts of peace, as mills, cranes, presses, clocks, watches, &c, &c.

ENGINEER is applied to a contriver or maker of any kind of useful engines or machines; or who is particularly skilled or employed in them. And he is denominated either a civil or military engineer, according as the objects of his profession respect civil or military purposes.

A military engineer should be an expert mathematician and draughtsman, and particularly versed in fortification and gunnery, being the person officially employed to direct the operations both for attacking and defending works. When at a siege the engineers have narrowly surveyed the place, they are to make their report to the general, or commander, by acquainting him which part they judge the weakest, and where approaches may be made with most success. It is their business also to draw the lines of circumvallation and contravallation; also to mark out the trenches, places of arms, batteries, and lodgments, and in general to direct the workmen in all such operations.

ENHARMONIC, the last of the three kinds of music. It abounds in dieses, or the least sensible divisions of a tone. See Philos. Trans. No. 481; also Wallis's Appendix to Ptolem. pa. 165, 166.

ENNEADECATERIS, in Chronology, a cycle or period of 19 solar years, being the same as the golden number and lunar cycle, or cycle of the moon; which see; as also *EMBOLISMIC*.

ENNEAGON, a plane geometrical figure of 9 sides and angles; and is otherwise called a nonagon. If each side of this figure be 1, its area will be $6\cdot1818242 = \frac{1}{2}$ of the tang, of 70 degrees, to the radius 1. See my Mensuration, pa. 85, 4th edit. See also the article *REGULAR Figure*.

ENTABLATURE, in Architecture, is that part of the

order of a column which is over the capital, comprehending the architrave, frieze, and cornice.

ENTABLATURE, or ENTABLEMENT, is sometimes also used for the last row of stones on the top of the wall of a building, on which the timber and covering rest; sometimes also called the drip, because it projects a little, to throw the water off.

ENVELOPE, in Fortification, is a mound of earth, sometimes raised in the ditch of a place, and sometimes beyond it, being either in form of a single parapet, or of a small parapet bordered with a parapet. These envelopes are made only to cover weak parts with single lines, without advancing towards the field, which cannot be done without works that require a great deal of room, such as horn-works, half-moons, &c. Envelopes are sometimes called Sillons, Contregards, Conserves, Lunettes, &c.

ENUMERATION, numbering or counting. Sir Isaac Newton wrote a very ingenious treatise on the enumeration of the lines of the 3d order.

EOLIPILE. See *ÆOLIPILE*.

EPACT, in Chronology, the excess of the solar month above the lunar synodical month; or of the solar year above the lunar year of 12 synodical months; or of several solar months above as many synodical months; or of several solar years above as many periods each consisting of 12 synodical months.

The epacts therefore are either annual or menstrual.

Menstrual Epacts, are the excesses of the civil calendar month above the lunar month. Suppose, for example, it were new moon on the 1st day of January: then since the month of January contains 31 days, And the lunar month - - 29^a 12^b 44^c 3^d; The menstrual epact is - - 1 11 15 57

Annual Epacts, are the excesses of the solar year above the lunar. Hence,

As the Julian solar year is - 365^a 6^b 0^c 0^d, And the Julian lunar year - 354 8 48 38,

The annual epact will be - 10 21 11 22, that is, almost 11 days. Consequently the epact of 2 years, is 22 days; of 3 years, 33 days; or rather 3, since 30 days make an embolismic, or intercalary month; therefore, adding still 11, the epact of 4 years is 14 days; and so of the rest as in the following table, where it may be observed, that they do not become 30, or 0 again, till the 19th year; so that at the 20th year the epact is 11 again; and hence the cycle of epacts expires with the golden number, or lunar cycle of 19 years, and begins with the same again.

Table of Julian Epacts.

Golden Numb.	Epacts.	Golden Numb.	Epacts.	Golden Numb.	Epacts.
I	11	VIII	28	XV	15
II	22	IX	9	XVI	26
III	3	X	20	XVII	8
IV	14	XI	1	XVIII	19
V	25	XII	12	XIX	30
VI	6	XIII	23		or 0
VII	17	XIV	4		

Again, as the new moons are the same, or fall on the same day, every 19 years, so the difference between the solar and lunar years is the same every 19 years. And because the said difference is always to be added to the lunar year, to adjust or make it equal to the solar year; therefore the said difference respectively belonging to each year

of the moon's cycle, is called the epact of the said year, that is, the number to be added to the said year, to make it equal to the solar year; and upon this mutual relation between the cycle of the moon and the cycle of the epacts, is founded this.

Rule for finding the Julian Epact, belonging to any year of the Moon's Cycle.—Multiply the golden number, or the given year of the moon's cycle, by 11, and the product will be the epact, if it be less than 30; but if it exceed 30, then reject as many 30's as the product contains, and the remainder will be the epact.

Rule to find the Gregorian Epact.—1st, The difference between the Julian and Gregorian years being equal to the difference between the solar and lunar year, or 11 days, therefore the Gregorian epact for any year is the same with the Julian epact for the preceding year; and hence the Gregorian epact will be found, by subtracting 1 from the golden number, multiplying the remainder by 11, and rejecting the 30's; which rule will serve till the year 1900; but after that year, the Gregorian epact will be found by this rule: Divide the centuries of the given year by 4; multiply the remainder by 17; and to this product add 43 times the quotient, as also the number 86, and divide the whole sum by 25, reserving the quotient: next multiply the golden number by 11, and from the product subtract the reserved quotient; so shall the remainder, after rejecting all the 30's contained in it, be the epact sought.

The following table contains the golden numbers, with their corresponding epacts, till the year 1900.

Table of Gregorian Epacts.

Golden Numb.	Epacts.	Golden Numb.	Epacts.	Golden Numb.	Epacts.
I	0	VIII	17	XV	4
II	11	IX	28	XVI	15
III	22	X	9	XVII	26
IV	3	XI	20	XVIII	7
V	14	XII	1	XIX	18
VI	25	XIII	12	I	0
VII	6	XIV	23		

On the subject of epacts, see Wolfsius's *Elementa Chronologica*; apud Opera, tom. 4, pa. 133; also Philos. Trans. vol. 46, pa. 417, or No. 495, art. 5.

EPAULE, or ESPAULE, in Fortification, the shoulder of the bastion, or the angle made by the face and flank, otherwise called the angle of the epaule.

EPAULEMENT, in Fortification, a side-work hastily raised, to cover the cannon or the men; and is made either of earth thrown up, or bags filled with earth or sand, or of gabions, or fascines, &c.; of which latter sort are commonly constructed the epaulements of the places of arms for the cavalry behind the trenches.

EPAULEMENT, is also used for a demi-bastion, consisting of a face and flank, placed at the point of a horn-work or crown-work: and a little flank added to the sides of horn-works, to defend them when they are too long: also for the redoubts made on a right line, to fortify it. And lastly, for an orillon, or mass of earth almost square, faced and lined with a wall, and designed to cover the cannon of a casemate.

EPHEMERIS, EPHEMERIDES, tables calculated by astronomers, showing the present state of the heavens for every day at noon; that is, the places in which all the planets are found at that time; differing but little from an

astronomical almanac. It is from such tables as these that the eclipses, conjunctions, and aspects of the planets are computed; as also horoscopes, or celestial schemes, constructed, &c.

The following list of authors of published ephemerides has been chiefly collected from Weidler's History of Astronomy, in 4to. 7 + 1.

Regiomontanus, from 1475 to 1506	Beaulieu	from 1703 to 1714
Angelas	Manfredi	1715 — 1725

— 1701 — 1702	Maskelyne	—

There are now published such ephemerides by the Academies of several other nations; but that which is in most esteem for its accuracy and use in finding the longitude, is the Nautical Almanac, or Astronomical Ephemeris, published in England by the Board of Longitude, under the direction of the astronomer royal, which commenced with the year 1767, by Dr. Maskelyne; besides many other smaller annual ephemerides, by White, Partridge, Parker, and many more.

EPICHARMUS, an ancient poet and philosopher, born in Sicily, was a scholar of Pythagoras, and flourished in the time of Hiero, in whose reign it is said he introduced comedy at Syracuse. He also wrote treatises on philosophy and medicine; but none of his works have been preserved. He died at 90 years of age, according to Laertius, who has preserved four verses inscribed on his statue.

EPICURUS, a celebrated ancient philosopher, was born at Gargettium in Attica, in the 109th Olympiad, or about 340 years before Christ. He settled at Athens in a fine garden he had bought; where he lived with his friends in much tranquillity, and educated a great number of disciples; who lived all in common with their master. His school was never divided, but his doctrine was followed as an oracle; and the respect which his disciples paid to his memory is admirable; his birth-day being kept even in Pliny's time, and the month he was born in was observed as a continued festival; his picture was also displayed in numberless places. He wrote a great many books, and valued himself upon making no quotations. He raised the atomical system to great reputation, though he

was not the inventor of it, but only made some change in that of Democritus. As to his doctrine concerning the supreme good or happiness, it was very liable to be misrepresented, and some ill effects proceeded from thence, which discredited his sect, though undeservedly. He was charged with perverting the worship of the gods, and inciting men to debauchery. But he did not forget himself on this occasion : he published his opinions to the whole world; wrote some books of devotion; recommended the veneration of the gods, sobriety, and chastity, living in an exemplary manner, and conformably to the rules of philosophical wisdom and frugality. Gassendus has given us all that he could collect from the ancients concerning the person and doctrine of this philosopher; by whom we are informed that he died of a suppression of urine, at the age of 72 years.

EPICUREAN Philosophy, the doctrine, or system of philosophy, maintained by Epicurus and his followers; which consisted of three parts; canonical, physical, and ethical. The first respected the canons or rules of judging; in which soundness and simplicity of sense, assisted by some natural reflections, chiefly formed his art. His search after truth proceeded only by the senses; to the evidence of which he gave so great a certainty, that he considered them as an infallible rule of truth, and termed them the first natural light of mankind. In the 2d part of his philosophy he laid down atoms, space, and gravity, as the first principles of all things. He asserted the existence of a God, whom he accounted a blessed immortal being, but who did not concern himself with human affairs.

As to his ethics, he made the supreme good of man to consist in pleasure, and consequently supreme evil in pain. Nature itself, says he, teaches us this truth; and prompts us from our birth to procure whatever gives us pleasure, and to avoid that which gives us pain. To this end he proposes a remedy against the sharpness of pain, which is to divert the mind from it, by turning our whole attention upon the pleasures we have formerly enjoyed. He held that the wise man must be happy, as long as he is wise: pain, by not depriving him of his wisdom, cannot deprive him of his happiness: from which it would seem that his pleasure consisted rather in intellectual than in sensual enjoyments: though this is a point strongly contested: probably in both.

EPICUREANS, the sect of philosophers holding or following the principles and doctrine of Epicurus. As the nature of the pleasure, in which the chief happiness of man is supposed to be seated, is a great problem in the morals of Epicurus, there hence arise two kinds of Epicureans, the rigid and the remiss: the first were those who understood Epicurus's notion of pleasure in the best sense, and placed all their happiness in the pure pleasures of the mind, arising from the practice of virtue: while the loose or remiss Epicureans, taking the words of that philosopher in a gross sense, placed all their happiness in bodily pleasures or debauchery.

EPICYCLE, in the ancient Astronomy, a little circle having its centre in the circumference of a greater one: or a small orb or spiere, which being fixed in the deferent of a planet, is carried along with it, and yet, by its own peculiar motion, carries the planet fastened to it round its proper centre.—It was by means of epicycles that Ptolemy and his followers solved the various phenomena of the planets, but more especially their stations and retrogradations.

EPICYCLOID, is a curve generated by the revolution of a point of the periphery of a circle, which rolls along or upon the circumference of another circle, either on the convex or concave side of it. When a circle rolls along a straight line, a point in its circumference describes the curve called a cycloid. But if, instead of the right line, the circle roll along the circumference of another circle, either equal to the former or not, then the curve described by any point in its circumference is what is called the epicycloid.

If the generating circle roll along the convexity of the circumference, the curve is called an upper, or exterior epicycloid; but if along the concavity, it is called a lower, or interior epicycloid. Also the circle that revolves is called the generant; and the arc of that circle along which it revolves, is called the base of the epicycloid.

Fig. 1.

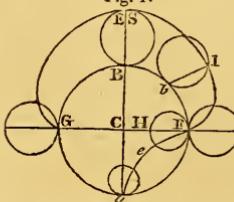

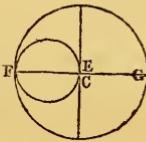

Fig. 2.

Thus, in the above figure, $GEIF$ is the exterior epicycloid, and ges the interior epicycloid, to the former of which EB is the generant, and geB the base, and to the latter the circle II is the generant, having the arc gf for its base.

The honour of the invention of this curve is due to M. Roemer, a celebrated Danish astronomer, who did not treat of it as a purely geometrical speculation; but as one of great utility, being, as he thought, the form which ought to be given to the teeth of wheels, in machinery, in order to diminish the friction of them against each other, and to render the action of the powers more equal. This idea occurred to M. Roemer while he was in Paris about the year 1674, notwithstanding M. Lahire, in 1694, published a work upon this subject, and seems to lay claim to the invention; but he was justly confuted by Leibnitz, who was in Paris during the visit of the Danish mathematician Roemer, and knew both of the invention and its application to mechanical purposes. Sir Isaac Newton and John Bernoulli have each considered the nature and properties of this curve, which are both numerous and interesting; but our limits will only admit the insertion of some of those which are more particularly deserving of attention. It is a remarkable property of circular epicycloids, that they are sometimes geometrical, though the common cycloid, which is much more simple in appearance, as a right is more simple than a curve, is always mechanical, or transcendental. The cases where the epicycloid is geometrical, are those in which there is a numerical ratio between the circumferences of the circle which forms the base, and the generant; for where there is no rational ratio between them, the curve becomes mechanical.

It is also a remarkable property of epicycloids, whether they be geometrical or transcendental, that they are always rectifiable, at least in the case where the describing point is taken in the circumference of the generating

circle. Thus, the curve of the epicycloid GEF , is to 4 times the diameter of the generating circle BE , as the sum of the diameters of the two circles, is to that of the base. But if the epicycloid is inferior, as EG , then instead of the sum of the diameters we must take their difference.

It may also be observed, as a curious circumstance, that when the diameter of the generant is equal to half that of the circle forming the base, as in fig. 2; then the epicycloid degenerates into a right line, describing the diameter of the latter circle. We may also further remark, that when the describing point is taken either within or without the generant, the length of the epicycloid is equal to the circumference of an ellipse, which is easily constructed."

As to the areas of epicycloids, they are determined from the following proportion. As the radius of the circle forming the base, is to 3 times that radius plus twice that of the generant; so is the circular segment bi , to the epicycloidal space bif ; or, so is the whole area of the generant, to the entire area of the epicycloid $FEGB$.

Dr. Halley has also given a general proposition for the measuring of all cycloids and epicycloids: which is this, the area of a cycloid, or epicycloid, either primary, or contracted, or prolate, is to the area of the generating circle; and also the areas of the parts generated in those curves, to the areas of analogous segments of the circle; as the sum of double the velocity of the centre and the velocity of the circular motion, is to this velocity of the circular motion. See the Demonstr. in the Philos. Trans. No. 218, or my Abridg. vol. 4. pa. 47.

Spherical Epicycloids are formed by a point of the revolving circle, when its plane makes a constant angle with the plane of the circle on which it revolves. Messrs. Bernoulli, Maupertuis, Nicole, and Clairaut, have demonstrated several properties of these epicycloids, in Hist. Acad. Sci. for 1732.

EPICYCLOIDS. *Parabolic, Elliptic, &c.*

If a parabola roll upon another equal to it; its focus will describe a right line perpendicular to the axis of the quiescent parabola: also the vertex of the rolling parabola will describe the cissoid of Diocles; and any other point of it will describe some one of Newton's defective hyperolas, having a double point in the like point of the quiescent parabola.

In like manner, if an ellipse revolve upon another ellipse, equal and similar to it, its focus will describe a circle, whose centre is in the other focus, and consequently the radius is equal to the axis of the ellipsis; and any other point in the plane of the ellipse will describe a line of the 4th order.

The same may be said also of an hyperola, revolving upon another, equal and similar to it; for one of the foci will describe a circle, having its centre in the other focus, and the radius will be the principal axis of the hyperola;

and any other point of the hyperola will describe a line of the 4th order.

Concerning these lines, see Newton's Principia, lib. 1; also Lahire's Mémoires de Mathématique &c, where he shows the nature of this line, and its use in mechanics; see also Maclaurin's Geometria Organica; the Philos. Trans. No. 217, pa. 113; and No. 218, pa. 125.

EPIPHANY, a Christian festival, otherwise called the Manifestation of Christ to the Gentiles, observed on the 6th of January, in honour of the appearance of Christ to the three magi or wise men, who came to adore him and bring him presents.

EPISTYLE, in the ancient Architecture, a term used by the Greeks for what we call the architrave, viz, a massive stone, or a piece of wood, laid immediately over the capital of a column.

EPOCH, or *EPOCHA*, a term or fixed point of time, whence the succeeding years are numbered or reckoned. Different nations make use of different epochs. The Christians chiefly use the epoch of the nativity or incarnation of Jesus Christ; the Mahometans, that of the Hegira; the Jews, that of the Creation of the World, or that of the Deluge; the ancient Greeks, that of the Olympiads; the Romans, that of the Building of their City; the ancient Persians and Assyrians, that of Nabonassar; &c.

The doctrine and use of epochs is of very great extent in chronology. To reduce the years of one epoch to those of another, i. e. to find what year of one corresponds to a given year of another; a period of years has been invented, which, commencing before all the known epochs, is, as it were, a common receptacle of them all, called the Julian Period. To this period all the epochs are reduced; that is, the year of this period when each epoch commences, is so determined; that, adding the given year of one epoch to the year of the period corresponding with its rise, and from the sum subtracting the year of the same period corresponding to the other epoch, the remainder is the year of the required epoch.

EPOCH of Christ, is the common epoch throughout Europe, commencing at the supposed time of his nativity, December 25; or rather, according to the usual account, from his circumcision, or the 1st of January. The author of this epoch was an abbot of Rome, one Dionysius Exiguus, a Scythian, about the year 507 or 527. Dionysius began his account from the conception or incarnation, usually called the Annunciation, or Lady-Day; which method obtained in the dominions of Great Britain till the year 1752, before which time the Dionysian was the same as the English epoch: but in that year the Gregorian calendar having been admitted by act of parliament, they now reckon from the first of January, as in the other parts of Europe, except in the court of Rome, where the epoch of the Incarnation still obtains for the date of their bulls.

A TABLE of the Years of the most remarkable Epochs or Eras and Events.

N. B. The years before Christ, are those before the reputed year of his birth, and not reckoned back from the first year of his age, as is generally done in such tables.	Julian Period.	Year of the World.	Years before Christ.
The Creation of the World	706	0	4007
The Deluge, or Noah's flood	2362	1656	2351
Assyrian monarchy founded by Nimrod	2537	1831	2167
The birth of Abraham	2714	2008	1999
Kingdom of Athens founded by Cecrops	3157	2451	1556
Entrance of the Israelites into Canaan	3262	2556	1451
The destruction of Troy	3529	2823	1184
Solomon's temple founded	3701	2995	1012
The Argonautic expedition	3776	3070	937
Lycurgus formed his laws	3829	3103	884
Arbaces, first king of the Medes	3888	3132	875
Olympiads of the Greeks began	3938	3232	775
Rome built, or Roman Era	3961	3255	752
Era of Nabonassar	3967	3261	746
First Babylonish captivity, by Nebuchadnezzar	4107	3401	606
The 2d ditto, and birth of Cyrus	4114	3408	599
Solomon's temple destroyed	4125	3419	588
Cyrus began to reign in Babylon	4177	3471	536
Peloponnesian war begun	4282	3576	431
Alexander the Great died	4390	3684	323
Captivity of 100,000 Jews by Ptolemy	4393	3687	320
Archimedes killed at Syracuse	4506	3800	207
Julius Cesar invaded Britain	4659	3953	54
He corrected the calendar	4667	3961	46
The true year of Christ's birth	4709	4003	4
Years since Christ.			
Dionysian, or vulgar era of Christ's birth	4717	4007	0
Christ crucified, Friday April 3d	4746	4040	33
Jerusalem destroyed	4783	4077	70
Adrian's wall built in Britain	4833	4127	120
Dioclesian Epoch, or that of Martyrs	4997	4291	284
The council of Nice	5038	4332	325
Constantine the Great died	5050	4344	337
The Saxons invited into Britain	5158	4452	445
Hegira, or flight of Mohammed	5335	4629	622
Death of Mohammed	5343	4637	630
The Persian Yesdegird	5344	4638	631
Sun, Moon, and Planets \textcircled{b} , $\textcircled{4}$, $\textcircled{3}$, $\textcircled{2}$, $\textcircled{8}$, $\textcircled{5}$ in Δ , seen from the earth	5899	5193	1186
Art of printing discovered	6153	5447	1440
The Reformation begun by Martin Luther	6230	5524	1517
The Calendar corrected by Pope Gregory	6295	5589	1582
Oliver Cromwell died	6371	5665	1658
Sir Isaac Newton born, Dec. 25	6355	5649	1642
Made President of the Royal Society.	6416	5710	1703
Died, March 20th	6440	5734	1727
New Planet discovered by Herschel	6494	5788	1781

EPROUVENTTE, in *Gunnery*, is a machine for showing the strength or quality of gunpowder. Eprouvettes have been made of various kinds and shapes. The best is that described in my Tracts, vol. 3, pa. 153.

EQUABLE Motion, Celerity, Velocity, &c, is that which is uniform, or without alteration, or by which equal spaces are passed over in equal times. Hence, the spaces, passed over in equable motions, are proportional to the times. So that if a body pass over 20 feet in 1 second of time, it will pass over 40 feet in 2 seconds, and so on.

EQUABLY Accelerated or Retarded, &c, is when the mo-

tion or change is increased or decreased by equal quantities or degrees in equal times.

EQUAL, a term of relation between different things, but of the same kind, magnitude, quantity, or quality.—Wolffius defines equals to be those things that may be substituted for each other, without any alteration of their quantity.—It is an axiom in mathematics &c, that two things which are equal to the same thing, are also equal to each other. And if equals be equally altered, by equal addition, subtraction, multiplication, division, &c, the results will be also equal.

EQUAL Circles, are those whose diameters are equal.

EQUAL Angles, are those whose sides are equally inclined, or which are measured by similar arcs of circles.

EQUAL Lines, are lines of the same length.

EQUAL Plane Figures, are those whose areas are equal; whether the figures be of the same form or not.

EQUAL Solids, are such as are of the same space, capacity, or solid content; whether they be of the same kind or not.

EQUAL Curvatures, are such as have the same or equal radii of curvature.

EQUAL Ratios, are those whose terms are in the same proportion.

EQUAL, in Optics, is said of things that are seen under equal angles.

EQUALITY, the exact agreement of two things in respect to their quantity. Those figures are equal which may occupy the same space, or may be conceived to possess the same space, by the flexion or transposition of their parts. See a learned discourse upon this subject, by Dr. Barrow, in his 11th and 12th Mathematical Lectures.

EQUALITY, in Algebra, the relation or comparison between two quantities that are really or effectually equal. See **EQUATION**.—Equality, in Algebra, is usually denoted by two equal parallel lines, as $=$: thus $2 + 3 = 5$, i. e. 2 plus 3, are equal to 5. This character $=$ was first introduced by Robert Recorde. Descartes, and some others after him, use the mark α instead of it: as $2 + 3 \alpha 5$.

EQUALITY, in Astronomy. *Circle of EQUALITY*, or the **EQUANT**. See **CIRCLE**, and **EQUANT**.

Ratio or Proportion of EQUALITY, is that between two equal numbers or quantities.

Proportion of EQUALITY evenly ranged, or *ex aequo ordinata*, is that in which two terms, in a rank or series, are proportional to as many terms in another series, compared to each other in the same order, i. e. the first of one rank to the first of another, the 2d to the 2d, &c.

Proportion of EQUALITY evenly disturbed, called also *ex aequo perturbata*, is that in which more than two terms of one rank, are proportional to as many terms of another, compared to each other in a different and interrupted order; viz, the 1st of one rank to the 2d of another, the 2d to the 3d, &c.

EQUANT, or *ÆQUANT*, in Astronomy, a circle formerly conceived by astronomers, in the plane of the deferent, or excentric; for regulating and adjusting certain motions of the planets, and reducing them more easily to a calculus: but in the modern astronomy they are not used.

'**EQUATED Anomaly**'. See **ANOMALY**.

EQUATED Bodies. On Gunter's Sector are sometimes placed two lines, answering to one another, and called the lines of equated bodies; being situated between the lines of superficies and solids, and are marked with the letters *D*, *I*, *C*, *S*, *O*, *T*, to signify dodecahedron, icosahedron, cube, sphere, octahedron, and tetrahedron.

The uses of these lines are, 1st, When the diameter of the sphere is given, to find the sides of the five regular bodies, each equal to that sphere; 2d, From the side of any one of those bodies being given, to find the diameter of the sphere, and the sides of the other bodies, which shall be each equal to the first given body. So that when the sphere is given, take its diameter, and apply it on the sector in the points *s*, *s*; but when one of the other five bodies is given, apply its side over in its proper points;

then the parallels taken from between the points of the other bodies, or sphere, will be the sides or diameter, equal severally to the sphere or body first given.

EQUATION, in Algebra, an expression of equality between two different quantities; or two quantities, whether simple or compound, with the mark of equality between them: as $2 + 3 = 7 - 2$; or $2 \times 3 = 6$; or $5 \times 3 = 30 \div 2$; or $a + b = c$; or $x^2 + ax = b$; &c. When the two sides of the equation are the same, the expression becomes an identity, as $5 = 5$, or $a = a$, &c. Sometimes the quantities are placed all on one side, and made equal to 0, or nothing, on the other side; as $5 - 5 = 0$, or $a - b = 0$: which is no more than setting down the difference of two equal quantities equal to nothing.—The character or sign usually employed to denote an equation, is $=$, which is placed between the two equal quantities, called the two sides of the equation.

The **Terms** of an **EQUATION**, are the several quantities or parts of which it is composed. Thus, of the equation $a + b = c$, the terms are a , b , and c : and the tenor or import of the expression is, that some quantity represented by c , is equal to two others represented by a and b .

Equations are either simple or affected or compound.

A **Simple EQUATION** is that which has only one power of the unknown quantity: as $a + x = 3b$, or $ax^2 = bc$, or $a^2 + 2x^2 = 5b$, &c; where x denotes the unknown quantity, and the other letters known ones.

An **Affected**, or **Adfected**, or **Compound EQUATION**, contains two or more different powers: as $x^2 + ax = b$, or $x^3 - 4x^2 + 3x = 25$, &c.

Again, equations are denominated from the highest power contained in them; as quadratic, cubic, biquadratic, &c. Thus,

A **Quadratic EQUATION**, is that in which the unknown quantity rises to two dimensions, or to the square or 2d power: as $x^2 + 20x = 200$, or $x^2 - ax = b$.

A **Cubic EQUATION**, is that in which the unknown quantity is of three dimensions, or rises to the 3d power: as $x^3 = 25$, or $x^3 - 2x^2 = 27$, or $x^3 - ax^2 + bx = c$.

A **Biquadratic EQUATION**, is that in which the unknown quantity is of 4 dimensions, or rises to the 4th or biquadratic power: as $x^4 = 25$, or $x^4 - 20x = 10$, or $x^4 + ax^3 + bx^2 + cx = d$.

And so on for other higher orders of equations.

The **Root** of an **EQUATION**, is the value of the unknown letter or quantity contained in it. And this value being substituted in the terms of the equation instead of that letter or quantity, will cause both sides to vanish, or will make the one side exactly equal to the other. So the root of the equation $3x + 18 = 24$, is 2; for by using 2 for x , it becomes $3 \times 2 + 18 = 6 + 18 = 24$.

Every equation has as many roots as it has dimensions, or as it contains units in the index of the highest power, when the powers are all reduced to integral exponents. So the simple equation of the 1st power, has only one root; but the quadratic has 2, the cubic 3, the biquadratic 4, &c. Thus the two roots of this equation $x^2 - 4x = -3$ are 1 and 3; for either of these substituted for x makes $x^2 - 4x = -3$. Also the three roots of $x^3 - 4x^2 - 11x = -30$, or $x^3 - 4x^2 - 11x + 30 = 0$, are 2, 5, and -3; as will appear by substituting each of these instead of x in the equation, by which means it will always be found to be equal to 0. And so of others.

On the Relation between the Roots of Equations, and the

Coefficients of their Terms.—In every equation, when the terms are ranged in order according to the order of the powers, the greater before the less; the first term or highest power being freed of its coefficient, by dividing all the terms of the equation by it, and all brought to one side, and made equal to nothing on the other side, then it will appear in this form,

$$x^n + ax^{n-1} + bx^{n-2} + cx^{n-3} \dots = 0;$$

and the relations between the roots and coefficients, are as follow :

1st, The coefficient a of the 2d term, is equal to the sum of all the roots.

2d, The coefficient b of the 3d term, is equal to the sum of all the products of the roots that can be made by multiplying every two of them together.

3d, The coefficients $c, d, e, \&c.$, of the following terms, are respectively equal to the sum of the products of the roots made by multiplying every three together, or every four together, or every five together, &c., the signs of all the roots being changed, as will be seen when we treat of the Generation of Equations.

The roots of equations are positive or negative, and real or imaginary. Thus, the two roots of the equation $x^2 - 4x = 3$, are 1 and 3, real and both positive; but the roots of the equation $x^2 - 4x^2 - 11x = -30$, are 2, 5, and -3, viz, real, two positive and one negative; and the roots of the equation $x^3 + 9x = 10$, are 1 and $-\frac{1}{2} \pm \frac{\sqrt{3}}{2}$, $\sqrt{-39}$, one real and positive, and two imaginary.

On the Generation of Equations.—This is only the multiplying of certain assumed simple equations together, to produce compound ones, with intent to show the nature of these; a method which was invented by Harriot, and is as follows: Suppose x to denote the unknown quantity of any equation, and let the roots of that equation, or the values of x , be, $a, b, c, d, \&c.$; that is $x = a$, and $x = b$, and $x = c, \&c.$; or $x - a = 0$, and $x - b = 0$, and $x - c = 0, \&c.$; then multiply these last equations together, thus,

$$x - a = 0$$

$$x - b = 0$$

$$x^2 - \underbrace{a}_{b} \{ x + ab = 0$$

$$x - c \dots = 0$$

$$\begin{aligned} x^3 - \underbrace{b}_{c} \{ x^2 + ac \{ x - abc = 0 \\ c \} bc \end{aligned}$$

$$x - d \dots = 0$$

$$\begin{aligned} &\quad \begin{matrix} ab \\ a \\ b \end{matrix} \\ x^4 - \underbrace{c}_{d} \{ x^3 - ad \{ x^2 - \underbrace{abd}_{bc} \{ x + abc = 0 \\ c \\ d \} bc \end{aligned}$$

Now the roots of these equations are $a, b, c, d, \&c.$; and it is obvious that the sum of all the roots is the coefficient of the 2d term, the sum of all the products of every two is the coefficient of the 3d term, the sum of all the products of every three that of the 4th term, and so on, to the last term, which is the continual product of all the roots; and the same law may always be observed, whatever be the dimension or degree of the equation.

On the Reduction of Equations.—This is to transform or change them to their simplest and most commodious form, in order to prepare them for finding or extracting their roots. It is always most convenient to arrange them

according to the powers of the unknown letter, the highest power being placed first on the left hand, and that term to have only + 1 for its coefficient; also all the terms containing the unknown letter to be on one side of the equation, and the absolute known term only on the other side.

Now this reduction chiefly respects the first term, or that which contains the highest power of the unknown quantity; and the general rule for reducing it is, to consider in what manner it is involved or connected with other quantities, and then perform the counter or opposite relation or operation; for every operation is undone or counteracted by the reverse of it; as addition by subtraction, multiplication by division, involution by evolution, &c.: then bring all the unknown terms to one side, and the known term to the other side, changing the signs, from + to -, or from - to +, of those terms which are changed from one side to the other; and lastly divide by the coefficient of the first term, with its sign.

Thus, for example, if $5x - 12 = 3x + 4$:

$$\text{then is } 5x - 3x = 12 + 4, \text{ or } 2x = 16; \\ \text{and so } x = \frac{16}{2} = 8.$$

See other examples in my Course of Mathematics, vol. 1.

On Extracting or Finding the Roots of Equations.

This is finding the value or values of the unknown letter in an equation, the rules for which are various, according to the degree of the equation.

1. For the Root of a Simple EQUATION.

Having reduced the equation as above, by bringing the unknown terms to one side, and the known ones to the other; freeing the former from radicals and fractions, by their counter operations, and lastly dividing by the coefficients of the unknown quantity, the value of it is then found: as in the example of reduction above given.

2. For the Roots of Quadratic EQUATIONS.

These are usually found by what is called completing the square; which consists in squaring half the coefficient of the 2d term, and adding it to both sides of the equation; for then the unknown side is a complete square of a binomial, and the other side consists only of known quantities. Therefore, extracting the root on both sides, the root of the first side will be a binomial, one part of which is the unknown letter, and the other a known quantity, and the root of the other side is taken either + or -, since the square of either of these is the same given quantity: lastly, bringing over the known part of the binomial root to the other side, with a contrary sign, it will give the two roots or values of the unknown letter sought. See examples in my Course, vol. 1.

3. For the Roots of Cubic EQUATIONS.

A Cubic EQUATION is that in which the unknown letter ascends to the 3d power; as $x^3 + a^3 = b^3$, or $x^3 + ax^2 + bx = c$. The 2d term of every cubic equation being taken away, (see TRANSFORMATION,) those equations may all be reduced to this form, $x^3 + ax = b$; and the general value of one root is $x = \sqrt[3]{\left[\frac{1}{2}b + \sqrt{\left(\frac{1}{4}b^2 + \frac{1}{27}a^3\right)}\right] + \sqrt{\left(\frac{1}{2}b - \sqrt{\left(\frac{1}{4}b^2 + \frac{1}{27}a^3\right)}\right)}}$. This rule is usually called Cardan's, because first published by him, but it was invented both by Scipio Ferreus, and Nich. Tartalea, by the latter of whom it was communicated to Cardan. See the article ALGEBRA.

When the 2d term is negative, or the equation of this form, $x^3 - ax = \pm b$, the radical $\sqrt[3]{\left(\frac{1}{4}b^2 + \frac{1}{27}a^3\right)}$ becomes $\sqrt[3]{\left(\frac{1}{4}b^2 - \frac{1}{27}a^3\right)}$, which will be imaginary or impossible when $\frac{1}{27}a^3$ is greater than $\frac{1}{4}b^2$, for $\sqrt[3]{\left(\frac{1}{4}b^2 - \frac{1}{27}a^3\right)}$

will then be the square root of a negative quantity, which is impossible: and yet, in this case, the root x is a real quantity; though algebraists have never been able to find a real finite general expression for it. And this is what is generally called the Irreducible Case.

This case may indeed be resolved by the trisection of an arc or angle; or by any of the usual methods of converging; or by general expressions in infinite series. See Saunderson's Algebra, pa. 713; Philos. Trans. vol. 18, pa. 136, and vol. 70, pa. 415, or my Abridg. vol. 3, pa. 396; vol. 5, pa. 334, and vol. 15, pa. 139. See also the article *Cubic Equations*.

Mr. Cotes observes, in his Logometria, p. 29, that the solution of all cubic equations depends either on the tri-section of a ratio, or of an angle: which method is explained in Saunderson's Algeb. pa. 718.

Biquadratic Equations, or those that are of 4 dimensions, are resolved after various methods. The first rule was given by Lewis Ferrari, the companion of Cardan, which is one of the best. A second method was given by Descartes, and another by Mr. Simpson and Dr. Waring. For the explanation of which, see *Biquadratic Equations*.

Equations of the Higher Degrees or Orders.

There is no general rule to express algebraically the roots of equations above those of the 4th degree; and therefore methods of approximation are here made use of, which, though not accurately, are yet practically true.

Some of these excel in ease and simplicity, and others in quickness of converging. Among these may be reckoned first, Double Position, or Trial-and-Error, both in respect of ease and universality, as it applies in the simplest manner to all kinds of equations whatever, not excepting even exponential ones, radical expressions of ever so complex a form, expressions of logarithms, of arches by the sines or tangents, of arcs of curves by the abscissæ, or any other fluents, or roots of fluxional equations. For an explanation of this and other methods of converging to the roots of equations, by Halley, Newton, Raphson, &c., &c., see *APPROXIMATION*, and *CONVERGING*; and my Course of Mathematics, vol. 1.

Besides the methods above adverted to, there have been some others, given in the Memoirs of several Academies, and elsewhere. As, by M. Daniel Bernoulli, in the Acta Petropolitana, tom. 3, pa. 92; by Euler, in the same, vol. 6, New Series, and tom. 5, pa. 63 and 82; by Mr. Thos. Simpson, in his Essays, pa. 82; in his Dissertations, pa. 102; in his Algebra, pa. 158; and in his Select Exercises, pa. 215.

EQUATION of Payments, in Arithmetic, is the finding a time when, if a sum of money be paid, which is equal to the sum of several others due at different times, no loss will be sustained by either party.—The rule usually given for this purpose, in the common books of arithmetic, is this: Multiply each payment by the time it is due at, then divide the sum of the products by the sum of the payments, for the equated time. For example, If $20l.$ be due at 2 months, and $40l.$ at 4 months, to find, as an equivalent, when the whole $60l.$ may be paid at once. Here then $20 \times 2 + 40 \times 4 = 40 + 160 = 200$, is the sum of the products; and $20 + 40 = 60$, is the sum of the payments; hence $200 \div 60 = \frac{20}{3}$ is the equated time, for making the whole payment at once.

This method, it is obvious, cannot be quite correct when the two payments, as here, are unequal, because no account of the interest on the two sums is considered. When this is allowed for, Mr. Malcolm, in his Arithmetic, has given a correct rule for two payments at simple interest, which is this: If p denote the first payment, and t the time till it is due; also r = another payment, and τ = its time; and if r denote one year's interest of it; next, putting $a = \tau + t + \frac{p+r}{pr}$, and $c = \tau t + \frac{pt+pr}{pr}$; then $\frac{1}{2}a - \frac{1}{2}\sqrt{(a^2 - 4c)}$ is the equated time for the two payments. And here if the former example be taken, it gives $p = 20$, $t = 2$, $r = 40$, $\tau = 4$, and $c = \frac{208}{24}$, for a rate of 5 per cent. Hence $a = 66$, and $c = 208$; then $\frac{1}{2}a - \frac{1}{2}\sqrt{(a^2 - 4c)} = 3\cdot3436$ is the true equated time, allowing simple interest, being very nearly equal to the former, which was $3\cdot3333$ &c. And if compound interest were allowed, the result would be a small matter different still.

When three or more payments are concerned, then Malcolm's method recommended, of first equating for two payments, and next for the result and a 3d payment, and so on, is not strictly just. But in all such cases, to obtain a true answer, Malcolm's general principle ought to be used, viz., making the interests of the sums that are kept later than they are due, equal to the discounts of those that are paid before they are due. The resolution of the resulting equation will, indeed, require some knowledge in algebra. But for ordinary use, the common rule will bring out answers sufficiently near the truth.

EQUATION of a Curve, is an equation showing the nature of a curve by expressing the relation between any abscissæ and its corresponding ordinate, or else the relation of their fluxions, &c. Thus, the equation to the circle, is $ax - x^2 = y^2$, where a is its diameter, x any abscissæ, or part of that diameter, and y the ordinate at that point of the diameter; that is, whatever abscissæ is denoted by x , the square of its corresponding ordinate will be $ax - x^2$. In like manner the equation

of the ellipse is $\frac{p}{a}(ax - x^2) = y^2$,

of the hyperbola is $\frac{p}{a}(ax + x^2) = y^2$,

of the parabola is $-px = y^2$,

Where a is an axis, and p the parameter.

And in like manner for any other curves. See ABSCESS.
This method of expressing the nature of curves by algebraical equations, was first introduced by Descartes, who, by thus connecting together the two sciences of algebra and geometry, made them mutually assist each other, and so laid the foundation of the great improvements that have been made in every branch of them since that time. See Descartes's Geometry; also Newton's Lines of the 3d Order, and many other similar works on curve lines, by several authors. See CURVE.

EQUATION, in Astronomy, as Annual EQUATION, is either of the mean motion of the sun and moon, or of the moon's apogee and nodes.

The annual equation of the sun's centre being given, the other three correspondent annual equations will be also given, and therefore a table of the first will serve for them all. Thus, if the annual equation of the sun's centre, taken from such a table for any time, be called s ; and if $\frac{1}{12}s = a$, and $\frac{1}{6}s = b$; then will the other annual equations for that time be as follow:

$A + \frac{1}{36}A = m$, that of the moon's mean motion;
and $B + \frac{1}{36}B = a$, that of the moon's apogee;
and $\frac{1}{2}B - \frac{1}{12}B = n$, that of her nodes.

And here it must be observed, that when s , or the equation of the sun's centre, is additive; then m is negative, a is positive, and n is negative. But on the contrary, when s is negative or subtractive; then m is positive, a negative, and n positive.

There is also an Equation of the moon's mean motion, depending on the situation of her apogee in respect of the sun; which is greatest when the moon's apogee is in an octant with the sun, and is nothing at all when it is in the quadratures or syzygies. This equation when greatest, and the sun in perige, is $3' 56''$. But it is never above $3' 34''$ when the sun is in apogee. At other distances of the sun from the earth, this equation when greatest, is reciprocally as the cube of that distance. But when the moon's apogee is any where out of the octants, this equation becomes commonly less, and is at the same distance between the earth and sun, as the sine of double the distance of the moon's apogee from the next quadrature or syzygy, is to radius. This is to be added to the moon's motion while her apogee passes from a quadrature with the sun to a syzygy; but is to be subtracted from it, while the apogee moves from the syzygy to the quadrature.

There is another Equation of the moon's motion, which depends on the aspect of the nodes of the moon's orbit with respect to the sun: and this is greatest when her nodes are in octants to the sun, and quite vanishes when they come to their quadratures or syzygies. This equation is proportional to the sine of double the distance of the node from the next syzygy or quadrature; and at the greatest is only $47''$. This must be added to the moon's mean motion while the nodes are passing from the syzygies with the sun to their quadratures; but subtracted while they pass from the quadratures to the syzygies. From the sun's true place subtract the equated mean motion of the lunar apogee, as was shown above, and the remainder will be the annual argument of the said apogee; from which the eccentricity of the moon and the 2d equation of her apogee may be compared. See Theory of the MOON's motions, &c.

EQUATION of the Centre, called also Prosthapheresis, and Total Prosthapheresis, is the difference between the true and mean place of a planet, or the angle made by the lines of the true and mean place; or, which amounts to the

same, between the mean and equated anomaly. The greatest equation of the centre may be obtained by finding the sun's longitude at the times when he is near his mean distances, for then the difference will give the true motion for that interval of time: next find the sun's mean motion for the same interval of time; and then half the difference between the true and mean motions will show the greatest equation of the centre.

For example, by observations made at the Royal Observatory at Greenwich, it appears that at the following mean times the sun's longitudes were as expressed below, viz,

		Sun's longitudes.
1769 Oct. 1 at 23 ^h 49 ^m 12 ^s	-	6° 9' 32" 0.6"
1770 Mar. 29 at 0 4 50	.	0 8 50 27.5"
diff. of time 1784 0 15 38;	true dif. lon.	5 29 18 27
tropical year	=	365 ^d 5 ^h 48 ^m 42 ^s = 365 ^d 2421527;
observed interval	=	178 0 15 38 = 178 ^d 0108565
then 365 ^d 2421527 : 178 ^d 01085648 :: 360 ^d : 175 ^d 455948		'or 175° 27' 21" the mean motion.

Therefore - 175° 27' 21" of mean motion,
answers to - 179 18 27 of true motion;
their difference is 3 51 6

and its half - 1 55 33

is the greatest equation of the centre according to these observations.

To find the Equation of the Centre, which is Kepler's problem, and requires a very troublesome operation, especially in the more eccentric orbits. The method of performing this, has been shown by Newton, Gregory, Keil, Machin, Lacaille, and others, by methods little differing from one another; which consist principally in finding a certain intermediate angle, called the excentric anomaly; having known the mean anomaly, and the dimensions of the sun's orbit. The mean anomaly is easily found, by determining the exact time when the sun is in the aphelion, and using the following proportion, viz, As the time of a tropical revolution, or solar year, Is to the interval between the aphelion and given time, So is 360 degrees, to the degrees of the mean anomaly. Or it may be found by taking the sun's mean motion at the given time out of tables.

To find the Excentric Anomaly, say,

As the aphelion distance,
Is to the perihelion distance;
So is the tangent of half the mean anomaly,
To the tangent of an arc.

Which arc added to half the mean anomaly, gives the excentric anomaly. Then,

To find the True Anomaly, say,
As the square root of the aphelion distance,
Is to the square root of the perihelion distance;
So is the tangent of half the excentric anomaly,
To the tangent of half the true anomaly.

Then, the difference between the true and mean anomaly, gives the equation of the centre, sought. Which is subtractive, from the aphelion to the perihelion, or in the first 6 signs of anomaly; and additive, from the perihelion to the aphelion, or in the last 6 signs of anomaly; and hence called Prosthapheresis.

By this problem a table may easily be formed. When the equations of the centre for every degree of the first 6 signs of mean anomaly are found, they will serve also for the degrees of the last 6 signs, because equal anomalies are at equal distances on both sides of their apses. Therefore set these equations orderly to their signs and degrees

of anomaly; the first 6 being reckoned from the top of the table downwards, and signed *subtract*; the last 6, for which the same equations serve, in a contrary order, being reckoned from the bottom upwards, and marked *add*. Let also the difference between every adjacent two equations, called tabular differences, be set in another column. Hence, from these equations of the centre, augmented or diminished by the proportional parts of their respective tabular differences, for any given minutes and seconds, may easily be deduced equations of the centre to any mean anomaly proposed. See Robertson's Elem. of Navig. book 5, pa. 286, 290, 295, and 308, where such a table of equations is given.

Euler has particularly considered this subject, in the Mem. de l'Acad. de Berlin, tom. 2, pa. 225 et seq. where he resolves the following problems:

1. To find the true and mean anomaly corresponding to the planet's mean distance from the sun; that is, where the planet is in the extremity of the conjugate axis of its orbit.—2. The excentricity of a planet being given, to find the excentric anomaly corresponding to the greatest equation.—3. The excentricity being given, to find the mean anomaly corresponding to the greatest equation.—4. From the same data, to find the true anomaly corresponding to this equation.—5. From the same data, to find the greatest equation.—6. The greatest equation being given, to find the excentricity.

Euler observes, that this problem is very difficult, and that it can only be resolved by approximation and tentatively, in the manner he mentions: but if the excentricity be not great, it may then be found directly from the greatest equation. Thus, if the greatest equation be $= m$, and the excentricity $= n$; then is

$$m = 2n + \frac{11}{2^2 \cdot 3} n^3 + \frac{599}{2^2 \cdot 3 \cdot 5 \cdot 7} n^5 + \&c; \text{ and by reversion}$$

$$n = \frac{1}{2}m - \frac{11}{2^2 \cdot 3} m^3 - \frac{578}{2^2 \cdot 3 \cdot 5} m^5 - \&c. \text{ Where the greatest equation } m \text{ must be expressed in parts of the radius, which may be done by reducing the angle } m \text{ into seconds, and adding } 46855749 \text{ to the log. of the resulting number, which will be the log. of the number } m. \text{ The mean anomaly to which this greatest equation corresponds, will be } x = 90^\circ + \frac{4}{5}m - \frac{5}{2^2 \cdot 3} m^3 - \frac{1}{2^2 \cdot 5} m^5 - \&c. \text{ Whence, if } 90^\circ \text{ be added to } \frac{4}{5} \text{ of the greatest equation, the sum will be the mean anomaly sufficiently exact.}$$

Euler subjoins a table, by which may be found the greatest equations, with the mean and excentric anomalies corresponding to these greatest equations for every 100th part of unity, which he supposes equal to the greatest excentricity, or when the transverse and distance of the foci become infinite. The last column of the table gives also the logarithm of that distance of the planet from the sun where its equation is greatest. By means of this table, any excentricity being given, the corresponding greatest equation will be found by interpolation. But the principal use of the table is to determine the excentricity when the greatest equation is known; and without this help Euler thinks the problem cannot be resolved.

EQUATION of Time, denotes the difference between mean and apparent time, or the reduction of the apparent unequal time, or motion of the sun or a planet, to equal and mean time, or motion; or the equation of time is the difference between the sun's mean motion, and his right ascension. Apparent time is that which takes its beginning from the passage of the sun's centre over the meridi-

dian of any place; and had the sun no motion in the ecliptic, or was his motion reduced to the equator or in right ascension uniform, he would always return to the meridian after equal intervals of time. But his apparent motion in the ecliptic being continually varying, and his motion in right ascension being rendered further unequal on account of the obliquity of the ecliptic to the equator, it follows from these causes that the intervals of his return to the meridian become unequal, and the sun will gradually come too slow or too soon to the meridian for an equal motion, such as that of clocks and watches ought to be; and this retardation or acceleration of the sun's coming to the meridian, is called the equation of time.

Now, computing the celestial motions according to equal time, it is necessary to turn that time back again into apparent time, that they may correspond to observation: on the contrary, any phenomenon being observed, the apparent time of it must be converted into equal time, to have it correspond with the times marked in the astronomical tables.

The equation of time is nothing at four different times in the year, at which time the whole mean and unequal motions exactly agree; viz, about the 15th of April, the 15th of June, the 31st of August, and the 24th of December: but at all other times the sun is either too fast or too slow for mean, equal, or clock time, by a certain number of minutes and seconds, which at the greatest is $16^\circ 14''$, and happens about the 1st of November; every other day throughout the year having a certain quantity of this difference belonging to it; which however is not exactly the same every year, but only every 4th year; for which reason it is necessary to have 4 tables of this equation, viz, one for each of the four years in the period of leap-years. Instead of these, we shall insert here, one general equation of time, according to the place of the sun, in every point of the ecliptic: where it is to be observed, that the sign of the ecliptic is placed at the tops of the columns, and the particular degree of the sun's place, in each sign, in the first and last columns; and in the angle of meeting in all the other columns, is the equation of time, in minutes and seconds, when the sun has any particular longitude: supposing the obliquity of the ecliptic $23^\circ 28'$, and the sun's apogee in 90° of ss .

The equations with the sign $+$, are to be added to, and those with the sign $-$ are to be subtracted from, the apparent time, to give the mean time. The preceding sign, whether it be $+$ or $-$, at the top of any column, belongs to all the numbers or equations in that column till the sign changes; after which, the remainder of the column takes the contrary sign.

The equation answering to any point of longitude between one degree and another, or any number of minutes or parts of a degree, is to be found by proportion in the usual way, viz, as 1° or $60'$ is to that number of minutes, so is the whole difference in the equation, from the given whole degree of longitude to the next degree, to the proportional part of it answering to the given number of minutes.

See Tables of the Equation of Time computed for every year, in the Nautical Almanac, by a method proposed and illustrated by Dr. Maskelyne, late astronomer royal, viz, by taking the difference between the sun's true right ascension and his mean longitude, corrected by the equation of the equinoxes in right ascension, and turning it into time at the rate of 1 minute of time to $15.$ of right ascension. Philos. Trans. vol. 54, pa. 336.

TABLE of the Equation of Time, for every Degree of the Sun's Longitude.

EQUATOR, in Geography, a great circle of the earth, equally distant from its two poles, and dividing it into two equal parts, or hemispheres, the northern and southern. The equator is sometimes simply called the line.

The circle in the heavens conceived directly over the equator, is the equinoctial. See EQUINOCTIAL. The greatest height of the equator above the horizon, is equal to the latitude of the place.

TABLE for turning Degrees and Minutes into Time, and the Contrary.

As one whole revolution of the earth, or of the 360° of the equator, is performed in 24 hours, which is at the rate of 15° per hour; hence the number of degrees of the equator, answering to any other given time, or the time answering to any given number of degrees of the equator, will be easily found by proportion, viz,

$$\text{as } 1^{\text{h}} : 15^{\circ} :: \text{any time} : \text{its degrees},$$

$$\text{or as } 15^{\circ} : 1^{\text{h}} :: \text{any degrees} : \text{their time}.$$

And thus is computed the foregoing table for turning time into degrees of the equator, and the contrary.

EQUATORIAL, Universal, or PORTABLE OBSERVATORY, is an instrument intended to answer a number of useful purposes in practical astronomy, independently of any particular observatory. It may be employed in any steady room or place, and it performs most of the useful problems in the science of astronomy. The following is the description of one lately invented by Mr. Ramsden, and named the Universal Equatorial, the description of which was given by the Hon. Stewart Mackenzie.

The principal parts of this instrument (fig. 2, plate viii.) are, 1st, The azimuth or horizontal circle *a*, which represents the horizon of the place, and moves on a long axis *b*, called the vertical axis. 2d, The equatorial or hour-circle *c*, representing the equator, placed at right angles to the polar axis *d*, or the axis of the earth, upon which it moves. 3d, The semicircle of declination *e*, on which the telescope is placed, and moving on the axis of declination, or the axis of motion of the line of collimation *f*; which circles are measured and divided as in the following table :

Measures of the several circles and divisions on them	Radius, inches	Limb divided to	Non. of 30 gives seconds	Divid. on limb into pts. of Inc.	Divided by Non. into pts. of Inc.
Azimuth or horizontal circle	5' 1	15'	30"	45th	1350th
Equatorial or hour circle	5' 1	15', or t.m. in time	30" 2"	45th	1350th
Vertical semicircle for declination or latitude.	5'	15'	30"	42d	1260th

4th, The telescope, is an achromatic refractor with a triple object-glass, whose focal distance is 17 inches, and its aperture 2.45 inc., and it is furnished with 6 different eye-tubes; so that its magnifying powers extend from 44 to 168. The telescope in this equatorial may be brought parallel to the polar axis, as in the figure, so as to point to the pole-star in any part of its diurnal revolution; and thus it has been observed near noon, when the sun has shone very bright. 5th, The apparatus for correcting the error in altitude occasioned by refraction, which is applied to the end of the telescope next the eye-glass, and consists of a slide *g* moving in a groove or dove-tail, and carrying the several eye-tubes of the telescope, on which slide there is an index corresponding to five small divisions engraved on the dove-tail; a very small circle, called the refraction circle *h*, moveable by a finger-screw at the extremity of the end of the telescope next the eye-glass; which circle is divided into half minutes, one whole revolution of it being equal to $3' 18''$, and by its motion it raises the centre of the cross hairs on a circle of altitude; and also a quadrant *i* of 12 inc. radius, with divisions on

each side, one expressing the degree of altitude of the object viewed, and the other expressing the minutes and seconds of the error occasioned by refraction, corresponding to that degree of altitude. To this quadrant is connected a small round level *k*, which is adjusted partly by the pinion that turns the whole of this apparatus, and partly by the index of the quadrant; for which purpose the refraction circle is set to the same minute &c, which the index points to on the limb of the quadrant; and if the minute &c, given by the quadrant, exceed the $3' 18''$ contained in one entire revolution of the refraction circle, this must be set to the excess above one or more of its entire revolutions; then the centre of the cross hairs will appear to be raised on a circle of altitude to the additional height which the error of refraction will occasion at that altitude.

The principal adjustment in this instrument, is that of making the line of collimation to describe a portion of an hour-circle in the heavens: in order to which, the azimuth circle must be truly level; the line of collimation, or some corresponding line represented by the small brass rod *m* parallel to it, must be perpendicular to the axis of its own proper motion; and this last axis must be perpendicular to the polar axis. On the brass rod *m* there is occasionally placed a hanging level *n*, the use of which will appear from the following directions :

The azimuth circle may be made level by turning the instrument till one of the levels be parallel to an imaginary line joining two of the feet screws; then adjust that level with these two feet screws; turn the circle 180° , or half round; and if the bubble be not then right, correct half the error by the screw belonging to the level, and the other half error by the two foot screws, repeating this operation till the bubble come right; then turn the circle 90° from the two former positions, and set the bubble right again, if it be wrong, by the foot screw at the end of the level; when this is done, adjust the other level by its own screw, and the azimuth circle will be truly level. The hanging level must then be fixed to the brass rod by two hooks of equal length, and made truly parallel to it: for which purpose, the polar axis must be made perpendicular or nearly perpendicular to the horizon; then adjust the level by the pinion of the declination semicircle: reverse the level, and if it be wrong, correct half the error by a small steel screw that lies under one end of the level, and the other half error by the pinion of the declination-semicircle, repeating the operation till the bubble be right in both positions. To make the brass rod, on which the level is suspended, at right angles to the axis of motion of the telescope, or line of collimation, make the polar axis horizontal, or nearly so; set the declination semicircle to 0° , and turn the hour-circle till the bubble be properly adjusted; then turn the declination-circle to 90° ; adjust the bubble by raising or depressing the polar axis (first by hand till it be nearly right, afterwards tighten with an ivory key the socket which runs on the arch with the polar axis, and then apply the same ivory key to the adjusting screw at the end of the said arch till the bubble be properly adjusted); then turn the declination-circle to the opposite 90° ; and if the level be not then right, correct half the error by the aforesaid adjusting screw at the end of the arch, and the other half error by the two screws that raise or depress the end of the brass rod. The polar axis remaining nearly horizontal as before, and the declination-semicircle at 0° , adjust the

bubble by the hour-circle; then turn the declination-semicircle to 90° , and adjust the bubble by raising or depressing the polar axis; then turn the hour-circle 12 hours; and if the bubble be wrong, correct half the error by the polar axis, and the other half error by the two pair of capstan screws at the feet of the two supports on one side of the axis of motion of the telescope; and thus this axis will be at right angles to the polar axis. The next adjustment, is to make the centre of the cross hairs remain on the same object, while the eye-tube is turned quite round by the pinion of the refraction apparatus: in order to perform this, set the index on the slide to the first division on the dove-tail; and set the division marked $18''$ on the refraction-circle to its index; then look through the telescope, and with the pinion turn the eye-tube quite round; then if the centre of the hairs do not remain on the same spot during that revolution, it must be corrected by the four small screws, 2 and 2 at a time, which will be found upon unscrewing the nearest end of the eye-tube that contains the first eye-glass; repeating this correction till the centre of the hairs remain on the spot looked at during a whole revolution. To make the line of collimation parallel to the brass rod on which the level hangs, set the polar axis horizontal, and the declination-circle to 90° , adjust the level by the polar axis; look through the telescope on some distant horizontal object, covered by the centre of the cross hairs: then invert the telescope, which is done by turning the hour-circle half round; and if the centre of the cross hairs do not cover the same object as before, correct half the error by means of the upper and lower of the 4 small screws at the eye-end of the large tube of the telescope; this correction will give a second object, now covered by the centre of the hair: which must be adopted instead of the first object; then invert the telescope as before; and if the second object be not covered by the centre of the hairs, correct half the error by the same two screws as were used before: this correction will give a third object, now covered by the centre of the hairs, which must be adopted instead of the second object; repeat this operation till no error remains; then set the hour-circle exactly to 12 hours, the declination-circle remaining at 90° as before; and if the centre of the cross hairs do not cover the last object fixed on, set it to that object by the two remaining small screws at the eye-end of the large tube, and then the line of collimation will be parallel to the brass rod. For rectifying the nonius of the declination and equatorial circles, depress the telescope as many degrees &c below 0° or π on the declination-semicircle, as are equal to the complement of the latitude; then elevate the polar axis till the bubble be horizontal; and thus the equatorial circle will be elevated to the co-latitude of the place: set this circle to 6 hours; and adjust the level by the pinion of the declination-circle; now turn the equatorial circle exactly 12 hours from the last position; and if the level be not right, correct one half of the error by the equatorial circle, and the other half by the declination-circle: then turn the equatorial circle back again exactly 12 hours from the last position; and if the level be still wrong, repeat the correction as before, till it be right, when turned to either position: which being done, set the nonius of the equatorial circle exactly to 6 hours, and the nonius of the declination-circle exactly to 0° .

The principal uses of this equatorial are,

1st, *To find the meridian by one observation only:* For

which purpose, elevate the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the sun's declination for the day and hour of the day required; then move the azimuth and hour-circles both at the same time, either in the same or in contrary direction, till you bring the centre of the cross hairs in the telescope exactly to cover the centre of the sun; then, the index of the hour-circle will give the apparent or solar time at the instant of observation; and thus the time is known, though the sun be at a distance from the meridian; after which turn the hour-circle till the index points precisely to 12 o'clock, and lower the telescope to the horizon, in order to observe some point there in the centre of the glass; and that point is the meridian mark, found by one observation only. The best time for this operation is 3 hours before, or 3 hours after, 12 at noon.

2d, *To point the telescope to a star, though not on the meridian, in full day-light.*—Having elevated the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the star's declination, move the index of the hour-circle till it points to the precise time at which the star is then distant from the meridian, found in the tables of the right ascension of the stars, and the star will then appear in the glass.

Besides these uses, peculiar to this instrument, it may also be applied to all the purposes to which the principal astronomical instruments are applied; such as a transit instrument, a quadrant, and an equal-altitude instrument, &c.

See the description and drawing of an equatorial telescope, or portable observatory, invented by Mr. Short, in the Philos. Trans. No. 493, or vol. 46, pa. 242; and another by Mr. Nairne, vol. 61, pa. 107; also the description by Sir Geo. Shuckburgh, in the Philos. Trans. vol. 83, pa. 67; or my Bridg. vol. 17, pa. 299.

EQUIANGULAR *Figure*, is one that has all its angles equal among themselves; as the square, and all regular polygons. An equilateral figure inscribed in a circle, is always equiangular. But an equiangular figure inscribed in a circle, is not always equilateral, except when it has an odd number of sides: If the sides be of an even number, then they may either be all equal, or else half of them will be equal to each other, and the other half to each other, the equals being placed alternately. See the demonstration in my Mathematical Miscellany, pa. 272.

EQUIANGULAR, is also said of any two figures of the same kind, when each angle of the one is equal to a corresponding angle in the other, whether each figure, separately considered in itself, be an equiangular figure or not; that is, having all its angles equal to each other. Thus, two triangles are equiangular to each other, if, ex. gr. one angle in each be of 30° , a second angle in each of 50° , and the third angle of each equal to 100 degrees.—Equiangular triangles have not their like sides necessarily equal, but only proportional to each other; but such triangles being always similar to each other.

EQUICRURAL Triangle, is one that has two of its sides equal to each other; but is more usually called an Isosceles triangle.

EQUICULUS, **EQUELEUS**, or **EVUS Minor**, a constellation of the northern hemisphere. See **EQUELEUS**.

EQUIDIFFERENT, are such things as have equal differences, or arithmetically proportional. If the terms have all the same difference, viz. the 1st and 2d, the 2d. and 3d, the 3d and 4th, &c, they are said to be continually

equidifferent; as the numbers 3, 6, 9, 12, &c, where the common difference is 3. But if the several different couples only have the same difference, as the 1st and 2d, the 3d and 4th, the 5th and 6th, &c, they are said to be discretely equidifferent; as the terms 3 and 6, 7 and 10, 9 and 12, &c. See *ARITHMETICAL Progression* and *Proportion*.

EQUILATERAL Figure, is one that has all its sides equal to each other. Such as the square, and all regular polygons, or a triangle that has all its angles equal. See *EQUANGULAR*.

EQUILATERAL Hyperbola, is that which has the two axes equal to each other, and every pair of conjugate diameters also equal to each other. The asymptotes also are at right angles to each other, and make each half a right angle with either axis. Also, such an hyperbola is equal to its conjugate hyperbola, as well as to its opposite hyperbola; so that all the four conjugate hyperbolas are mutually equal to each other.

Moreover, as the 3d proportional to the two axes is the parameter; therefore, in such figure, the parameter and two axes are all three equal to one another. Hence, as the general equation to hyperbolas is $y^2 = \frac{p}{t}(tx + x^2)$ or $= \frac{c^2}{t^2}(tx + x^2)$, where t is the transverse axis, c the conjugate, p the parameter, x the absciss, and y the ordinate; then making t, c , and p all equal, the equation, for the equilateral hyperbola, becomes $y^2 = tx + x^2$; differing from the equation of the circle only in the sign of the term x^2 , which in the circle is $tx - x^2$, when t is taken to represent the diameter of the circle.

EQUILIBRIUM, is an equality between two equal forces acting in opposite directions; so that they mutually balance each other; like the two equal arms, or scales, of a balance, &c.

EQUILIBRIUM, in solid bodies, forms a considerable part of the science of Statics. And Equilibrium of fluids, a considerable part of the doctrine of Hydrostatics.

EQUIMULTIPLES, the products of quantities equally multiplied.

Thus $3a$ and $3b$ are equimultiples of a and b ;

and mc and md are equimultiples of c and d .

Equimultiples of any quantities, have the same ratio as the quantities themselves. Thus $a:b::3a:3b::ma:mb$.

EQUINOCTIAL, a great circle in the heavens under which the equator moves in its diurnal motion. The poles of this circle are the poles of the world, and it divides the sphere into two equal parts, the northern and southern. It cuts the horizon of any place, in the east and west points; and at the meridian its elevation above the horizon is equal to the co-latitude of the place. It has also various other properties; as,

1. When the sun is in this circle, the days and nights in all parts of the earth are equal; because he then rises due east, and sets due west. Hence it has the name equinoctial. All stars which are under this circle, or have no declination, also rise due east, and set due west.—2. All people living under this circle, or upon the equator, or line, have their days and nights at all times equal to each other.—3. From this circle, on the globe, is counted, upon the meridian, the declination in the heavens, and the latitude on the earth.—4. Upon the equinoctial, or equator, is counted the longitude, making in all 360° , that is, 180° east, and 180° west.—5. And as the time of one whole

revolution is divided into 24 hours; therefore 1 hour answers to 15° , or the 24th part of 360° . Hence,
 1° of longitude answers to 4 min. of time,
 $15' - - - - -$ to 1 min. of time,
 $1' - - - - -$ to 4 sec. of time, &c.

6. The shadows of objects situated under this circle are cast to the southward one half of the year, and to the northward during the other half; and twice in a year, viz. at the time of the equinoxes, the sun at noon casts no shadow, being exactly in their zenith.

EQUINOCTIAL Colure, is the great circle passing through the poles of the world and the equinoctial points, or first points of Aries and Libra.

EQUINOCTIAL Dial, is one whose plane is parallel to the equinoctial. Its properties or principles are:

1. The hour-lines are all equally distant from each other, viz. 15° ; and the style is straight pin, or wire, set up in the centre of the circle, perpendicular to the plane of the dial.

2. The sun shines upon the upper part of this dial-plane from the 21st of March to the 22d of September, and on the under part the other half of the year.

Some of these dials are made of brass, &c.; and set up in a frame, to be elevated to any given latitude.

EQUINOCTIAL Points, are the two opposite points where the ecliptic and equinoctial cross each other; the one point being in the beginning of Aries, and called the vernal point, or vernal equinox; and the other in the beginning of Libra, and called the autumnal point, or autumnal equinox.—It is found by observation, that the equinoctial points, and all the other points of the ecliptic, are continually moving backwards, or in antecedentia, i.e. westwards. This retrograde motion of the equinoctial points, arises from the Precession of the equinoxes, and is made at the rate of $50\frac{1}{2}$ seconds every year nearly. See *PRECESSION*, also the preface to the Nautical Almanac for the year 1797.

EQUINOXES, the times when the sun enters the equinoctial points; that is, about the 21st of March and 22d of September: the former being the vernal or spring equinox, and the latter the autumnal equinox.—As the sun's motion is unequal, being sometimes quicker and sometimes slower, it hence happens that there are about 8 days more from the vernal to the autumnal equinox, or while the sun is on the northern side of the equator, than while he is in moving through the southern signs, from the autumnal to the vernal equinox, or on the southern side of the equator. According to the observations of M. Cassini, the sun is $186^\mathrm{d} 14^\mathrm{h} 53^\mathrm{m}$ in the northern signs, and only $178^\mathrm{d} 14^\mathrm{h} 56^\mathrm{m}$ in the southern signs, so that $7^\mathrm{h} 23^\mathrm{m} 57^\mathrm{s}$ is their diff., or nearly 8 days.

EQUINUS Barbatus, a kind of comet. See *HIPPEUS*.

EQUITANGENTIAL Curve, is one that was first constructed by Mr. J. Perks, the tangent of which is always equal to a constant line. It is the involute of the catenaria; and is also the curve of traction to a straight line.—For the various properties of this curve, its mechanical construction, its relation to the catenaria, and its use in dividing the meridian in Mercator's projection, we refer to the Philos. Trans. No. 345: see also Brougham's paper on Porisms, in the Philos. Trans. vol. 88; or my Abridg. vol. 18, pa. 354, for other curious properties of this curve.

EQUULEUS, **EQUICULUS**, and **Eqvus Minor**, *Eqvici* *secatio*, the Horse's Head, one of the 48 old constellations, in the northern hemisphere. Its stars in Ptolemy's cata-

ogue are 4, in Tycho's 4, in Hevelius's 6, and in Flamsteed's 10.

ERATOSTHENES, a learned Greek philosopher of Cyrene, and librarian of Alexandria under Ptolemy Euergetes, king of Egypt. He was learned in all the sciences, and first discovered a method of measuring the earth's magnitude; whence he was called the Cosmographer and Surveyor of the Universe. He gave a mechanical solution to the famous problem of doubling the cube. And he gave a method of finding prime numbers, in arithmetic, commonly called Eratosthenes' Sive, a learned account of which is given by Dr. Horsley, in the Philos. Trans. of 1772; or in my Abridgment, vol. 13, pa. 314. Some of his works remain, which were printed at Oxford, in Greek, 1672, 8vo. Eratosthenes died about 194 before the year Christ, at 81 years of age.

ERECT Vision. See **VISION**.

ERECT Dials, such as stand perpendicular to the horizon, and are of various kinds; as erect direct, when they face exactly one of the four cardinal points, east, west, north, south; and erect declining, when they decline from the cardinal points. See **DIAL**.

To **Erect a Perpendicular**, is a popular problem in practical geometry, and denotes to raise a perpendicular from a given line, &c, as distinguished from demitting or letting fall a perpendicular on a line, &c, from some point out of it. See **PERPENDICULAR**.

ERIDANUS, the River, a constellation of the southern hemisphere, and one of the 48 old asterisms. The stars in this constellation, in Ptolemy's catalogue, are 34, in Tycho's 19, and in the British catalogue 84.

ERRATIC, an epithet applied to the planets, which are called erratic or wandering stars, in contradistinction to the fixed stars.

ESCALADE, or **SCALADE**, a furious attack on a wall or a rampart; carried on with ladders, to pass the ditch, or mount the rampart; without proceeding in form, breaking ground, or carrying on regular works to secure the men.

ESPAULE, or EPAULE. See **EPAULE**.

ESPLANADE, in Fortification, called also **Glaçis**, a part which serves as a parapet to the counterscarp, or covert way; being a declivity or slope of earth, commencing from the top of the counterscarp, and losing itself insensibly in the level of the champaign.

ESPLANADE means also the ground which has been levelled from the glacis of the counterscarp, to the first houses; or the vacant space between the works and the houses of the town. The term is also applied, in the general, to any piece of ground that is made flat or level, and which before had some eminence that incommodeed the place.

ESTIVAL Occident, Orient, or Solstice. See **Occident, ORIENT, SOLSTICE**.

ESTUARY, an arm of the sea; a frith; or the mouth of a lake or river in which the tide reciprocates.

ETHER, an element more fine and subtle than air; or air refined and sublimed; or the matter of the highest regions above.

ETHER, in Chemistry, a certain very light, volatile, fragrant, inflammable liquor, procured by distillation, by heat, from a mixture of alcohol, and sulphuric or some other acid, in equal quantities.

The specific gravity of ether, is from 0.725 to 0.632, according to its different degrees of purity. It appears a

limpid and colourless liquor, of a hot pungent taste, highly fragrant, and so volatile that it can hardly be poured from one vessel to another without much loss by evaporation, the purest portion of it assuming the state of elastic fluid.

When exposed to a cold of -46° , ether freezes and crystallizes. In moderate temperatures it is not affected by oxygen gas or common air; but when kindled in a state of vapour, it burns rapidly with a fine white flame, and leaves behind trace of charcoal. In the state of vapour it detonates with common air and oxygen gas.

EVAPORATION, the act of dissipating the humidity of a body in fumes or vapour; differing from exhalation, which is properly a dispersion of dry particles issuing from a body.—Evaporation is usually produced by heat, and by the change of air: thus, common salt is formed by evaporating all the humidity from the brine or salt water; which evaporation is either performed by the heat of the sun, as in the salt-works on the sea-coast, &c; or by means of fire, as at the salt-springs, &c: and it is well known how useful a brisk wind is in drying wet clothes, or the surface of the ground; while in a calm, still atmosphere, they dry extremely slow.

But, though evaporation be generally considered as an effect of the heat and motion of the air, yet M. Gauteron, in the Mémoires de l'Acad. des Scienç. an. 1705, shows, that a quite opposite cause may have the same effect, and that fluids lose more of their parts in the severest frost than when the air is moderately warm: thus, in the great frost of the year 1708, he found that the greater the cold, the more considerable the evaporation; and that ice itself lost full as much as the warmer liquors that did not freeze.

There are indeed few subjects of philosophical investigation that have occasioned a greater variety of opinion than the theory of evaporation, or of the ascent of water in such a fluid as air, between 8 and 9 hundred times lighter than itself, to different heights, according to the different densities or states of the atmosphere; in which case it must be specifically lighter than the air through which it ascends. The Cartesians account for it by supposing, that by the action of the sun upon the water, small particles of the water are formed into hollow spheres and filled with the *materia subtilis*, which renders them specifically lighter than the ambient air, so that they are buoyed up by it.

Dr. Nieuwentyt, in his Religious Philosopher, cont. 19, and several others, have alleged, that the sun emits particles of fire, which adhere to those of water, and form moleculeæ, or small bodies, lighter than an equal bulk of air, which consequently ascend till they come to a height where the air is of the same specific gravity with themselves; and that these particles being separated from the fire with which they are incorporated, coalesce and descend in dew or rain.

Dr. Halley has advanced another hypothesis, which has been more generally received: he imagined, that by the action of the sun on the surface of the water, the aqueous particles are formed into hollow spherules, that are filled with a finer air highly rarefied, so as to become specifically lighter than the external air. Philos. Trans. No. 192, or my Abridg. vol. 3, pa. 427.

Dr. Desaguliers, dissatisfied with these hypotheses, proposes another in the Philos. Trans. No. 407, or Abridg. vol. 7, pa. 323. See also his Course of Experimental Philosophy, vol. 2, pa. 336. He supposes that heat acts

more powerfully on water than on common air; that the same degree of heat which rarefies air two-thirds, will rarefy water nearly 14,000 times; and that a very small degree of heat will raise a steam or vapour from water, even in winter, while it condenses the air; and thus the particles of water are converted into vapour by being made to repel each other strongly, and, deriving electricity from the particles of air to which they are contiguous, are repelled by them and by each other, so as to form a fluid which, being lighter than the air, rises in it, according to their relative gravities. The particles of this vapour retain their repellent force for a considerable time, till, by some diminution of the density of the air in which they float, they are precipitated downwards, and brought within the sphere of each other's attraction of cohesion, and so join again into drops of water.

Many objections have been urged against this opinion; as, by Mr. Clare, in his Treatise of the Motion of Fluids, pa. 294; and by Mr. Rowning in his System of Philosophy, part 2, diss. 6; to which Dr. Hamilton has added the two following, viz, That if heat were the only cause of evaporation, water would evaporate faster in a warm close room, than when exposed in a colder place, where there is a constant current of air; which is contrary to experience; and that the evaporation of water is so far from depending on its being rarefied by heat, that it is carried on even while water is condensed by the coldness of the air, till it freezes; and since it evaporates even when frozen into hard ice, it must also evaporate in all the lesser degrees of cold. And therefore heat does not seem to be the principal, much less the only cause of evaporation.

Others have more successfully accounted for the phenomena of evaporation on another principle, viz, that of solution; having shown, from a variety of experiments, that what we call evaporation, is nothing more than a gradual solution of water in air, produced and supported by the same means, viz, attraction, heat, and motion, by which other solutions are effected.

It seems however that the Abbé Nollet first started this opinion, in his *Leçons de Physique Expérimentale*, published in 1743, without pursuing it much further: he there only conjectures that the air of the atmosphere may serve as a solvent or sponge, with regard to the bodies that encompass it, and receive into its pores the vapours and exhalations that are detached from the masses to which they belong in a fluid state; and he accounts for their ascent on the same principles with the ascent of liquors in capillary tubes. On his hypothesis, the condensation of the air contributes, like the squeezing of a sponge, to their descent.

Dr. Franklin, in a paper of Philosophical and Meteorological Observations, Conjectures, and Suppositions, delivered to the Royal Society about the year 1747, and read in 1756, suggested a similar hypothesis: he observes, that air and water mutually attract each other; and hence he concludes, that water will dissolve in air, as salt in water; every particle of air assuming one or more particle of water; and when too much is added, it precipitates in rain. But as there is not the same contiguity between the particles of air as there is between those of water, the solution of water in air is not carried on without a motion of the air, so as to cause a fresh accession of dry particles. A small degree of heat so weakens the cohesion of the particles of water, that those on the surface easily quit it, and adhere to the particles of air: a greater degree of heat is necessary to break the cohesion between water and air;

for its particles being by heat repelled to a greater distance from each other, they thereby more easily keep the particles of water, that are annexed to them, from running into cohesions that would obstruct, refract, or reflect the heat; and hence it happens that when we breathe in warm air, though the same quantity of moisture may be taken up from the lungs as when we breathe in cold air, yet that moisture is not so visible. On which principles he accounts for the production and different appearances of fogs, mists, and clouds. And he adds, that if the particles of water bring with them electrical fire when they attach themselves to air, the repulsion between the particles of water electrified, joins with the natural repulsion of the air to force its particles to a greater distance, so that the air being more dilated, it rises and carries the water up with it; which mutual repulsion of the particles of air is increased by a mixture of common fire in the particles of water. When air, loaded with surrounding particles of water, is compressed by adverse winds, or by being driven against mountains, &c, or condensed by taking away the fire that assisted it in expanding, then the particles will approach one another, and the air with its water will descend as a dew; or if the water surrounding one particle of air come in contact with the water surrounding another, they will coalesce and form a drop, producing rain; and since it is a well-known fact, that vapour is a good conductor of electricity, as well as of common fire, it is reasonable to conclude with Mr. Henley, that evaporation is one great cause of the clouds becoming at times surcharged with this fluid. Philos. Trans. vol. 67, pa. 134. See also vol. 55, pa. 182; or Franklin's Letters and Papers on Philosophical Subjects, pa. 42, &c, and pa. 182, ed. 1769.

M. le Roi, of the Academy of Sciences at Paris, has also advanced the same opinion, and supported it by a variety of facts and observations in the Memoirs for the year 1751. He shows, that water undergoes in the air a real dissolution, forming with it a transparent mixture, and possessing the same properties with the solutions of most salts in water; and that the two principal causes which promote the solution of water in the air, are heat and wind; that the hotter the air is, within a certain limit, the more water it will dissolve; and that at a certain degree of heat the air will be saturated with water; and by determining at different times the degree of the air's saturation, he estimates the influence of those causes on which the quantity depends that is suspended in the air in a state of solution. Accordingly, the air, heated by evaporating substances to which it is contiguous, becomes more rare and light, rises and gives way to a denser air; and, by being thus removed, contributes to accelerate the evaporation. The fixed air contained in the internal parts of evaporating bodies, put into action by heat, seems also to increase their evaporation. The wind is another cause of the increase of evaporation, chiefly by changing and renewing the air which immediately encompasses the evaporating substances; and from the consideration of these two causes combined, it appears why the quantity of vapour raised in the night is less than that raised in the day, since the air is then both less heated and less agitated. To the objection urged against this hypothesis, on account of the evaporation of water in a vacuum, this ingenious writer replies, that the water itself contains a great quantity of air, which gradually disengages itself, and causes the evaporation; and that it is impossible that a space containing water which evaporates should remain perfectly free from air. To this

objection Dr. Dobson of Liverpool replies, that though air appears, by unquestionable experiments, to be a chemical solvent of water, and, as such, is to be considered as one cause of its evaporation; heat is another cause, acting without the intervention of air, and producing a copious evaporation in an exhausted receiver; agreeably to an experiment of Dr. Irving, who says, that in an exhausted receiver water rises in vapour more copiously at 180° of Fahrenheit's thermometer, than in the open air at 212°, its boiling point. Dr. Dobson further adds, that water may exist in air in three different states; in a state of perfect solution, when the air will be clear, dry, and heavy, and its powers of solution still active; in a state of beginning precipitation, when it becomes moist and foggy, its powers of solution are diminished, and it becomes lighter in proportion as its water is deposited; and also, when it is completely precipitated, which may happen either by a slower process, when the dissolved water falls in a drizzling rain, or by a more sudden process, when it descends in brisk showers. *Philos. Trans.* vol. 67, pa. 257; and Phipps's *Voyage towards the North Pole*, pa. 211.

Dr. Hamilton, professor of philosophy in the university of Dublin, transmitted to the Royal Society in 1765, a long dissertation on the nature of evaporation, in which he proposes and establishes this theory of solution; and though other writers had been prior in their conjectures, and even in their reasoning on this subject, Dr. Hamilton assures us, that he has not represented any thing as new which he was conscious had ever been proposed by any one before him, even as a conjecture. Dr. Hamilton having evinced the agreement between solution and evaporation, concludes, that evaporation is nothing more than a gradual solution of water in air, produced and promoted by attraction, heat, and motion, just as other solutions are effected.

In order to account for the ascent of aqueous vapours into the atmosphere, this ingenious writer observes, that the lower beds of the air being pressed by the weight of the upper beds against the surface of the water, and continually rubbing upon it by its motion, attracts and dissolves those particles with which it is in contact, and separates them from the rest of the water. And since the cause of solution in this case is the stronger attraction of the particles of water towards the air than towards each other, those that are already dissolved and taken up, will be still further raised by the attraction of the dry air that lies over them, and thus they will diffuse themselves, rising gradually higher and higher, and so leave the lower strata of air not so much saturated but that it will still be able to dissolve and take up fresh particles of water; which process is greatly promoted by the motion of the wind. When the vapours are thus raised and carried by the winds into the higher and colder parts of the atmosphere, some of them will coalesce into small particles, which slightly attracting each other, and being intermixed with air, will form clouds; and these clouds will float at different heights, according to the quantity of vapour borne up, and the degree of heat in the upper parts of the atmosphere: and thus clouds are generally higher in summer than in winter. When the clouds are much increased by a continual addition of vapours, and their particles are driven close together by the force of the winds, they will run into drops heavy enough to fall down in rain. If the clouds be frozen before their particles are gathered into drops, small pieces of them, being condensed and made

heavier by the cold, fall down in thin flakes of snow. When the particles are formed into drops before they are frozen, they become hailstones. When the air is replete with vapours, and a cold breeze springs up, which checks the solution of them, clouds are formed in the lower parts of the atmosphere, and compose a mist or fog, which usually happens in a cold morning, and is dispersed when the sun has warmed the air, and made it capable of dissolving these watery particles. Southerly winds commonly bring rain, because, being warm and replete with aqueous vapours, they are cooled by coming into a colder climate; and therefore they part with some of them, which precipitate in rain: whereas northerly winds, being cold, and acquiring additional heat by coming into a warmer climate, are ready to dissolve and receive more vapour than they before contained; and therefore are commonly attended with fair weather.

Changes of the air, with respect to its density and rarity, as well as its heat and cold, will produce contrary effects in the solution of water, and the consequent ascent or fall of vapours. Several experiments have been made which prove that air, when rarefied, cannot keep so much water dissolved in it as it does in a more condensed state; and therefore when the atmosphere is saturated with water, and changes from a denser to a rarer state, the high and colder parts of it will let go some of the water before it is dissolved, forming new clouds, and disposing them to fall down in rain: but a change from a rarer to a denser state will stop the precipitation of the water, and enable the air to dissolve, either in whole or in part, some of those clouds that were formed before, and render their particles less apt to run into drops and fall down in rain: on this account, we generally find that the rarefied and condensed states of the atmosphere are respectively attended with rain or fair weather. See more on this subject in the *Philos. Trans.* vol. 55, pa. 146; or Hamilton's *Philosophical Essays*, pa. 33.

Dr. Halley, before mentioned, furnished several experiments on the evaporation of water; the result of which is contained in the following articles: 1. That water salted to about the same degree as sea-water, and exposed to a heat equal to that of a summer's day, did, from a circular surface of about 8 inches diameter, evaporate at the rate of 6 ounces in 24 hours: whence by a calculus he finds that, in such circumstances, the water evaporates 1-10th of an inch deep in 12 hours: which quantity, he observes, will be found abundantly sufficient to furnish all the rains, springs, dews, &c. By this experiment, every 10 square inches of surface of the water, yield in vapour, per diem, a cubic inch of water: and each square foot half a wine pint; every space of 4 feet square, a gallon; a mile square, 6914 tons; and a square degree, of 69 English miles, will evaporate 33 millions of tons a day; and thus the whole Mediterranean, which is computed to contain 160 square degrees, will yield at least 5280 millions of tons each day. *Philos. Trans.* No. 189; or my *Abridg.* vol. 3, pa. 387.—2. A surface of 8 square inches, evaporated purely by the natural warmth of the weather, without either wind or sun, in the course of a whole year, 16292 grains of water, or 64 cubic inches; consequently, the depth of water thus evaporated in one year, amounts to 8 inches. But this being too little to answer the experiments of the French, who found that it rained 19 inches of water in one year at Paris; or those of Mr. Townley, who found the annual quantity of rain in Lancashire above 40 inches;

he therefore concludes, that the sun and wind contribute more to evaporation than any internal heat or agitation of the water. In effect, Dr. Halley fixes the annual evaporation of London at 48 inches; and Dr. Dobson states the same for Liverpool at $36\frac{3}{4}$ inches. Philos. Trans. vol. 67, p. 252.

3. The effect of the wind is very considerable, on a double account; for the same observations show a very singular quality in the vapours of water, viz., that of adhering to the surface that exhaled them, which they clothe as it were with a fleece of vaporous air; which once investing the vapour, it afterwards rises in much less quantity. Whence the quantity of water lost in 24 hours, when the air is very still, was very small, in proportion to what went off when there was a brisk gale of wind abroad to dissipate the fleece, and make room for the emission of vapour; and this, even though the experiment was made in a place as secure from the wind as could be contrived. Moreover, this fleece of water, hanging to the surface of waters in still weather, is the occasion of very singular appearances, by the refraction of the vapours differing from and exceeding that of common air; whence every thing appears more lofty, or raised above its usual level, as houses, steeples, ships, &c.

4. The same experiments show that the evaporation in May, June, July, and August, which are nearly equal, are about three times as great as those in the months of November, December, January, and February. Philos. Trans. No. 212, or my Abridg. vol. 3, pa. 658.

Dr. Brownrigg, in his Art of making common salt, pa. 189, fixes the evaporation of some parts of England at 73.8 inches during the months of May, June, July, and August; and the evaporation of the whole year at more than 140 inches. But the evaporation of the four summer months at Liverpool, on a medium of 4 years, was found to be only 18.88 inches. Also Dr. Hales calculates the greatest annual evaporation from the surface of the earth in England at 6.65 inches; and therefore the annual evaporation from a surface of water, is to the annual evaporation from the surface of the earth at Liverpool, nearly as 6 to 1. Philos. Trans. vol. 67, ubi supra.

In the Transactions of the American Philosophical Society, vol. 3, pa. 125, there is an ingenious paper on evaporation, by Dr. Wistar: where he shows that evaporation arises when the moist body is warmer than the medium it is inclosed in; and, on the contrary, it acquires moisture from the air, the colder the body is. This carrying off, and acquiring of moisture, it is shown, is by the passage of heat out of the body, or into it.

EUCLID, of Megara, a celebrated philosopher and logician; he was a disciple of Socrates, and flourished about 400 years before Christ. The Athenians having prohibited the Megarians from entering their city on pain of death, this philosopher disguised himself in women's clothes to attend the lectures of Socrates. After the death of Socrates, Plato and other philosophers went to Euclid at Megara, to shelter themselves from the tyrants who governed Athens. Euclid admitted but one chief good; which he at different times called God, or the Spirit, or Providence.

This philosopher has, by some, been confounded with Euclid of Alexandria, the prince of geometers; but independently of the different subject of their writings, it is well known that Euclid of Megara flourished at least a century before Euclid of Alexandria was born.

EUCLID, the celebrated mathematician, according to the

account of Pappus and Proclus, was born at Alexandria, in Egypt, where he flourished and taught mathematics with great applause, under the reign of Ptolemy Lagos, about 280 years before Christ. Some Arabian historians, however, inform us, that he was born at Tyre, that his father's name was Naucrates, an inhabitant of Damas.—The particular place of his nativity appears, therefore, to be uncertain; but whether or not Alexandria had the honour of giving birth to this celebrated mathematician, all historians agree that he flourished and taught mathematics there, at the time above mentioned; which city, from that period to the conquest of it by the Saracens, seems to have been the residence, if not the birth-place, of all the most eminent mathematicians of that time. Euclid reduced into regularity and order all the fundamental principles of pure mathematics, which had been delivered down by Thales, Pythagoras, Eudoxus, and other mathematicians before him, and added many others of his own: on which account it is said he was the first who reduced arithmetic and geometry into the form of a science. He likewise applied himself to the study of mixed mathematics, particularly to astronomy and optics.

His works, as we learn from Pappus and Proclus, are the Elements, Data, Introduction to Harmony, Phenomena, Optics, Catoptrics, a Treatise on the Division of Superficies, Porisms, Loci ad Superficem, Fallacies, and Four books of Conics. The most celebrated of these, is the first work, the Elements of Geometry; of which there have been numberless editions, in all languages; and a fine edition of all his works, now extant, was printed in 1703, by David Gregory, Savilian professor of astronomy at Oxford.

The Elements, as commonly published, consist of 15 books, of which the last two, it is suspected, are not Euclid's, but a comment of Hypsicles of Alexandria, who lived 200 years after him. They are divided into three parts, viz., the Contemplation of Superficies, Numbers, and Solids: the first 4 books treat of planes only; the 5th of the proportions of magnitudes in general; the 6th of the proportion of plane figures; the 7th, 8th, and 9th, give us the fundamental properties of numbers; the 10th contains the theory of commensurable and incommensurable lines and spaces; the 11th, 12th, 13th, 14th, and 15th, treat of the doctrine of solids.

There is no doubt but, before Euclid, Elements of Geometry were compiled by Hippocrates of Chios, Eudoxus, Leon, and many others, mentioned by Proclus in the beginning of his second book; for he affirms that Euclid new-ordered many things in the Elements of Eudoxus, completed many things in those of Theatetus, and besides strengthened such propositions as before were too slightly, or but superficially established, with the most firm and convincing demonstrations.

History is silent as to the time of Euclid's death, or his age. But Pappus represents him as a person of a courteous and agreeable behaviour, and in great esteem with Ptolemy Lagos, king of Egypt; who one day asking him, whether there was not any shorter way of coming at geometry than by his Elements, Euclid is said to have answered, "that there was no royal road to geometry."

EUDIOMETER, an instrument for determining the purity of the air, or the quantity of pure and dephlogisticated or vital air contained in it, chiefly by means of its diminution on a mixture with nitrous air.

Instruments of this kind were first made, in consequence of the experiments and discoveries of Dr. Priestley, for de-

termining the salubrity of different kinds of air. That writer having discovered, that when nitrous air is mixed with any other air, their original bulk is diminished; and that the diminution is nearly, if not exactly, in proportion to its salubrity; he was hence led to adopt nitrous air as a true test of the purity of respirable air; and nothing more seemed to be necessary but an easy, expeditious, and accurate method of estimating the degree of diminution in different cases; and for this purpose, the eudiometer was contrived; of which several kinds have been invented, the principal of which are the following.

I. The eudiometer originally used by Dr. Priestley is a divided glass tube, into which, after having filled it with common water, and inverted it into the same, one measure or more of common air, and an equal quantity of nitrous air, are introduced by means of a small phial, which is called the measure; and thus the diminution of the volume of the mixture, which is seen at once by means of the graduations of the tube, instantly discovers the purity of the air required.

II. The discovery of Dr. Priestley was announced to the public in the year 1772; and several persons, both at home and abroad, presently availed themselves of it, by framing other more accurate instruments. The first of these was contrived by M. Landriani; a description of which is given in the 6th volume of Rosier's Journal, for the year 1775. It consists of a glass tube, fitted, by grinding, to a cylindrical vessel, to which are joined two glass cocks and a small basin; the whole being fixed to a wooden frame. In this instrument quicksilver is used instead of water; though that is attended with an inconvenience, because the nitrous air acts upon the metal, and renders the experiment ambiguous.

III. In 1777, Mr. Magellan published an account of three eudiometers invented by himself, consisting of glass vessels of rather difficult construction, and troublesome to use. M. Cavallo observes, that the construction of all the three is founded on a supposition, that the mixture of nitrous and atmospherical air, having continued for some time to diminish, afterwards increases again; which it seems is a mistake: nor do they give accurate or uniform results, in experiments made with nitrous and common air of precisely the same quality.

IV. A preferable and very accurate method of discovering the purity of the air by means of a eudiometer, is recommended by M. Fontana. The instrument is originally nothing more than a divided glass tube, though the inventor afterwards added to it a complicated apparatus, perhaps of little or no use. The first simple eudiometer consisted only of a glass tube, uniformly cylindrical, about 18 inches long, and $\frac{3}{4}$ ths of an inch diameter within-side, the outside being marked with a diamond at such distances as are exactly filled by equal measures of elastic fluids: and when any parts of these divisions are required, the edge of a ruler, divided into inches and smaller parts, is held against the tube, so that the first division of the ruler may coincide with one of the marks on the tube. The nitrous and atmospherical air are introduced into this tube, in order to be diminished, and thence the purity of the atmospheric air ascertained.

V. M. Saussure of Geneva also invented a eudiometer, which he thinks is more exact than any of those before described; the apparatus of which is as follows: 1. A cylindrical glass bottle, with a ground stopple, containing about $5\frac{1}{2}$ ounces of air, which serves as a receiver for mix-

ing the two airs.—2. A small glass phial, to serve as a measure, and is about one-third the size of the receiver.—3. A small pair of scales that may weigh very exactly.—4. Several glass bottles, for containing the nitrous or other air to be used, and which may supply the place of the recipient when broken. The method of using this instrument is as follows:—The receiver is to be filled with water, closed exactly with its glass stopper, wiped dry on the outside, and then weighed very accurately. Being then immersed in a vessel of water, and held with the mouth downwards, the stopple is removed, and, by means of a funnel, two measures of common and one of nitrous air are introduced into it, one after another: these diminish as soon as they come into contact; in consequence of which the water enters the recipient in proportionable quantity. After being stopped and well shaken, to promote the diminution, the receiver is to be opened again under water; then stopped and shaken again, and so on for three times successively, after which the bottle is stopped for the last time under water, then taken out, wiped very clean and dry, and exactly weighed as before. It is plain that now, the bottle being filled partly with elastic fluid and partly with water, it must be lighter than when quite full of water; and the difference between those two weights, shows nearly what quantity of water would fill the space occupied by the diminished elastic fluid. But, in making experiments with airs of different degrees of purity, the said difference will be greater when the diminution is less, or when the air is less pure, and vice versa; by which means the comparative purity between two different kinds of air is determined.

VI. But as this method, notwithstanding the encomiums bestowed on it by the inventor, is subject to several errors and inconveniences; to remedy all these, another instrument was invented by M. Cavallo; the description of which, being long, may be seen in his Treatise on the Nature and Properties of Air, pa. 344.

Other constructions of the eudiometer have also been given by Mr. Cavendish and Mr. Scheele. For further information, see Magellan's Letter to Dr. Priestley, containing the Description of a Glass Apparatus, &c, and of New Eudiometers, &c, 1777, pa. 15, &c; Priestley's Exp. and Obs. on Air, vol. 3, preface and appendix; the methods of Dr. Ingelhousz in Philos. Trans. vol. 66, art. 15; see also the Philos. Trans. vol. 73; and Cavallo's Treatise on Air, pa. 274, 315, 316, 317, 328, 340, 344, and 348.

EUDOXUS, of Cnidus, a city of Caria in Asia Minor, flourished about 370 years before Christ. He learned geometry from Archytas, and afterwards travelled into Egypt to learn astronomy and other sciences. There he and Plato studied together, as Laertius informs us, for the space of 13 years; and afterwards came to Athens, fraught with all sorts of knowledge, which they had learned from the priests. Here Eudoxus opened a school; which he supported with so much glory and renown, that even Plato, though his friend, is said to have envied him. Eudoxus composed Elements of Geometry, from which Euclid liberally borrowed, as mentioned by Proclus. Cicero calls Eudoxus the greatest astronomer that had ever lived: and Petronius says, he spent the latter part of his life upon the top of a very high mountain, that he might contemplate the stars and the heavens with more convenience and less interruption: and we learn from Strabo, that there were some remains of his observatory at Cnidus to be seen even in his time. He died in the 55d year of his age.

EVECTION, is used by some astronomers for the libration of the moon; being an inequality in her motion, by which, at or near the quadratures, she is not in a line drawn through the centre of the earth to the sun, as she is at the syzygies, or conjunction and opposition, but makes an angle with that line of about $2^{\circ} 51'$. The motion of the moon about her axis only is equable, which rotation is performed exactly in the same time as she revolves about the earth; for which reason it is that she turns always the same face towards the earth nearly, and would do so exactly were it not that her menstrual motion about the earth, in an elliptic orbit, is not equable; on which account the moon, seen from the earth, appears to liberate a little upon her axis, sometimes from east to west, and sometimes from west to east; or some parts in the eastern limb of the moon go backwards and forwards a small space, and some that were conspicuous, are hid, and then appear again.

The term **Evection** is used by some astronomers to denote that equation of the moon's motion, which is proportional to the sine of double the distance of the moon from the sun, diminished by the moon's anomaly: this equation is not yet accurately determined; some state it at $1^{\circ} 30'$, others at $1^{\circ} 16'$, &c. It is the greatest of all the moon's equations, except the equation of the centre.

EVEN Number, is that which can be divided into two equal whole numbers; such as the series of alternate numbers, 2, 4, 6, 8, 10, &c, and is therefore properly expressed by the form $2n$.

EVENLY Even Number, is that which can be twice divided by 2, and therefore is expressed by the form $4n$.

EVENLY Odd Number, is that which can be only divided by 2 once, the quotient being an odd number, and is therefore of the form $4n + 2 = 2(m+1)$, that is, the quotient is of the form $2m+1$, which is therefore necessarily an odd number.

EVERARD'S SLIDING RULE, a particular sort of rule invented by Mr. Thomas Everard, for the purpose of gauging. See **SLIDING RULE**.

EULER (LEONARD), one of the most celebrated mathematicians of the 18th, or perhaps of any other century. He was a native of Basil, and was born April 15, 1707. The years of his infancy were passed at Richen, where his father was minister. He was afterwards sent to the university of Basil; and as his memory was astonishingly retentive, and his application regular, he performed his academical tasks with great rapidity; and all the time that he saved by this, was consecrated to the study of mathematics, which soon became his favourite science. The early progress he made in this branch of study, added fresh ardour to his application; by which he likewise obtained a distinguishing mark of the attention and esteem of professor John Bernoulli, who was then one of the most eminent mathematicians in Europe.

In 1723, M. Euler took his degree as master of arts; and delivered on that occasion a Latin discourse, in which he drew a comparison between the philosophy of Newton and the Cartesian system, which was received with the greatest applause. At his father's desire, he next applied himself to the study of the logy and the oriental languages; and though these studies were foreign to his predominant propensity, his success was considerable even in this respect: however, with his father's consent, he afterwards returned to mathematics as his principal object. In continuing to avail himself of the counsels and instructions of

M. Bernoulli, he contracted an intimate friendship with his two sons Nicholas and Daniel; and it was chiefly in consequence of these connexions that he afterwards became the principal ornament of the philosophical world.

The project of erecting an academy at Petersburg, which had been formed by Peter the Great, was executed by Catharine the 1st; and the two young Bernoullis being invited to Petersburg in 1725, promised Euler, who was desirous of following them, that they would use their endeavours to procure for him an advantageous settlement in that city. In the mean time, by their advice, he made close application to the study of philosophy, to which he made happy applications of his mathematical knowledge, in a dissertation on the nature and propagation of sound, and an answer to a prize question concerning the nassing of ships; to which the Academy of Sciences adjudged the accessit, or second rank, in the year 1727. From this latter discourse, and other circumstances, it appears that Euler had very early embarked in the curious and useful study of naval architecture, which he afterward enriched with so many valuable discoveries. The study of mathematics and philosophy however did not solely engage his attention, as he in the mean time attended the medical and botanical lectures of the professors at Basil.

Euler's merit would have given him an easy admission to honourable preferment either in the magistracy or university of his native city, if both civil and academical honours had not been there distributed by lot. This being against him in a certain promotion, he left his country, set out for Petersburg, and was made joint professor with his countrymen Hermann and Daniel Bernoulli, in the university of that city.

At his first setting out in his new career, he enriched the academical collection with many memoirs, which excited a noble emulation between him and the Bernoullis; an emulation that always continued, without either degenerating into a selfish jealousy, or producing the least alteration in their friendship. It was at this time that he carried to new degrees of perfection the integral calculus, invented the calculation by sines, reduced analytical operations to a greater simplicity, and thus was enabled to throw new light on all the parts of mathematical science.

In 1730, Euler was promoted to the professorship of natural philosophy; and in 1733 he succeeded his friend D. Bernoulli in the mathematical chair. In 1735, a problem was proposed by the academy, which required expedition, and for the calculation of which some eminent mathematicians had demanded the space of some months. The problem was undertaken by Euler, who completed the calculation in three days, to the great astonishment of the academy: but the violent and laborious efforts that he made to accomplish it, threw him into a fever, that endangered his life, and deprived him of the use of his right eye, which afterwards brought on a total blindness.

The Academy of Sciences at Paris, which in 1738 had adjudged the prize to his memoir Concerning the Nature and Properties of Fire, proposed for the year 1740 the important subject of the Tides of the Sea; a problem whose solution comprehended the theory of the solar system, and required the most arduous calculations. Euler's solution of this question was adjudged a master-piece of analysis and geometry; and it was more honourable for him to share the academical prize with such illustrious competitors as Maclaurin and Daniel Bernoulli, than to have carried it away from rivals of less magnitude. Seldom, if

ever, did such a brilliant competition adorn the annals of the academy; and perhaps no subject, proposed by that learned body, was ever treated with such force of reasoning and accuracy of investigation, as that which here displayed the philosophical powers of this extraordinary triumvirate.

In the year 1741, Euler was invited to Berlin to direct and assist the academy that was there rising into fame. On this occasion he enriched the last volume of the Miscellanies (Melanges) of Berlin with five memoirs, which form an eminent, perhaps the principal, figure in that collection. These were followed, with amazing rapidity, by a great number of important researches, which are dispersed through the memoirs of the Prussian academy; a volume of which has been regularly published every year since its establishment in 1744. The labours of Euler will appear more particularly astonishing, when it is considered, that while he was enriching the academy of Berlin with a profusion of memoirs, on the deepest parts of mathematical science, contained always under some new points of view, and often replete with sublime truths, and sometimes discoveries of great importance; he still continued his philosophical contributions to the Petersburg academy, whose memoirs display the marvellous fecundity of his genius.

It was with great difficulty that this extraordinary man, in 1766, obtained permission from the king of Prussia to return to Petersburg, where he wished to pass the remainder of his days; but soon after his return, which was graciously rewarded by the munificence of Catharine the 2d, he was seized with a violent disorder, which ended in the total loss of his sight: a cataract, formed in his left eye, which had been essentially damaged by the loss of the other eye, and too close an application to study, deprived him entirely of the use of that organ. It was in this distressing situation that he dictated to his servant, a tailor's apprentice, who was absolutely devoid of mathematical knowledge, his Elements of Algebra; which by their intrinsic merit in point of perspicuity and method, and the unhappy circumstances in which they were composed, have equally excited the wonder and applause of the learned. This work, though purely elementary, plainly exhibits the proofs of an inventive genius; and it is perhaps here alone that we meet with a complete theory of the Diophantine analysis.

About this time M. Euler was honoured by the Academy of Sciences at Paris with the place of one of the foreign members of that learned body; after which, the academical prize was adjudged to three of his memoirs, Concerning the Inequalities in the Motions of the Planets. The two prize questions proposed by the same Academy for 1770 and 1772 were designed to obtain from the labours of astronomers a more perfect Theory of the Moon. M. Euler, assisted by his eldest son, was a competitor for these prizes, and obtained them both. In this last memoir, he reserved for further consideration several inequalities of the moon's motion, which he could not determine in his first theory, on account of the complicated calculations in which the method he then employed had engaged him. He afterwards revised his whole theory, with the assistance of his son and Messrs. Kraft and Lexell; and pursued his researches till he had constructed the new tables, which appeared, together with the great work, in 1772. Instead of confining himself, as before, to the fruitless integration of three differential equations of the second de-

gree, which are furnished by mathematical principles, he reduced them to the three ordinates, which determine the place of the moon: and he divided into classes all the inequalities of that planet, as far as they depend either on the elongation of the sun and moon, or on the excentricity, or the parallax, or the inclination of the lunar orbit. All these means of investigation, employed with such art and dexterity as could only be expected from a genius of the first order, were attended with the greatest success; and it is impossible to observe without admiration, such immense calculations on the one hand, and on the other the ingenious methods employed by this great man to abridge them, and to facilitate their application to the real motion of the moon. But this admiration will become astonishment, when we consider at what period and in what circumstances all this was effected. It was when our author was totally blind, and consequently obliged to arrange all his computations by the sole powers of his memory and his genius: it was when he was embarrassed in his domestic affairs by a dreadful fire, that had consumed great part of his substance, and forced him to quit a ruined house, every corner of which was known to him by habit, which in some measure supplied the want of sight. It was in these circumstances that Euler composed a work which alone was sufficient to render his name immortal.

Some time after this, the famous oculist Wentzell, by couching the cataract, restored sight to our author; but the joy produced by this operation was of short duration. Some instances of negligence on the part of his surgeons, and his own impatience to use an organ, whose cure was not completely finished, deprived him a second time and for ever of his sight: a relapse which was also accompanied with tormenting pain. With the assistance of his sons, however, and of Messrs. Kraft and Lexell, he continued his labours: neither the infirmities of old age, the loss of his sight, nor the acuteness of the pain, could quell the ardour of his genius. He had engaged to furnish the Academy of Petersburg with as many memoirs as would be sufficient to complete its acts for 20 years after his death. In the space of 7 years he transmitted to the Academy above 70 memoirs, and above 200 more, left behind him, were revised and completed by a friend. Such of these memoirs as were of ancient date were separated from the rest, and form a collection that was published in the year 1783, under the title of Analytical Works.

The general knowledge of our author was more extensive than could well be expected, in one who had pursued, with such unremitting ardour, mathematics and astronomy as his favourite studies. He had made a very considerable progress in medical, botanical, and chemical science. What was still more extraordinary, he was an excellent scholar, and possessed in a high degree what is generally called erudition. He had attentively read the most eminent writers of ancient Rome; the civil and literary history of all ages and all nations was familiar to him; and foreigners, who were only acquainted with his works, were astonished to find in the conversation of a man, whose long life seemed solely occupied in mathematical and physical researches and discoveries, such an extensive acquaintance with the most interesting branches of literature. In this respect, no doubt, he was much indebted to a very uncommon memory, which seemed to retain every idea that was conveyed to it, either from reading or from meditation. He could repeat the Æneid of Virgil, from the beginning to the end, without hesitation, and indi-

cate the first and last line of every page of the edition he used.

Several attacks of a vertigo, in the beginning of September 1783, which did not prevent his computing the motions of the aerostatic globes, were however the fore-runners of his mild passage out of this life. While he was amusing himself at tea with one of his grand-children, he was struck with an apoplexy, which terminated his illustrious career at 76 years of age.

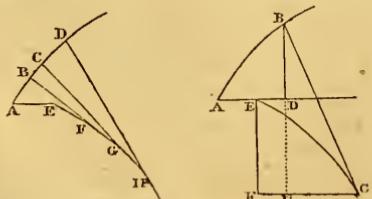

M. Euler's constitution was uncommonly strong and vigorous. His health was good; and the evening of his long life was calm and serene, sweetened by the fame that follows genius, the public esteem and respect that are never withheld from exemplary virtue, and several domestic comforts, which he was capable of feeling, and therefore deserved to enjoy.

The catalogue of his works has been printed in 50 pages, 14 of which contain the manuscript works.—The printed ones consist of works published separately, and works to be found in the memoirs of several Academies, viz, in 38 volumes of the Petersburg Acts (from 6 to 10 papers in each volume);—in several volumes of the Paris Acts;—in 26 volumes of the Berlin Acts (about 5 papers to each volume);—in the Acta Eruditiorum, in 2 volumes;—in the Miscellanea Taurinensis;—in vol. 9 of the Society of Ulysses;—in the Ephemerides of Berlin;—in the Mémoires de la Société Économique for 1766;—and in the Philos. Trans. by seven memoirs, from vol. 44 to vol. 62.

E VOLVENT, in the Higher Geometry, a term used by some writers for the involute, or curve resulting from the evolution of a curve, in contradistinction to that evolute, or curve supposed to be opened or evolved. See E VOLUTE, and INVOLUTE.

E VOLUTE, in the Higher Geometry, a curve first proposed by M. Huygens, and since much studied by many eminent mathematicians. It is any curve supposed to be evolved or opened, by having a thread wrapped close upon it, fastened at one end, and beginning to evolve or unwind the thread from the other end, keeping stretched the part evolved, or wound off; then this end of the thread will describe another curve called the Involute. Or the same involute is described in the contrary way, by wrapping the thread upon the evolute, keeping it always stretched.

Thus, if $EFGH$ is any curve, and AE either a part of the curve, or a right line; then if a thread be wound close upon the curve from A to H , where it is fixed, and then be unwound from A ; the curve $AEGFH$, from which it is evolved, is called the evolute; and the other curve $ABCD$, described by the end of the thread, as it evolves or unwinds, is the involute. Or, if the thread HD , fixed at H , be wound or wrapped upon the evolute $HGEFA$, keeping it always stretched, as at the several positions of it H , GC , FB , EA , the extremity will describe the involute curve $DCBA$.

From this description it appears, 1. That the parts of the thread at any positions, as EA , EF , GC , HD , &c, are radii of curvature, or osculatory radii, of the involute curve, at the points A , B , C , D .

2. The same parts of the thread are also equal to the corresponding lengths AE , AEP , $AEFG$, &c, of the evolute; that is,

$$AE = AE \text{ is the rad. of curvature to the point } A,$$

$$BF = AF \quad \vdots \quad \vdots \quad \vdots \quad B,$$

$$CG = AG \quad \vdots \quad \vdots \quad \vdots \quad C,$$

$$DH = AH \quad \vdots \quad \vdots \quad \vdots \quad D,$$

3. Any radius of curvature BF , is perpendicular to the involute at the point B , and is a tangent to the evolute curve at the point F .—4. The evolute is the locus of the centre of curvature of the involute curve.

The finding the radii of evolutes, is a matter of great importance in the higher speculations of geometry; and is even sometimes useful in practice; as is shown by Huygens, the inventor of this theory, in applying it to the pendulum. Horol. Oscil. part 3. For the doctrine of the oscula of evolutes we are indebted to M. Leibnitz, who first showed the use of evolutes in the measuring of curves.

To find the EVOLUTE and INVOLUTE CURVES, the one from the other.—For this purpose, put

$$z = AB \text{ the involute curve,}$$

$$x = AD \text{ the absciss of the involute,}$$

$$y = DB \text{ its ordinate,}$$

$$r = BC \text{ its radius of curvature,}$$

$$v = EF \text{ the absciss of the evolute,}$$

$$u = FC \text{ its ordinate, and}$$

$$a = AE \text{ a given line (fig. 2 above).}$$

Then, by the nature of the radius of curvature, it is

$$r = \frac{\dot{x}^2}{\ddot{x} - \ddot{y}} = EC = AE + EC; \text{ also by sim. triangles,}$$

$$\dot{z} : \dot{x} :: r : GB = \frac{\dot{x}\dot{z}}{z} = \frac{\dot{x}\dot{z}}{\ddot{x} - \ddot{y}},$$

$$\dot{z} : j :: r : GC = \frac{\dot{y}\dot{z}}{z} = \frac{\dot{y}\dot{z}}{\ddot{x} - \ddot{y}}.$$

$$\text{Hence } EF = GB - DB = \frac{\dot{x}\dot{z}}{\ddot{x} - \ddot{y}} - y = v; \text{ and}$$

$$FC = AD - AE + GC = x - a + \frac{\dot{y}\dot{z}}{\ddot{x} - \ddot{y}} = u; \text{ which are the values of the absciss and ordinate of the evolute curve } EC; \text{ which therefore may be found when the involute is given.}$$

On the other hand, if v and u , or the evolute be given: then, putting the given curve $EC = s$; since $CB = AE + EC$, or $r = a + s$, this gives r the radius of curvature. Also, by similar triangles, there result these proportions, viz,

$$s : \dot{v} :: r : \frac{\dot{y}\dot{z}}{s} = \frac{a+s}{s} \dot{v} = GB,$$

$$s : \dot{u} :: r : \frac{\dot{y}\dot{z}}{s} = \frac{a+s}{s} \dot{u} = GC; \text{ therefore}$$

$$AD = AE + FC - GC = a + u - \frac{a+s}{s} \dot{u} = x,$$

and $DB = GB - EF = \frac{a+s}{s} \dot{v} - v = y$; which are the absciss and ordinate of the involute curve, and which may therefore be found, when the evolute is given. It may also be observed that $\dot{s}^2 = \dot{v}^2 + \dot{u}^2$, and $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$. And either of the quantities x , y , may be supposed to flow equably, in which case the respective second fluxion \ddot{x} or \ddot{y} will be nothing, and the corresponding term in the denominator $\ddot{x} - \ddot{y}$ will vanish, leaving only the other

term in it; which will have the effect of rendering the operation simpler.

For Example. If it be required to find the evolution EC when the given involute AB is the common parabola, whose equation is $px = y^2$, the parameter being p .

Here $y = \sqrt{px}$, $j = \frac{1}{2} \dot{x} \sqrt{\frac{p}{x}}$ and $\dot{y} = \frac{-\dot{x}^2}{4x^2} \sqrt{\frac{p}{x}}$, making $\ddot{x} = 0$. Then, to find first AE the radius of curvature of the parabola AB at the vertex, when $\dot{x} = 0$, the general value of the radius of curvature above given becomes

$$r = \frac{\dot{x}^2}{-x\ddot{y}} = \frac{(\dot{x}^2 + \dot{y}^2)^{\frac{3}{2}}}{-x\dot{y}} = (\text{by substituting the value of } \dot{y} \text{ and } \ddot{y} \text{ &c})$$

$\frac{(p+4x)^{\frac{3}{2}}}{2\sqrt{x}}$, which is the general value of r or BC , the radius of curvature, for any value of x or AD ; and when x or AD is $= 0$ or nothing, the value of r , or AE , becomes

then $a = \frac{p^{\frac{3}{2}}}{2\sqrt{p}} = \frac{1}{2}p$ only; or half the parameter of the axis is the radius of curvature at the vertex of the parabola.

Again, in the general values of v and u above given, by substituting the values of j , \dot{y} , and \ddot{x} , also 0 for \dot{x} , and $\frac{1}{2}p$ for a ; those quantities become

$$v = \frac{\dot{x}^2}{-} - y = \frac{\dot{x}^2 + \dot{y}^2}{-\dot{y}} - y = \frac{4x^{\frac{3}{2}}}{p^{\frac{1}{2}}} = 4x\sqrt{\frac{x}{p}}$$

$$u = x - a + \frac{\dot{x}\dot{y}}{-\dot{x}\dot{y}} = 3x + \frac{1}{2}p - a = 3x.$$

Hence then, comparing the values of x^2 in both of these, we have $x^2 = \frac{1}{16}pv^2 = \frac{1}{16}u^2$, and conse^q. $27pv^2 = 16u^2$; which is the equation between the absciss and ordinate of the evolute curve EC , showing it to be the semicubical parabola.

In like manner the evolute to any other curve is found. The evolute to the common cycloid, is an equal cycloid; a property first demonstrated by Huygens, and which he used as a contrivance to make a pendulum vibrate in the curve of a cycloid. See his *Horolog. Oscil.* See also, on the subject of evolute and involute curves, the *Fluxions* of Newton, Maclaurin, Simpson, De l'Hôpital, &c; Wolf. *ELEM. MATH.* tom. I, &c., &c.

M. Varignón has applied the doctrine of the radius of the evolute, to that of central forces; so that having the radius of the evolute of any curve, there may be found the value of the central force of a body; which, moving in that curve, is found in the same point where that radius terminates; or reciprocally, having the central force given, the radius of the evolute may be determined. *Hist. de l'Acad. an. 1706.*

The variation of curvature of the line described by the evolution of a curve, is measured by the ratio of the radius of curvature of the evolute, to the radius of curvature of the line described by the evolution. See Maclaurin's *Flux.* art. 402, prop. 36.

Imperfect Evolute, a name given by M. Reaumur to a new kind of evolute. Mathematicians had hitherto only considered the perpendiculars let fall from the involute on the convex side of the evolute: but if other lines not perpendicular be drawn upon the same points, provided they be all drawn under the same angle, the effect will still be the same; that is, the oblique lines will all intersect in the curve, and by their intersections form the infi-

nitely small sides of a new curve, to which they would be so many tangents.—Such a curve is a kind of evolute, and has its radii; but it is an imperfect one, since the radii are not perpendicular to the first curve, or involute. *Hist. de l'Acad. &c., an. 1709.*

EVOLUTION, in Arithmetic and Algebra, denotes the extraction of roots. In which sense it stands opposed to involution, which is the raising of powers.

EVOLUTION, in Geometry, the opening, or unfolding of a curve, and making it describe an evolvent.

The equable evolution of the periphery of a circle, or other curve, is such a gradual approach of the circumference to rectitude, as that its parts do all concur, and equally evolve or unbend; so that the same line becomes successively a less arc of a reciprocally greater circle; till at last they change into a straight line. In the *Philos. Trans.* No. 260, a new quadratrix to the circle is found by this means, being the curve described by the equable evolution of its periphery.

EURYTHMY, in Architecture, Painting, and Sculpture, is a kind of majesty, elegance, and easiness appearing in the composition of certain members or parts of a body, building, or painting, and resulting from the fine and exact proportions of them.

EUSTYLE, is the best manner of placing columns, with regard to their distance; which, according to Vitruvius, should be 4 modules, or $2\frac{1}{2}$ diameters.

EUTOCIUS, a respectable Greek mathematician, of Ascalon, in Palestine, about the year of Christ 550. He was one of the most considerable mathematicians that flourished about the decline of the sciences among the Greeks, and had for his preceptor Isidorus, the principal architect of the church of St. Sophia at Constantinople. He is chiefly known however by his commentaries on the works of the two ancient authors, Archimedes and Apollonius. Those two commentaries are both excellent compositions, to which we owe many useful observations in the history of the mathematics.

His commentaries on Apollonius are published in Halley's edition of the works of that author; and those on Archimedes, first in the Basle edition, in Greek and Latin, in 1543, and since in some others, as the late Oxford edition, in 1792. Of these commentaries, those rank the highest, which illustrate Archimedes's work on the Sphere and Cylinder; in one of which we have a recital of the various methods practised by the ancients in the solution of the Delian problem, or that of doubling the cube. The others are of less value; though it cannot be regretted that Eutocius did not pursue his plan of commenting on all the works of Archimedes, with the same attention and diligence which he employed in his remarks on the sphere and cylinder.

EXCENTRIC, is applied to such figures, circles, spheres, &c., as have not the same centre; as opposed to concentric, which have the same centre.

EXCENTRIC, or *Excentric Circle*, in the ancient Ptolemaic Astronomy, was the very orbit of the planet itself which it was supposed to describe about the earth, and which was conceived excentric with it; called also the deferent. But instead of these excentric circles round the earth, the planets are now known to describe elliptic orbits about the sun; which accounts for all the irregularities of their motions, and their various distances from the earth, &c., more justly and naturally.

EXCENTRIC, or Excentric Circle, in the Modern Astronomy, is the circle described from the centre of the orbit of a planet, with half the greatest axis as a radius; or it is the circle that circumscribes the elliptic orbit of the planet; as the circle $\Delta Q B$.

EXCENTRIC Anomaly, or Anomaly of the Centre, is an arc AQ of the excentric circle, intercepted between the aphelion A , and the right line QB , drawn through the centre P of the planet perpendicular to the line of the apes AB .

EXCENTRIC Equation, in the Astronomy of the ancients, is an angle made by a line drawn from the centre of the earth, with another line drawn from the centre of the excentric, to the body or place of any planet. This is the same with the prosthapheresis; and is equal to the difference, accounted in an arch of the ecliptic, between the real and apparent place of the sun or planet. See *EQUATION OF the Centre*.

EXCENTRIC Place of a planet, in its orbit, is the heliocentric place, or that in which it appears as seen from the sun.

EXCENTRIC Place in the ecliptic, is the point of the ecliptic to which the planet is referred as viewed from the sun; and which coincides with the heliocentric longitude.

EXCENTRICITY, is the distance between the centres of two circles, or spheres, which have not the same centre.

EXCENTRICITY, in the Old Astronomy, is the distance between the centre of a planet and the centre of the earth. — That the planets have such an eccentricity, is allowed on all sides, being evident from various circumstances; and particularly from this, that the planets at some times appear larger, and at other times less; which can only proceed from hence, that their orbits being excentric to the earth, in some parts of those orbits the planets are nearer to us, and in others more remote. And as to the eccentricities of the sun and moon, it is thought they are sufficiently proved, both from eclipses, from the moon's greater and less parallax at the same distance from the zenith, and from the sun's continuing longer by 8 days in the northern hemisphere than in the southern one.

EXCENTRICITY, in the new Astronomy, is the distance cs between the sun s and the centre c of a planet's orbit; or the distance of the centre from the focus of the elliptic orbit; called also the Simple or Single Excentricity.

When the greatest equation of the centre is given, the excentricity of the earth's orbit may be found by the following proportion; viz,

As the diameter of a circle in degrees,

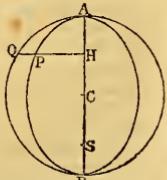

Is to the diameter in equal parts;

So is the greatest equation of the centre in degrees,

To the excentricity in equal parts. Thus,

Greatest equat. of the cent. $1^{\circ}55'33'' = 1^{\circ}9258333 \&c.$ The diam. of a circ. being 1, its circumf. is $3\cdot1415926$. Then $3\cdot1415926 : 1 : : 360^{\circ} : 114^{\circ}5915609$ diam. in deg. And $114^{\circ}5915609 : 1 : : 1^{\circ}9258333 : 0^{\circ}016806$, the ex. Hence, by adding this to 1, and subtracting it from 1, gives $0^{\circ}016806 = as$ the aphelion distance, and $0^{\circ}983194 = bs$ the perihelion distance.

See Robertson's Elem. of Navig. book 5, pa. 286.

Otherwise, thus: Since it is found that the sun's greatest apparent semi-diameter is to his least, as $32'43''$ to $31'38''$, or as $1963''$ to $1898''$; the sun's greatest distance from the earth will be to his least, or as to bs , as 1963 to 1898 ; of which,

$$\text{the half dif. is } 32\frac{1}{2} = cs,$$

and half sum $1930\frac{1}{2} = cb$; therefore,

as $1930\frac{1}{2} : 32\frac{1}{2} : 1 : 1 : 016835 = cs$ the excentricity, to the mean distance or semi-axis 1 ; which is nearly the same as before.

The excentricities of the orbits of the several planets, in parts of their own mean distances 1000, and also in English miles, are as below, viz, the excentricity of the orbit of

	Parts.	Miles.
Mercury	210	$7,730,000$
Venus	7	$482,000$
Earth	17	$1,618,000$
Mars	93	$13,486,000$
Vesta	36	$8,112,500$
Juno	254	$64,315,000$
Pallas	246	$73,600,000$
Ceres	78	$20,615,000$
Jupiter	48	$23,760,000$
Saturn	55	$49,940,000$
Herschel	$47\frac{1}{2}$	$86,000,000$

Or the excentricities of the orbits in parts of their own mean distances 1, and the secular variations of the same, according to Laplace, are as below:

	Excentr.	Sec. Variat.
Mercury	$0\cdot02551494$	$0\cdot00000387$
Venus	$0\cdot00685298$	$0\cdot00006371$
Earth	$0\cdot01683518$	$0\cdot00004163$
Mars	$0\cdot09313400$	$0\cdot00009018$
Jupiter	$0\cdot04817840$	$0\cdot00015935$
Saturn	$0\cdot05616830$	$0\cdot00031240$
Herschel	$0\cdot04667030$	$0\cdot00002507$
or Uranus }	$0\cdot04667030$	$0\cdot00002507$

Excentricities of the Orbits of the new or Telescopic Planets, are,

Piazzi, or Ceres (discovered 1801)	$- - -$	$0\cdot078349$
Olbers, or Pallas (- - 1802)	$- - -$	$0\cdot245584$
Harding, or Juno (- - 1804)	$- - -$	$0\cdot254944$
Ditto, according to Burckhardt	$- - -$	$0\cdot25096$
Olbers 2d, or Vesta (discov. 1807)	$- - -$	$0\cdot093220$

The excentricity of the moon's orbit is $0\cdot0548553$, the greater semi-axis being 1.

Double EXCENTRICITY, is the distance between the two foci of the elliptic orbit, and is equal to double the single excentricity above given.

EXCESS (Spherical) in Trigonometry, is the excess of the sum of the three angles, of any spherical triangle, above 2 right angles. Let, a , b , c , be the angles of a spherical triangle; and a , b , c , the sides opposite to the angles A , B , C , respectively; $n = 2$ right angles, and $r =$ the radius of the sphere; then the spherical excess (α) is ascertained by the following theorem, first given by Simon Lhuillier of Geneva: Tan. $\frac{1}{2}E$, or tan. $\frac{1}{2}(A + B + c - n) = \frac{1}{r\sqrt{(tan. \frac{a+b+c}{4}. tan. \frac{a+b-c}{4}. tan. \frac{a+c-b}{4}. tan. \frac{b+c-a}{4})}}$, or $= \frac{1}{r\sqrt{(tan. \frac{s}{2}. tan. \frac{s-a}{2}. tan. \frac{s-b}{2}. tan. \frac{s-c}{2})}}$; where $s = \frac{1}{2}(a + b + c)$, half the sum of the sides. M. Puissant gives the following theorems for the excess:

$$e = \left(\frac{r''}{r}\right) a^2 \sin. 2c + \left(\frac{r''}{r}\right) c^2 \cdot \sin. 2a, \text{ or}$$

$e = \left(\frac{r''}{2r'}\right) bh$; where b = the base, and h = the height of the triangle, also r'' = the number of seconds contained in radius.

In a memoir on this by Burckhardt, in vol. 7 of the Memoirs of the National Institute of France, it is shown that the same property equally applies to such small triangles on the spheroidal surface of the earth as occur in the usual geodetical operations; as no appreciable error will arise by considering such triangles as spherical ones, nor in any whose sides are small in comparison with a great circle of the sphere. It follows, says the author, that the small triangles traced on the surface of a spheroid may be calculated on the same principles as such triangles traced on the surface of a sphere; and both of them may be reduced to rectilinear triangles, by diminishing their angles, each by a quantity equal to one-third of the area of a similar triangle, described on a sphere whose radius is 1.—The solution of spheroidal triangles, whose sides are small with regard to the dimensions of the spheroid, depends therefore immediately on that of rectilinear triangles; not only when the spheroid is elliptical and of revolution, but when it is in any manner irregular, provided only that it differs but little from a sphere.

EXCHANGE, in Arithmetic, is the bartering or exchanging the money of one place for that of another; or finding what quantity of the money of one place is equal to a given sum of another, according to a certain course of exchange.—The several operations in this rule are only different applications of the Rule of Three: which may be seen in most books of arithmetic.

Arbitration of Exchange, is the method of remitting to, and drawing upon, foreign places, in such a manner as shall turn out the most profitable.

Arbitration is either simple or compound.

Simple Arbitration respects three places only. Here, by comparing the par of arbitration between a first and second place, and between the 1st and a 3d, the rate between the 2d and 3d is discovered; whence a person can judge how to remit or draw to the most advantage, and to determine what that advantage is.

Compound Arbitration respects the cases in which the exchanges among three, four, or more places are concerned. A person who knows at what rate he can draw or remit directly, and also has advice of the course of exchange in foreign parts, may trace out a path for circulating his money, through more or fewer of such places, and also in such order, as to make a benefit of his skill and credit: and in this lies the great art of such negotiations. See Hutton's Arithmetic, pa. 105; also the articles **ARBITRATION**, and the **CURIA RUE**.

EXCURSION, in Astronomy. See **ELONGATION**.

Circles of Excursion. See **CIRCLES**.

EXEGESIS, or **EXEGETICA**, in Algebra, is the finding, either in numbers or lines, the roots of the equation of a problem, according as the problem is either numeral or geometrical.

EXHALATION, a fume or steam, issuing from a body, and diffusing itself in the atmosphere. The terms exhalation and vapour are often used indifferently; but the more accurate writers distinguish them, appropriating the term vapour to the moist fumes raised from water and other

liquid bodies; and the term exhalation to the dry ones emitted from solid bodies; as earth, minerals, &c. In this sense, exhalations are dry and subtle corpuscles, or effluvia, loosened from hard terrestrial bodies, either by the heat of the sun, or the action of the air, or some other cause; being emitted upwards to a certain height in the atmosphere, where, mixing with the vapours, they help to constitute clouds, and return back in dews, mists, rains, &c. Sir Isaac Newton thinks, that true and permanent air is formed from the exhalations raised from the hardest and most compact bodies.

EXHAUSTED RECEIVER, is a glass, or other vessel, applied on the plate of an air-pump, to have the air extracted out of it by the action of the pump.—Things placed in such an exhausted receiver, are said to be in vacuo.

EXHAUSTIONS, or the *Method of Exhaustions*, is a mode of demonstration founded on the principle of exhausting a quantity by continually taking away certain parts of it. The method of exhaustions was frequently resorted to by the ancient mathematicians; as Euclid, Archimedes, &c. And it is founded on what Euclid says in the 10th book of his Elements; viz, that those quantities are equal, whose difference is less than any assignable quantity. Or it may be otherwise expressed thus: two quantities a and b are equal, when, if to or from one of them as a , any other quantity as d be subtracted, however small it may be, the sum or difference thus obtained is respectively greater or less than the other quantity b : d being an indefinitely small quantity,

if $a + d$ be greater than b ,

and $a - d$ less than b , then is a equal to b .

This principle is used in the 1st prop. of the 10th book, which imports, that if from the greater of two quantities be taken more than its half, and from the remainder more than its half, and so on; there will at length remain a quantity less than either of those proposed. On this foundation it is demonstrated, that if a regular polygon of infinite sides be inscribed in a circle, or circumscribed about it; that the space, which is the difference between the circle and the polygon, will by degrees be quite exhausted, and the circle become ultimately equal to the polygon. And in this way it is that Archimedes demonstrates, that a circle is equal to a right-angled triangle, whose two sides about the right angle are equal, the one to the semidiameter, and the other to the perimeter of the circle. Prop. 1 De Dimensione Circuli.

On the method of exhaustions depends the method of indivisibles introduced by Cavalierius, which is but a shorter way of expressing the method of exhaustions; as also Wallis's Arithmetic of Infinites, which is a further improvement of the method of indivisibles; and hence also the methods of increments, differentials, fluxions, and infinite series. See some account of the method of exhaustions in Wallis's Algebra, chap. 73, and Romayne's Algebra, part 3, pa. 395.

EXPANSION, is the dilating, stretching, or spreading out of a body; whether from any external cause, as the cause of rarefaction, or from an internal cause, as elasticity. Bodies naturally expand by heat, and are contracted by cold; and hence it happens that their dimensions and specific gravities are different in different temperatures and seasons of the year. Air compressed or condensed, as soon as the compressing or condensing force

is removed, expands itself by its elastic power to its former dimensions.

In some few cases indeed, bodies seem to expand as they cool, as water in the act of freezing: but this is owing to the extrication of a number of air bubbles from the fluid at a certain time; and is not at all a regular and gradual expansion like that of metals, &c, by means of heat. Mr. Boyle, in his History of Cold, says that ice takes up a 12th part more space than water; but by Major Williams's experiments on the force of freezing water, I have found it occupies only about the 17th or 18th part more space. Transact. of the R. Soc. of Edinb. vol. 2, pa. 28. In certain metals also, an expansion takes place when they pass from a fluid to a solid state: but this too is not to be accounted any proper effect of cold, but of the arrangement of the parts of the metal in a certain manner; and is therefore to be considered as a kind of crystallization.

The expansion of different bodies by heat is very various; and many experiments upon it are to be met with in the volumes of the Philos. Trans. and in other places. In the 48th vol. in particular, Mr. Smeaton has given a table of the expansion of many different substances, as determined by experiment, from which the following particulars are extracted. Where it is to be noted, that the quantities of expansion which answer to 180 degrees of Fahrenheit's thermometer, are expressed in ten-thousandth parts of an English inch, each substance being 1 foot or 12 inches in length.

Zinc or Spelter	-	-	353
Zinc hammered $\frac{1}{2}$ an inch per foot	-	-	373

By other experiments it has likewise been found that, for each thermometrical degree of heat, mercury, water, and air, expand the following parts of their own bulk, viz,

Mercury the 9600th
Water the 6666th } part of its bulk.
Air the 435th }

From the foregoing table it appears, that there is no general rule for the degree of expansion to which bodies are subject by the same degree of heat, either from their specific gravity or otherwise. Zinc, which is much lighter than lead, expands more with heat; while glass, which is lighter than either, expands much less; and copper, which is heavier than a mixture of brass and tin, expands less. It seems also that metals observe a proportion of expansion in a fluid state, quite different from what they do in a solid one: for regulus of antimony seemed to con-

tract in fixing, after having been melted, considerably more than zinc under similar circumstances.

But of all known substances, those of the aerial kind expand most by an equal degree of heat; and in general the greater quantity of latent heat that any substance contains, the more easily is it expanded: yet even here no general law can be observed. It is indeed certain that the densest fluids, such as mercury, oil of vitriol, &c, are less expansible than water, spirit of wine, or ether. Which last is so easily expanded, that were it not for the pressure of the atmosphere it would be in a continual state of vapour. And indeed this is the case, in some measure, with perhaps all fluids; as it has been found, by experiments with the best air-pumps, that water, and other fluids, ascend in vapours the more as the exhaustion is the more perfect; from which it would seem that water would wholly rise in vapour, in any temperature, if the pressure of the atmosphere was entirely taken off.

After bodies are reduced to a state of vapour, their expansion seems to go on without any limitation, in proportion to the degree of heat applied; though it may be impossible to say what would be the ultimate effects of that principle acting upon them in this manner. The force with which these vapours expand on the application of high degrees of heat is so great, that no body or force appears to be sufficient to counteract their effects.

On this principle depends the construction of steam-engines, so much employed in various mechanical operations; likewise some hydraulic machines; and the instruments called manometers, which show the variation of gravity in the external atmosphere, by the expansion or condensation of a small quantity of air confined in a proper vessel. On this principle also, perpetual movements might be constructed similar to those invented by Mr. Coxe, on the principle of the barometer. And a variety of other curious machines may be constructed on the principle of aerial expansion; an account of some of which is given under the articles HYDROSTATICS and PNEUMATICS.

The construction of thermometers depends also on the principle of the expansion of fluids. See THERMOMETER. And for the effects of the different expansions of metals, in correcting the vibrations of pendulums, see PENDULUM.

The expansion of solid bodies is measured by an instrument called the pyrometer; and the force with which they expand is still greater than that of aerial vapours; the flame of a small candle produces an expansion in a bar of iron capable of counteracting a weight of 500 pounds. The quantity of expansion, however, is so small, that it has never been applied to the movement of any mechanical engine.

EXPECTATION, in the Doctrine of Chances, is applied to any contingent event, on the happening of which, some benefit &c, is expected. This is capable of being reduced to the rules of computation: for a sum of money in expectation when a particular event happens, has a determinate value before that event happens. Thus, if a person is to receive any sum, as $10l$, when an event takes place which has an equal chance or probability of happening and failing, the value of the expectation is half that sum, or $5l$: but if there are 3 chances for failing, and only 1 for its happening, or 1 chance only in its favour out of all the 4 chances; then the probability of its happening is only $\frac{1}{4}$ out of 4, or $\frac{1}{4}$; and the value of the expectation is but $\frac{5}{4}l$.

of $10L$, which is only $2L$. $10s.$ or half the former sum. And in all cases, the value of the expectation of any sum is found by multiplying that sum by the fraction expressing the probability of obtaining it. So the value of the expectation on $100L$, when there are 3 chances out of 5 for obtaining it, or when the probability of obtaining it is $\frac{3}{5}$, is $\frac{3}{5}$ of $100L$, which is $60L$. And if s be any sum expected on the happening of an event, h the chances for that event happening, and f the chances for its failing; then, there being h chances out of $f + h$ for its happening, the probability will be

$$\frac{h}{f+h}$$
 and the value of the expectation is $\frac{hs}{f+h}$. Suppose, for example, that a person is entitled to $100L$, if, in casting a die, he brings up an ace; and to $50L$, if he brings up a six; but, in all other cases he is to have nothing, to find the value of his expectation before the die is cast. In each case the number of chances, both for happening and failing, are 6, but for the event taking place only 1; therefore $\frac{1}{6}$ of $100L = 16L$. $18s. 4d.$ is the value of his expectation in the first case, and $\frac{5}{6}$ of $50L = 8L$. $6s. 8d.$ is its worth in the second case; consequently, their sum $25L$, is the entire value of his expectation before he undertakes to throw. See Simpson's or De Moivre's Doctrine of Chances.

EXPECTATION of Life, in the Doctrine of Life Annuities, is the share, or number of years of life, which a person of a given age may, on an equality of chance, expect to enjoy. By the expectation or share of life, says Mr. Simpson (Select Exercises, pa. 273), is not here to be understood that particular period which a person hath an equal chance of surviving; this last being a different, and more simple consideration. The expectation of a life, to put it in the most familiar light, may be taken as the number of years at which the purchase of an annuity, granted upon it, without discount of money, ought to be valued. Which number of years will differ more or less from the period above-mentioned, according to the different degrees of mortality to which the several stages of life are incident. Thus it is much more than an equal chance, according to the table of the probability of the duration of life (pa. 254 ut supra), that an infant, just come into the world, arrives not to the age of 10 years; yet the expectation or share of life due to it, on an average, is near 20 years. The reason of which wide difference, is the great excess of the probability of mortality in the first tender years of life, above that respecting the more mature and stronger ages. Indeed, if the numbers that die at every age were to be the same, the two quantities above specified would also be equal; but when the said numbers become continually less and less, the expectation must of consequence be the greater of the two.

Mr. Simpson has given a table and rule for finding this expectation, pa. 255 and 273 as below.

For example, if it be required to find the expectation or share of life, due to a person of 30 years old. Opposite the given age in the first column of the table, stands 23·6 in the second col. for the years in the expectation sought. See De Moivre's Doctrine of Chances applied to the valuation of annuities, pa. 288; or Dr. Price's Observations on Reversionary Payments, pa. 168, 364, 374, &c; or Philos. Trans. vol. 59, pa. 89.

A Table of the Expectations of Life in London.

Age.	Expectation.	Age.	Expectation.	Age.	Expectation.
1	27·0	28	24·6	55	14·2
2	32·0	29	24·1	56	13·8
3	34·0	30	23·6	57	13·4
4	35·6	31	23·1	58	13·1
5	36·0	32	22·7	59	12·7
6	36·0	33	22·3	60	12·4
7	35·8	34	21·9	61	12·0
8	35·6	35	21·5	62	11·6
9	35·2	36	21·1	63	11·2
10	34·8	37	20·7	64	10·8
11	34·3	38	20·3	65	10·5
12	33·7	39	19·9	66	10·1
13	33·1	40	19·6	67	9·8
14	32·5	41	19·2	68	9·4
15	31·9	42	18·8	69	9·1
16	31·3	43	18·5	70	8·8

27	25·1	54	14·5		

EXPERIMENT, in Philosophy, a trial of the effect or result of certain applications and motions of natural bodies, in order to discover something of their laws and relations, &c. The making of experiments is become a kind of art; and there are now many collections of them, mostly under the denomination of Courses of Experimental Philosophy. Sturmius made a curious collection of the principal discoveries and experiments of the 17th century, under the title of *Collegium Experimentale*. Other courses of experiments have been published by Gravesande, Desaguliers, Heselham, Cotes, &c.

EXPERIMENTAL Philosophy, is that which proceeds on experiments, or which deduces the laws of nature and the properties and powers of bodies, and their actions upon each other, from sensible experiments and observations. Experiments are of the utmost importance in philosophy; and the great advantages the modern physics have over the ancient, is chiefly owing to our making more experiments, and then founding our theories on the results thus obtained: whereas the method of the ancients was chiefly to begin with the assumed causes of things, and thence argue to the phenomena and effects; on the contrary, that of the moderns proceeds from experiments and observations, whence the properties and laws of natural things are deduced, and general theories are formed.

Several of the ancients indeed thought as highly of experiments as the moderns, and practised them also. Plato omits no occasion of speaking of the advantages of them; and Aristotle's history of animals bears ample testimony for him. Democritus's great employment was to make experiments; and even Epicurus himself owes part of his glory to the same cause.

Among the moderns, the making of experiments was chiefly begun by Friar Bacon, in the 13th century, who

spent a great deal of money and labour in this pursuit. After him, the lord chancellor Bacon is considered as the founder of the present mode of philosophising by experiments. And his method has been prosecuted with laudable emulation by the Academy del Cimento, the Royal Society, the Royal Academy at Paris; by Mr. Boyle, and, above all, by Sir Isaac Newton, with many other illustrious names.

Indeed, the making of experiments, within the last century, is so much practised, that nothing will pass in philosophy, but what is either founded on experiments, or confirmed by them; so that the new philosophy is almost wholly experimental.

Yet there are some, even among the learned, who speak of experiments in a different manner, or perhaps rather of the abuse of them, and in derision of the pretenders to this practice. Thus, though Dr. Keil allows that philosophy has received considerable advantages from those who make experiments; yet he complains of their disingenuity, in too often wresting and distorting their experiments and observations, to favour some darling theories they had espoused. Nay more, M. Hartsoeker, in his Recueil de plusieurs Pièces de Physique, undertakes to show, that such as employ themselves in the making of experiments, are not properly philosophers, but as it were the labourers or operators of philosophers, that work under them, and for them, furnishing them with materials to build their systems and hypotheses on. And the learned M. Dacier, in the beginning of his discourse on Plato, at the head of his translation of the works of that philosopher, deals still more severely with the makers of experiments. He breaks out with a kind of indignation at a tribe of idly curious people, whose sole employment consists in making experiments on the gravity of the air, the equilibrium of fluids, the loadstone, &c, and yet arrogate to themselves the noble title of philosophers.

EXPLOSION, a sudden and violent expansion of an elastic fluid, by which it instantly throws off any obstacle that happens to be in the way, sometimes with astonishing force and rapidity, as the explosion of fired gunpowder, &c.

Explosion differs from expansion, in this, that the latter is a gradual and continued power, acting uniformly for some certain time; whereas the former is always sudden, and only of momentary or immensurably short duration. The expansions of solid substances do not terminate in violent explosions, on account of their slowness of action, and the small space through which the expanding substance moves; though their strength may be equally great with that of the most active aerial fluids. Thus we find that though wedges of wood, when wetted, will cleave solid blocks of stone, they never throw them to any distance, as is the case with gunpowder. On the other hand, it is seldom that the expansion of any elastic fluid bursts a solid substance without throwing the fragments of it to a considerable distance, with effects that are often very terrible.

The greater number of explosive substances are either aerial, or convertible into such, and raised into an elastic fluid. Thus gunpowder, whose essence seems to consist in common air fixed in the nitre, or at least an air of similar elasticity, where it is condensed into a bulk many hundred times less than the natural state of the atmosphere; which air being suddenly disengaged by the firing of the gunpowder, and the decomposition of its parts, it rapidly expands itself again with a force proportioned to the degree

of its condensation when fixed in the gunpowder, and so explodes, and produces all those terrible effects that attend the explosion. The elastic fluid generated by fired gunpowder expands itself with a velocity of almost 10,000 feet per second, and with a force nearly 2000 times greater than the pressure of the atmosphere on the same base.

The electric explosions seem to be still much more strong and astonishing; as in the cases of lightning, earthquakes, and volcanoes; and even in the artificial electricity produced by the ordinary machines. The astonishing strength of electric explosions, which is beyond all possible means of measuring it, manifests itself by the many tremendous effects we hear of fire-balls and lightning.

In cases where the electric matter acts like common fire, the force of the explosions, though very great, is capable of measurement, by comparing the distances to which bodies are thrown, with their weight. This is most evident in volcanoes, where the projections of the burning rocks and lava manifest the immensity of the power, at the same time that they afford a method of measuring it: and these explosions are owing to the extrication of aerial vapours, and their rarefaction by intense heat.

Next in strength to the aerial vapours, are those of aqueous and other liquids. Very remarkable effects of these are observed in steam-engines; and there is one case from which it has been inferred that aqueous steam is even much stronger than fired gunpowder. This is when water is thrown upon melted copper: for here the explosion is so strong as almost to exceed imagination; and the most terrible accidents have happened, even from so slight a cause as one of the workmen spitting in the furnace where copper was melting; arising probably from a sudden decomposition of the water. Explosions happen also from the application of water to other melted metals, though in a lower degree, when the fluid is applied in small quantities, and even to common fire itself, as every person's own experience must have informed him; and this seems to be occasioned by the sudden rarefaction of the water into steam. Examples of this kind often occur when workmen are fastening cramps of iron into stones; where there sometimes happens to be a little water in the hole into which the lead is poured; in this case the metal will fly out in such a manner as sometimes to burn them very severely. Terrible accidents of this kind sometimes occur in foundries, when large quantities of melted metal is poured into wet or damp moulds. In these cases, the sudden expansion of the aqueous steam has thrown out the metal with great violence; and if any decomposition has taken place at the same time, so as to convert the aqueous vapour into an aerial one, the explosion must be still greater.

To this last kind of explosion must be referred that which takes place on pouring cold water into boiling or burning oil or tallow, or in pouring the latter upon the former; the water however being always used in a small quantity.—Another remarkable kind of explosion is that produced by inflammable and dephlogisticated air, when mixed together, and set on fire; a circumstance that often happens in coal-mines, &c. This differs from any of the cases before mentioned; for here is an absolute condensation rather than an expansion throughout the whole of the operation; and could the airs be made to take fire throughout their whole substance absolutely at the same instant, there would be no explosion, but only a sudden production of heat.

Though explosions be sometimes very destructive, they are also of considerable use in life, as in removing obstacles that could scarcely be overcome by any mechanical power whatever. The principal of these are the blowing-up of rocks, the separating of stones in quarries, and other purposes of that kind. The destruction occasioned by them in times of war, and the machines formed upon the principle of explosion for the destruction of the human race, are well known; and if we cannot call these useful, they must be allowed at least to be necessary evils.

The effects of explosions, when violent, are felt at a considerable distance, by reason of the concussions they give to the atmosphere. Sir Wm. Hamilton relates, that at the explosions of Vesuvius, in 1767, the doors and windows of the houses at Naples flew open if unbolted, and one door was burst open that had been locked, though at the distance of 6 miles: and the explosion of a powder-magazine, or a powder-mill, it is well known, spreads destruction for many miles round; and even kills people by the mere concussion of the air. A curious effect of them also is, that they electrify the air, and even glass windows, at a considerable distance. This is always observable in firing the guns at the Tower of London: and some years ago, after an explosion of some powder mills near that city, many people were alarmed by a rattling and breaking of their china-ware. In this respect, however, the effects of electrical explosions are the most remarkable, though not in the uncommon way just mentioned; but it is certain that the influence of a flash of lightning is diffused for a great way round the place where the explosion happens, producing very perceptible changes both on the animal and vegetable creation.

EXPONENT of a Power, in Arithmetic and Algebra, denotes the number or quantity expressing the degree or elevation of the power, or which shows how often a given power is to be divided by its root before it be brought down to unity or 1. Thus, the exponent or index of a square number, or the 2d power, is $\frac{1}{2}$; of a cube 3; and so on; the square being a power of the 2d degree; the cube, of a 3d, &c. It is otherwise called the Index.

Exponents, as now used, are rather of modern invention. Diophantus, with the Arabian and the first European authors, denoted the powers of quantities by subjoining an abbreviation of the name of the power; though with some variation, and difference from one another. The names of the powers, and the marks for denoting them, according to Diophantus, are as follow: viz., Names, μονας, αριθμος, δυναμις, κυβος, δυναμοδυναμις, Marks, ρ^0 , ρ^1 , ρ^2 , ρ^3 , ρ^4 , ρ^5 , ρ^6 , &c. ; which we now denote by 1, a , a^2 , a^3 , a^4 , &c.

F. Lucas Paciolus, or De Burgo, for the root, square, cube, &c, uses the terms cosa, censo, cubo, relato (primo, secundo, tertio, &c), or the abbreviations co. ce. cu.; and R. for root or radicality.

Cardan used the Latin contractions of the names of the powers; and other contemporary, and ever succeeding authors, especially the Germans, as Stifelius, Scheubelin, Pelitarius, &c, used the like contractions, but somewhat varied, thus:

8, 2 ρ , 3, 4, 33, 13, 316, &c.

or 1, 2 ρ , 3, 4, 33, 13, 316, &c.

or 1, R ρ , q, 4, 9, 13, 916, &c.

exp. 0, 1, 2, 3, 4, 5, 6, &c.

But besides that method of representation, the same authors also made use of the numbers as in the last line here

above, and it was Stifelius who first called them exponents.

Bombelli, whose Algebra was published in 1579, denotes the res, or unknown quantity, by this mark \cup , and the powers by numeral exponents set over it, thus: \cup^1 , \cup^2 , \cup^3 , &c. And

Stevinus, who published his Arithmétic in 1585, and his Algebra soon afterwards, makes use of a similar method, but instead of \cup he uses a small circle \circ , within which he places the numeral exponent of the power; thus \circ_1 , \circ_2 , \circ_3 , \circ_4 , &c: and in this way he extends his notation to fractional exponents, and even to radical ones; thus $\circ\frac{1}{2}$, $\circ\frac{3}{4}$, $\circ\frac{5}{6}$, $\circ\frac{7}{8}$, &c.

Vigeta after this used words again to denote the powers. And Harriot denoted the powers by a repetition of the root; as a , aa , aaa , for the 1st, 2d, and 3d powers. Instead of which, Descartes again restored the numeral exponents, placing them after the root, when the power is high, in order to avoid a too frequent repetition of the same letter; as a^3 , a^4 , &c, the same as is used at present. Also Albert Girard, in 1629, used the exponents to roots, thus: \sqrt{a} , $\sqrt[3]{a}$, $\sqrt[4]{a}$, &c.

The notation of powers and roots by the present mode of exponents, has introduced a new and general arithmetic of exponents or powers; for hence powers are multiplied by only adding their exponents, divided by subtracting the exponents, raised to other powers, or roots of them extracted, by multiplying or dividing the exponent by the index of the power or root.—

$$\text{So } a^2 \times a^3 = a^5, \text{ and } a^{\frac{1}{2}} \times a^{\frac{1}{3}} = a^{\frac{5}{6}};$$

$$a^5 \div a^3 = a^2, \text{ and } a^{\frac{3}{2}} \div a^{\frac{1}{2}} = a^{\frac{1}{2}};$$

the 2d power of a^3 is a^6 ,

and the 3d root of a^6 is a^2 .

This algorithm of powers led the way to the invention of logarithms, which are only the indices or exponents of powers: and hence the addition and subtraction of logarithms, answer to the multiplication and division of numbers; while the raising of powers, and extracting of roots, is effected by multiplying the logarithm by the index of the power, or dividing the logarithm by the index of the root.

EXPONENT of a Ratio, is, by some, understood to be the quotient arising from the division of the antecedent of the ratio by the consequent: in which sense, the exponent of the ratio of 3 to 2 is $\frac{1}{2}$; and that of the ratio of 2 to 3 is $\frac{2}{3}$. But others, and those among the best mathematicians, understand logarithms as the exponents of ratios; in which sense they coincide with the idea of measures of ratios, as delivered by Kepler, Mercator, Halley, Cotes, &c.

EXPONENTIAL Calculus, the method of differencing, or finding the fluxions of exponential quantities, and of summing up those differences, or finding their fluents. See **CALCULUS, FLUXIONS, and FLUENTS**.

EXPONENTIAL Curve, is that whose nature is defined or expressed by an exponential equation; as the curve denoted by $x^a = y$, or by $x^x = y$.

EXPONENTIAL Equation, is one in which is contained an exponential quantity: as the equation $a^x = b$, or $x^a = ab$, &c. Exponential equations are commonly best resolved by means of logarithms, viz, first taking the log. of the given equation: thus, by taking the log. of the equation $a^x = b$, it is $x \times \log. a = \log. b$; and hence $x = \log. b \div \log. a$.

Also, the log. of the equation $x^x = ab$, is $x \times \log. x =$

log. ab ; and then x is easily found by trial-and-error, or the double rule of position.

EXPONENTIAL Quantity, is that whose power is a variable quantity; as the expression a^x , or x^y . Exponential quantities are of several degrees, and orders, according to the number of exponents or powers, one above another. Thus,

a^x is an exponential of the 1st order,

a^x , is one of the 2d order,

a^x , is one of the 3d order, and so on.

See Bernoulli Oper. tom. 1, pa. 182, &c.

EXPRESSION, in Algebra, is any algebraical quantity, simple or compound: as the expression, $3a$, or $2ab$, or $\sqrt{a^2 \pm c^2}$. Sometimes also called a function.

EXTENSION, one of the common and essential properties of body; or that by which it possesses or takes up some part of universal space, called the place of that body. The extension of a body, is properly speaking in every direction whatever; but it is usual to consider it as extended only in length, breadth, and thickness.

EXTERIOR Polygon, or **Talus**, is the outer or circumscribing one. See **POLYGON**, and **TALUS**.

EXTERMINATION, or **EXTERMINATING**, in Algebra, is to take away certain unknown quantities from depending equations, so as finally to have only one equation containing one unknown quantity; whence its value may be determined, and by means of this, and the equations obtained in the extermination, all the other quantities become known.

The rules for performing this are various, and after all, much must be left to the ingenuity of the algebraist, as the application and combination of those particular rules, depend, in a great measure, on the forms and nature of the equations, out of which the unknown quantities are to be exterminated. The following however may be considered as forming principles of the operation.

1. Find the value of one of the unknown letters, in terms of the other quantities, in each of the given equations. Next put two of these values equal to each other; then one of these and a third, fourth, &c; by which means one unknown quantity will be exterminated; and in the same way others may be taken away, till there remain only one equation and one unknown quantity, the value of which may then be found by the common rules.

2. Find the value of one of the unknown letters in one of the equations; then substitute this value of it in each of the other equations into which that letter enters, by which means it will be exterminated; and in the same manner we may take away all but one as before.

3. Multiply or divide the given equations by such numbers, that the coefficients of one of the unknown quantities in each of the equations may be equal to each other. Then by adding or subtracting them as the case requires, that unknown quantity will be taken away.

The following equations will serve to illustrate all these rules.

Given $ax + by = n$, and $cx + dy = m$.

By the first method, $x = \frac{n - by}{a}$; and $x = \frac{m - dy}{c}$;

therefore $\frac{n - by}{a} = \frac{m - dy}{c}$, or $(ad - bc)y = am - cn$, which is an equation containing only one unknown quantity.

Second method. Here

$x = \frac{n - by}{a}$; and substituting this value of x in the second equation, we have

$$\frac{cn - bcy}{a} + dy = m; \text{ which gives}$$

$$(ad - bc)y = am - cn, \text{ as before.}$$

Third method. By multiplying the first equation by c , and the second by a , we obtain

$$acx + bcy = cn,$$

and $adx + ady = am$; then by subtraction we have

$$(ad - bc)y = am - cn, \text{ still the same result as before.}$$

See Hutton's Course, Simple Equat. prob. 1, pa. 227, &c.

Many ingenious specimens of the different methods of extermination are given in Newton's Universal Arithmetic, and Maclaurin's Algebra. See also an excellent piece on this subject under the article **Elimination** in the Encyclopedia Methodique.

EXTERNAL Angles, are the angles formed without a figure, by producing its sides out. In a triangle, any external angle is equal to the sum of both the two internal opposite angles taken together: and, in any right-lined figure, the sum of all the external angles, is equal to 4 right angles, except in the case where one of them tends inwards. In which case, that angle must be taken from the sum of the others to leave four right angles. See Hutton's Geom. Theor. 16 and 20.

EXTRA-Constellary Stars, such as are not properly included in any constellation.

EXTRA-Mundane Space, is the infinite, empty, void space, which is by some supposed to be extended beyond the bounds of the universe, and consequently in which there is really nothing existing.

EXTRACTION of Roots, is finding the roots of given numbers, quantities, or equations. The roots of quantities are denominated from their powers; as the square or 2d root, the cubic or 3d root, the biquadratic or 4th root, the 5th root, &c; which are the roots of the 2d, 3d, 4th, 5th, &c powers. The extraction of roots has always made a part of arithmetical calculation, at least as far back as the composition of powers has been known: for the composition of powers always led to their resolution, or extraction of roots, which is performed by the rules exactly reverse of the former. Thus, if any root be considered as consisting of two parts $a + x$, of which the former a is known, and the latter x unknown, then the square of this root is $a^2 + 2ax + x^2$, which is its composition, and this indicated the resolution, or method of discovering the unknown part x : for having subtracted the nearest square a^2 from the given quantity, there remains $2ax + x^2$ or $(2a + x) \times x$; therefore divide this remainder by $2a$, the double of the first member of the root, and the quotient will be nearly equal to x the other member; then to x add this quotient x , and multiply the sum $2a + x$ by x , and the product will make up the remaining part $2ax + x^2$ of the given power.

The composition of the cubic or 3d power next presented itself, which consists of these four terms $a^3 + 3a^2x + 3ax^2 + x^3$; by means of which the cube roots of numbers have been extracted; viz, by subtracting the nearest cube a^3 from the given power, and dividing the remainder by $3a^2$, which gives x nearly for the quotient; then completing the divisor up to $3a^2 + 3ax + x^2$, multiply it by x for the other part of the power to be subtracted. And this was the extent of the extraction of roots in the time

of Lucas de Burgo, who, from 1470 to 1500, wrote several pieces on arithmetic and algebra, which were the first works of this kind printed in Europe.

It was not long however before the nature and composition of all the higher powers became known, and general tables of coefficients formed for raising them; the first of which is contained in Stifelius's Arithmetic, printed at Norimberg in 1543, where he fully explains their use in extracting the roots of all powers whatever, by methods similar to those for the square and cube roots, as above described; and thus completed the extraction of numerical roots, at least so far as that method of resolution extends. Since that time, however, many new modes of extraction have been devised, and the old method considerably improved.

The extraction of roots of equations followed closely that of known numbers. In De Burgo's time they extracted the roots of quadratic equations, the same way as at present. Ferreus, Tartalea, and Cardan extracted the roots of cubic equations, by general rules. Soon afterwards the roots of higher equations were extracted, at least in numbers, by approximation. And the late improvements in analytics have furnished general rules for extracting the roots, in infinite series, of all equations whatever. All which methods may be seen in most books of arithmetic and algebra; therefore it may be sufficient to give here a short specimen of some of the easiest rules for extracting the roots of quantities and equations.

1. To Extract the Square Root.

Separate the given numbers into periods of two figures each, by setting a point over the place of units, another over the place of hundreds; and so on, over every second figure, both to the left hand in integers, and to the right hand in decimals.

Find the greatest square in the first period on the left hand, and set its root on the right hand of the given number, after the manner of a quotient figure in division.

Subtract the square, thus found, from the said period, and to the remainder annex the two figures of the next following period for a dividend. Double the root above found for a divisor, and find how often it is contained in the said dividend, exclusive of its right-hand figure, and set that quotient figure both in the quotient and in the divisor.

Multiply the whole augmented divisor by the last quotient figure, and subtract the product from the said dividend; bringing down to it the next period of the given number for a new dividend.

Repeat the same process over again; namely, find another new divisor, by doubling all the figures now found in the root; from which, and the last dividend, find the next figure of the root as before, and so on through all the periods to the last.

But the best way of doubling the root, to form the new divisor, is by adding the last figure always to the last divisor; as appears from the following examples.

When the root is to be carried into decimals, couples of ciphers are to be added, instead of figures, as far as may be necessary. In which case also a considerable abbreviation is made, after the work has been carried on to half the number of figures, or one more than half, by continuing it to the other half only by the contracted method of division; as in the following example for the square root of 2 to eight decimals, or nine places of figures.

It may also not be amiss to add for the information of beginners, that when there are an odd number of decimals in the number whose root is to be extracted, they should be made even, by annexing a cipher, before the operation is begun. See the following examples.

.	root	2 (1
99856	(316	41421356
9	1	
61	24	100

To extract the square root of a number by continued fractions, see **CONTINUED FRACTIONS**.

II. To Extract the Cube Root.

Divide the given number into periods of three figures each, by setting a point over the place of units, another over the place of thousands, and so on, over every third figure, to the left hand in integers, and to the right in decimals. Find the nearest less cube to the first period; and set its root in the quotient, subtracting the said cube from the first period; and to the remainder bring down the second period, which forms the resolvent.

To three times the square of the root, thus found, add three times the root itself, setting this one place more to the right than the former, and call this sum the divisor. Then divide the resolvent, wanting the last figure, by the divisor, for the next figure of the root, which annex to the former; and let this last figure be called e , and the part of the root before found a .

Add altogether these three products, namely, three times a square multiplied by e , thrice a multiplied by e square, and e cube, setting each of them one place more to the right than the former, and call this sum the subtrahend; which should not exceed the resolvent; therefore if it do, make the last figure e less, and repeat the operation for finding the subtrahend, till one be found less than the resolvent.

From the resolvent take the subtrahend, and to the remainder join the next period of the given number for a new resolvent; to which form a new divisor from the whole root now found, and from thence another figure of the root as above directed, and so on, till all the figures are used. After which the operation may be continued to any length by bringing always new periods of three ciphers each.

Suppose for example it were required to extract the cube root of 48228.544.

$$\begin{array}{r|l} 3 \times 3^2 = 27 & 48228 \cdot 544 \text{ (36th root)} \\ 3 \times 3 = .09 & \\ \hline \text{Divisor } 279 & 21228 \text{ residuend} \end{array}$$

$$\begin{array}{r|l} 3 \times 3^2 \times 6 = 162 & \\ 3 \times 3 \times 6^2 = 324 & \\ 6^3 = 216 & \end{array}$$

$$\begin{array}{r|l} 3 \times 36^2 = 3888 & 19656 \text{ subtrahend} \\ 3 \times 36 = 108 & 1572544 \text{ residuend} \\ \hline 38988 & \end{array}$$

$$\begin{array}{r|l} 3 \times 36^2 \times 4 = 15552 & \\ 3 \times 36 \times 4^2 = 1728 & \text{add} \\ 4^3 = 64 & \end{array}$$

$$\begin{array}{r|l} 1572544 \text{ subtrahend} & \\ 0000000 \text{ remainder} & \end{array}$$

III. To Extract the Cube Root, or any other Root whatever.
This is easiest done by one general rule, that I have invented, and published in my new Tracts, vol. 1, pa. 210, which is to this effect: Let n be any number or power, whose n th root is to be extracted; and let r be the nearest rational root of n , of the same kind, or n^k the nearest rational power to n , either greater or less than it; then shall the true root be very nearly equal to
 $(n + 1)r + (n - 1)r^n$

$(n - 1)r + (n + 1)r^n \times r$; which rule is general for any root whose index is denoted by n . And by expounding n successively by all the numbers 2, 3, 4, 5, &c., this theorem will give the following particular rules for the several roots, viz,

2d or squ. root,	$\frac{3N + R^2}{N + 3R^2} \times R$;
3d or cube root,	$\frac{4N + 2R^3}{2N + 4R^3} \times R$, or $\frac{2N + R^3}{N + 2R^3} \times R$;
4th root	$\frac{5N + 3R^4}{3N + 5R^4} \times R$;
5th root	$\frac{6N + 4R^5}{4N + 6R^5} \times R$, or $\frac{3N + 2R^5}{2N + 3R^5} \times R$;
6th root	$\frac{7N + 5R^6}{5N + 7R^6} \times R$;
7th root	$\frac{8N + 6R^7}{6N + 8R^7} \times R$, or $\frac{4N + 3R^7}{3N + 4R^7} \times R$; <i>&c.</i>

Or the theorem may be stated in the form of a proportion, thus:

as $(n - 1)r + (n + 1)r^n : (n + 1)r + (n - 1)r^n :: r : \text{the root sought very nearly.}$

Suppose for example it was required to find the cube root of the number 2. Here $n = 2$, $n = 3$, and the nearest power, and root are each 1.

$$\text{Hence } 2N + R^3 = 4 + 1 = 5, \\ \text{and } N + 2R^2 = 2 + 2 = 4;$$

then $4 : 5 : 1 : \frac{1}{3} = 1:25$ the first approximation.

Again, taking $R = \frac{5}{4}$, and conse^t, $R^3 = \frac{125}{64}$:

$$\text{Hence } 2N + R^3 = 4 + \frac{125}{64} = \frac{381}{64},$$

$$\text{and } N + 2R^2 = 2 + \frac{125}{64} = \frac{377}{64};$$

then $378 : 381 : \frac{1}{4} : \frac{635}{512} = 1:239921$, for the cube root of 2, which is exact in the very last figure.

And again by taking $\frac{635}{512}$ for the value of R , a great many more figures may be found.

IV. To Extract the Roots of Algebraic Quantities.—This is done by the same rules, and in the same manner as for

the roots of numbers in arithmetic, as above taught. Thus, to extract the square root of $4a^2 + 12ax + 9x^2$.

$$\begin{array}{r|l} 4a^2 + 12ax + 9x^2 & 2a + 3x \text{ the root} \\ 4a^2 & \\ \hline 4a + 3x & 12ax + 9x^2 \\ 3x & 12ax + 9x^2 \end{array}$$

So also the root is carried out in an infinite series, in imitation of the like extraction of numbers in infinite decimals: thus, the square root of $a^2 + x^2$ is

$$a^2 + x^2 (a + \frac{x^2}{2a} - \frac{x^4}{8a^3} + \frac{x^6}{16a^5} \&c.)$$

$$\begin{array}{r|l} a^2 & \\ \hline 2a + \frac{x^2}{2a} & x^2 \\ x^2 & x^2 + \frac{x^4}{4a^2} \\ \hline 2a + \frac{x^2}{a} - \frac{x^4}{8a^2} & -\frac{x^5}{4a^2} \\ x^3 & -\frac{x^5}{4a^2} - \frac{x^6}{8a^3} + \frac{x^8}{16a^5} \&c. \end{array}$$

To extract the cube root of $a^3 - x^3$ by the general rule in the 2d article.—Here $N = a^3 - x^3$, $R = a$, or $R^3 = a^3$; $N + 2R^3 = 3a^3 - x^3$, and $2N + R^3 = 3a^3 - 2x^3$; therefore, by the rule,

$$3a^3 - x^3 : 3a^3 - 2x^3 :: a : a - \frac{x^3}{3a^2} - \frac{x^6}{9a^5} - \frac{x^9}{27a^8} \&c.,$$

which is the cube root of $a^3 - x^3$ very nearly.

But these kinds of roots are best extracted by the Binomial Theorem; which see.

V. To Extract the Roots of Equations.—This is the same thing as to find the value of the unknown quantity in an equation; which is effected by various means, depending on the form of the equation, and the dimension of the highest power of the unknown quantity in it: for which, see the respective terms, EQUATION, ROOT, QUADRATIC, CUBIC, &c.

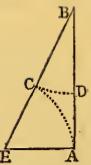

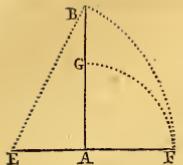

The most general, as well as the most easy, method of extracting the roots of all the higher equations, is by double position, or trial-and-error; as it easily applies to all kinds of equations, however complex they may be, even logarithmic and exponential ones. There are also several other good methods of approximating to the roots of equations, given by Newton, Halley, Raphson, De Moivre, Lagrange, &c.; of which the most general is a rule for extracting the root of the following indefinite equation,

$$\begin{aligned} \text{viz, } az + bz^2 + cz^3 + dz^4 + ez^5 \&c. \\ = gy + hy^2 + iy^3 + ky^4 + ly^5 \&c., \end{aligned}$$

given by M. De Moivre in the Philos. Trans. vol. 20, pa. 190, or my Abr. vol. 4, pa. 275.

EXTRADOS, the outside of an arch, or vault, &c.

EXTREME-and-MEAN Proportion, is when a line, or any quantity is so divided, as that the whole line is to the greater part, as that greater part is to the less. Hence, in any line so divided, the rectangle of the whole line and the less segment, is equal to the square of the greater segment. Euclid shows how to divide a line in extreme-and-mean ratio, in his Elements, book 2, prop. 11, to this effect: Let AB be the given line; to which draw AE perpendicular and equal to half AB ; in EA produced take $EF = EB$, so shall AF be equal to the greater part; consequently, if AG be taken equal to AF , the line AB will be divided in G as required.

The same may be done otherwise thus :

As before, make AE (fig. 2) perpendicular and $= \frac{1}{2}AB$; join EB , on which take $EC = EA$, and then take $BD = BC$, so shall the line be divided in D as required.

No number can be divided into extreme and mean proportion, so that its two parts shall be rational; as is well demonstrated by Clavius, in his Commentary on the 9th book of Euclid's Elements; and the same thing will also appear from the following algebraical solution of the same problem: Let a denote the whole line, and x the greater part; then shall $a-x$ be the less part, and the rectangle of the whole and less part being put equal to the square of the greater part, gives this equation, $x^2 = a(a-x) = a^2 - ax$; hence $x^2 + ax = a^2$ and by completing the square, and extracting the root, &c, there is at last obtained for the greater part $x = \frac{\sqrt{5}-1}{2}a$; conse^r. $a-x = \frac{3-\sqrt{5}}{2}a$ is the less part. And as the square root of 5, which cannot be exactly extracted, makes a portion of both these parts, it is manifest that neither of them can be obtained in rational numbers.

Euclid makes great use of this problem, in several parts of the 13th book of the Elements; and by means of it he constructs the 10th proposition of the 4th book, which is to construct an isosceles triangle having each angle at the base double the angle at the vertex.

EXTREMES Conjunct, and EXTREMES Disjunct, in Spherical Trigonometry, are in the former case the two circular parts that lie next the assumed middle part, and in the latter case they are the two that lie remote from the middle part. These were terms employed by lord Napier, in his universal theorem for resolving all right-angled and quadrantal spherical triangles, and published in his Logarithmorum Canonis Descriptio, an. 1614. In this theorem, Napier condenses into one rule, in two parts, the rules for all the cases of right-angled spherical triangles, which had been separately demonstrated by Pitiscus, Lansbergius, Copernicus, Regiomontanus, and others. In this theorem, neglecting the right angle, the author calls the other five parts, circular parts, which are, the two legs about the right angle, and the complements of the other three, viz of the hypothenuse, and the two oblique angles. Then, taking any three of these five parts, one of them will be in the middle between the other two, and these two are the extremes conjunct when they are immediately adjacent to that middle part, or they are the extremes disjunct when they are each separated from the middle one by another part. Thus, the five parts being AB , AC , and the complements of BC and of the two angles B and C : then if the three parts AB , and the complements of the angle B and hypothenuse BC be taken, these three are contiguous to each other, the angle B lying in the middle between the other two: therefore the complement of B is the middle part, and AB with

the complement of BC the extremes conjunct. But if the three sides be taken; BC is equally separated from the two legs AB and AC , by the two angles B and C ; and therefore these two legs AB and AC are the extremes disjunct, and the complement of BC the middle part.—The author's rule for resolving each of these cases is in two parts, as below:

The rectangle contained by radius and the sine of the middle part, is equal to the rectangle of the tangents of the extremes conjunct, or equal to the rectangle of the sines of the extremes disjunct. Which rule comprehends all the cases that can happen in right-angled spherical triangles; in the application of which rule, the equal rectangles are divided into a proportion or analogy, so that the term sought may be the last of the four terms that are concerned, and consequently its corresponding term in the same rectangle must be the first of those terms.

EYE, the organ of sight, consisting of several parts, and of such forms as best to answer the purpose for which it was designed. Vision or sight being effected by a refraction of light through the humours of the eye to the bottom or farther internal part of it, where the images of external objects are formed on a fine expansion of the optic nerve, called the retina, therefore the fore part of the eye must be of a convex figure, and of such a precise degree of convexity, as the particular refractive power of the several humours require, for forming the image of an object at a given focal distance, viz, the diameter of the eye. Hence we find,

1st; The external part of the eye-ball cd (Plate 2, fig. 8) is a strong pellucid substance, properly convex, and which, when dried, has some resemblance to a piece of transparent horn, for which reason it is called the cornea, or horny coat of the eye.

2dly; Immediately behind this coat there is a fine clear humour which, from its similarity to water, is called the aqueous or watery humour, and is contained in the space between cd and gfe .

3dly; In this space there is a membrane or diaphragm, called the uvea, with a hole in the middle as at r , called the pupil, of a muscular contexture for altering the dimensions of that hole, in order to adjust or admit a due quantity of light.

4thly; Immediately behind this diaphragm is placed a lenticular-formed substance ce , of a considerable consistence, called from its transparency the crystalline humour. This is contained in a fine tunic called the choroides, and is suspended in the middle of the eye by a ring of muscular fibres called the ligamentum ciliare, as at g and e ; by which means it is moved a little nearer to, or farther from, the bottom of the eye, to alter the focal distance.

5thly; All the remaining interior part of the eye, constituting the great body of it, from ghe to imk , is made up of a large quantity of a jelly-like substance, called the vitreous or glassy humour; though it resembles glass in nothing except its transparency; it being more like the white of an egg than any other thing.

6thly; On one side of the backward part of the eye, as at x , the optic nerve enters it from the brain, and is expanded over all the interior part of the eye to g and e , the expansion being named the retina. On this delicate membrane, the image im of every external object ob , is formed according to the optic laws of nature, in the following manner.

Let ob be any very distant object. Now a pencil of

rays proceeding from any point L , will fall on the cornea cD , and be refracted by the aqueous humour under it, to a point in the axis of that pencil continued out. Also the radius of convexity of the cornea being nearly $\frac{1}{3}$ of an inch; and the sine of incidence in air to that of refraction in the aqueous humour, being nearly as 4 to 3, supposing the rays parallel, or the object very far distant, the focal distance after the first refraction, by the proper theorem

(See OPTICS) $\frac{mr}{m-r}$, will be found $1\frac{1}{4}$ inch from the cornea:

r being the radius $\frac{1}{3}$, and m to n as 4 to 3, that is, the sine of the angle of incidence, to that of refraction.

The rays thus refracted by the cornea, fall converging on the crystalline humour, and tend to a point 1'228 inch behind it; also the radii of convexity in the said humour are $\frac{1}{4}$ and $\frac{1}{2}$ respectively; and the sine of incidence to that of refraction of the aqueous into the crystalline humour, having been found by experiments to be as

13 to 12; therefore, by this theorem $\frac{mdr}{md-md+nw}$, the focal distance after refraction in the crystalline, will be 1'02 inch from the fore part of it: where $m=13$, $n=12$, $r=\frac{1}{3}$, and $d=1\cdot228$.

The rays now pass from the crystalline to the vitreous humour still in a converging state, and the sines of incidence and refraction being here as 12 to 13, as found by experiment; and since the surface of the vitreous humour is concave which receives the rays, and is the same with the convexity of the hinder surface of the crystalline, the radius will be the same, viz $\frac{1}{2}$ of an inch. Therefore the focal distance after this third refraction will be found, by the same theorem $\frac{ndr}{nd-md+nw}$, to be 6 tenths of an inch nearly, from the hinder part of the cornea: where $m=12$, $n=13$, $r=\frac{1}{2}$, and $d=1\cdot82$: the thickness of the lens of the cornea being nearly $\frac{1}{2}$ of an inch.

Now experience shows that the distance of the retina in the back part of the eye, behind the cornea, is nearly equal to that focal distance; and therefore it follows that all objects at a great distance have their images formed on the retina in the bottom or hinder part of the eye, and thus is distinct vision produced by this wonderful organ.

When the distance of objects is not very great, the focal distance, after the last refraction in the vitreous humour, will be a little increased; and to do this we can move the crystalline a little nearer the cornea by means of the ligamentum ciliare, and thus on all occasions it may be adjusted for a due focal distance for every distance of objects, excepting that which is less than 6 or 7 inches, in persons whose sight is perfect. But many are of opinion, that this is effected by a power in the eye to alter the convexity of the crystalline humour as occasion requires; though this is rather doubtful.

By what has been said it appears, that rays of light flowing from every part of an object oB , placed at a proper distance from the eye, will have an image IM thereby formed on the retina in the bottom of the eye; and since the rays OM , NI , which come from the extreme parts of the object, cross each other in the middle of the pupil, the position of the image IM will be contrary to that of the object, or inverted, as in the case of a lens.

The apparent place of any part of an object is in the axis, and conjugate focus of that pencil of rays by which that part or point is formed in the image. Thus, OM is in the axis, and o the focus proper to the rays by which the

point M in the image is made; therefore the sensation of the place of that part will be conceived in the mind to be at o ; in like manner the idea of place belonging to the point I , will be referred in the axis IB , to the proper focus B ; therefore the apparent place of the whole image IM , will be conceived in the mind to occupy all the space between o and B , and at the distance AL from the eye.

Hence likewise appears the reason, why we see an object upright by means of an inverted image; for since the apparent place of every point M will be in the axis MO at o ; and this axis crossing the axis of the eye HL in the pupil, it follows, that the sensible place o of that point will lie, without the eye, on the contrary side of its axis, to that of the point in the eye; and since this is true of all other parts or points in the image, it is evident that the position of every part of the object will be on the contrary side of the axis to every corresponding part in the image, and therefore the whole object oB will have a contrary position to that of the image IM , or will appear upright.

If the convexity of the cornea cD happens not exactly to correspond to the diameter of the eye, considered as the natural focal distance, then the image will not be formed on the retina, and consequently no distinct vision can be effected in such an eye.

If the cornea be too convex, the focal distance in the eye will be less than its diameter, and the image will be formed short of the retina. Hence the reason why people having eyes thus formed are obliged to hold things very near them, to lengthen the focal distances; and also why they use concave glasses to counteract or remedy the excess of convexity, in order to view distant objects distinctly.

When the eye has less than a just degree of convexity, or is too flat, as is generally the case with old people, by a natural deficiency of the aqueous humour, then the rays tend to a point or focus beyond the retina or bottom of the eye; and to supply this want of convexity in the cornea, we use convex lenses in those frames called spectacles, or visual glasses.

Since the rays of light OA , BA , which constitute the visual angle OAB , will, when they are intercepted by a lens, be refracted sooner to the axis; the said angle will thereby be enlarged, and the object of course become magnified; which is the reason why those lenses are called magnifiers, or reading-glasses.

The dimensions, or magnitude, of an object OB , are judged of by the quantity of the angle OAB which it subtends at the eye. For if the same object be placed at two different distances L and N , the angles OAB , OAB , which in these two places it subtends at the eye, will be of different magnitudes, and the linear dimensions, viz, length and breadth, will be at N and at L , as the angle OAB is to the angle OAB . But the surfaces of the objects will be as the squares of those angles, and the solidities as the cubes of them.

It is found by experience, that two points O , L , in any object, will not be distinctly seen by the eye, till they are near enough to subtend an angle OL of one minute. And hence when objects, however large they may be, are so remote as not to be seen under an angle of one minute, they cannot properly be said to have any apparent dimensions or magnitude at all: such is the case of the large bodies of the planets, comets, and fixed stars. But the science of optics has supplied means of enlarging this natural small angle under which most distant objects appear, and thereby increasing their apparent magnitudes to a very

surprising degree, in the instance of that noble instrument the telescope.

On the other hand, there are in creation an infinity of objects, of such small dimensions, that they will not subtend the requisite angle, if brought to the nearest limits of distinct vision, viz, 6, 7, or 8 inches from the eye, as found by experience; and therefore to render them visible at a very near distance, we have a variety of glasses, and instruments of different constructions, as microscopes, &c, by which those minute objects appear many thousand times larger than to the naked eye; and thereby enrich the mind with discoveries of the sublimest nature, in regard to creative power, wisdom, and economy. See VISION.

EYE-glass, in Optical Instruments, is that which is

applied to the eye in using the instrument. This is usually a lens convex on both sides; but Eustachia Divini long since invented a microscope of this kind, the power of which he places very greatly above that of the common sort; and this chiefly depending on the eye-glass, which was double, consisting of two plano-convex glasses, so poised as to touch one another in the middle of their convex surface. This instrument is much commended by Fabri in his Optics, as possessing this peculiar excellence, that it shows all the objects flat, and not crooked, and takes in a large area, though it magnifies very much.

Bull's EY $\ddot{\text{e}}$, a star of the first magnitude, in the eye of the constellation Taurus, the bull, and by the Arabs called Aldebaran.

F.

F A C

FACE, or FAÇADE, in Architecture, is sometimes used for the front or outward part of a building, which immediately presents itself to the eye; or the side where the chief entrance is, or next the street, &c.

FACE, FACIA, or FASCIA, also denotes a flat member, having a considerable breadth, and but a small projection. Such are the bands of an architrave, larmier, &c.

FACES of a Bastion, in Fortification, are the two foremost sides, reaching from the flanks to the outermost point of the bastion, where they meet, and form the salient angle of the bastion. These are usually the first parts that are undermined, or beaten down; because they reach the farthest out, are the least flanked, and are therefore the weakest.

FACE of a Place, is the extent between the outermost points of two adjacent bastions; containing the curtain, the two flanks, and the two faces of those bastions that look towards each other. This is otherwise called the Tenuaille of the place.

FACE Prolonged, is that part of a line of defence rasant, which is between the angle of the epaule or shoulder of a bastion and the curtain; or the line of a defence rasant diminished by the face of the bastion.

FACIA, in Architecture, See FACE, and FASCIA.

FACTORS, in Multiplication, a name given to the two numbers that are multiplied together, viz, the multiplicand and multiplier; so called, because they are to facere productum, make or constitute the factum or product.

In algebra, we generally call all those quantities factors, the product of which constitute any algebraical expression: thus, $(a + b)$ and $(a - b)$ are the factors of the expression $a^2 - b^2$; also a, b, c, d , are the factors of the quantity $abcd$. But in arithmetic these are commonly called divisors. See DIVISORS.

In the Diophantine analysis, and in the theory of numbers, it is frequently very advantageous to be able to resolve certain algebraical formulae into their respective factors, as also in the investigation of the nature of equations, and in short almost every branch of algebra may sometimes derive peculiar advantages from such resolu-

tion. Suppose, for example, we had to multiply $\frac{x^2 - b^2}{x^2 - 2bx + b^2}$ by $\frac{x - b}{x^2 + bx}$. Now by resolving this into its factors it becomes $\frac{(x^2 + b^2) \cdot (x + b) \cdot (x - b)}{(x - b) \cdot (x - b) \cdot (x + b) \cdot x} = \frac{x^2 + b^2}{x}$, by canceling the common factors; which from the common mode of operation would have been attended with considerable labour.

The limits of this work will not however admit of our entering upon this subject to any extent; we therefore refer the reader for farther information on this subject to Euler's Algebra, vol. 2, chapter 11; to the additions in the same vol. by Lagrange; to the Analysis Infinitorum; and to Legendre's Theorie des Nombres; where most of the following theorems are demonstrated in a very masterly manner.

$a - b$ is a factor of $a^m - b^m$ for all values of m .
 $a + b - - - - a^m - b^m$ when m is even.
 $a + b - - - - a^m + b^m$ when m is odd.
 $a - 1 - - - - a^m - a^n$ for all values of m and n .
 $a + 1 - - - - a^m - a^n$ when $m - n$ is even.
 $a + 1 - - - - a^m + a^n$ when $m - n$ is odd.
 a is a numer. factor of $r^a - r$ when a is a prime number.
 $a - - - - - r^{a-1} - 1$ when a is also prime to r .
 $a - - - - (1.2.3 - a - 1) + 1$ when a is a prime.
The product of two factors, each of which is the sum of two squares, is itself the sum of two squares.
That is, $(a^2 + b^2) \cdot (c^2 + d^2) = m^2 + n^2$, also.
 $(a^2 + b^2 + c^2 + d^2) \cdot (a^2 + b^2 + c^2 + d^2) = m^2 + n^2 + p^2 + q^2$.

These two last properties were first demonstrated by Euler, in the Act. Petrop., where there are also many other ingenious papers on this subject.

IMAGINARY FACTORS. See IMAGINARY.

FACTUM, the product of two quantities multiplied together. As, the factum of 3 and 4 is 12; and the factum of 2a and 5b is 10ab.

FACULÆ, in Astronomy, a name given by Scheiner, and others after him, to certain bright spots on the sun's disc, that appear more bright and lucid than the rest of his body.—Hevelius assures us that, on July 20, 1634, he observed a facula whose breadth was equal to a 3d part

of the sun's diameter. He says also that the maculae often change into faculae; but these seldom or never into maculae. And some authors even contend that all the maculae degenerate into facula before they quite disappear. Many authors, after Kircher and Scheiner, have represented the sun's body full of bright, fiery spots, which they conceive to be a kind of volcanos in the body of the sun: but Huygens, and others of the latest and best observers, finding that the best telescopes discover nothing of the matter, they therefore agree in exploding entirely the phenomena of faculae. All the foundation he could see for the notion of faculae, he says, was, that in the darkish clouds which frequently surround the maculae, there are sometimes seen little points or sparks brighter than the rest: the cause of which is attributed by these authors to the tremulous agitation of the vapours near our earth; the same as sometimes shows a little unevenness in the circumference of the sun's disc when viewed through a telescope. Strictly therefore, the faculae are not eruptions of fire and flame, but refractions of the sun's rays in the rarer exhalations, which, being condensed near that shade, seem to exhibit a light greater than that of the sun.

FAHRENHEIT (**GABRIEL DANIEL**), by some writers said to be a native of Dantzig, and by others to be born at Hamburg, in 1686. He was intended for mercantile affairs. But his inclination led him to the study of natural philosophy, and he applied particularly to the improvement of barometers and thermometers, constructing great numbers of them, which were much valued. He improved the thermometer, by substituting mercury instead of spirits of wine, and formed a new scale for the instrument, founded on accurate experiments, fixing the freezing point of water at 32°, and that of boiling at 212°. This was probably done about the year 1720; as, in his Dissertation on Thermometers, published 1724, he speaks of having used it some years, to ascertain M. Amonton's experiment, who asserted, that the heat of boiling water was constant. The English have generally adopted this scale, though the French preferred that of Reaumur, and very lately their own centigrade thermometer. Fahrenheit by some is said to have been living in 1740, while others say he died in 1736.

FALCATED, one of the phases of the planets, vulgarly called horned. Astronomers say, the moon, or any planet, is falcated, when the enlightened part appears in the form of a crescent, like a sickle, or reaping-hook, which by the Latins is called falx. The moon is falcated while she moves from the 3d quarter to the conjunction, and so on from hence to the first quarter; the bright part appearing then like a crescent, viz, during the first and last quarters. But during the 2d and 3d quarters, the light part appears gibbous, and the dark part falcated.

FALCON or **FAUCON**, and **FALCONET** or **FAUCONET**, certain old species of cannon, long since disused.

FALL, the descent or natural motion of bodies towards the centre of the earth, &c. Galileo first discovered the law of the acceleration of falling bodies; viz, that the spaces descended from rest are as the squares of the times of descent; or, which comes to the same thing, that if the whole time of falling be divided into any number of equal parts, whatever space it falls through in the first part of the time, it will fall 3 times as far in the 2d part of time, and 5 times as far in the 3d portion of time, and so on,

according to the uneven numbers 1, 3, 5, 7, &c. See ACCELERATION, DESCENT, GRAVITY, &c.

FALSE-BRAVE, in Fortification. See FAUSSE-BRAYE.

FALSE Position, in Arithmetic. See POSITION.

FALSE Root, a name given by Cardan, to the negative roots of equations, and numbers. So the root of 9 may be either 3 or -3, the former he calls the true, and the latter the false or fictitious root; also of this equation $x^2 - x = 6$, the two roots are 3 and -2, the former true, and the latter false.

FASCIA, in Architecture. See FACIA and FACE.

FASCIÆ, in Astronomy, are certain stripes or rows of bright parts, observed on the bodies of some of the planets, like swathes, bands, or belts; especially on the planet Jupiter. The fascie, or belts of Jupiter, are more lucid than the rest of his disc, and are terminated by parallel lines. They are sometimes broader and sometimes narrower; and do not always possess the same part of the disc.

M. Huygens also observed a very large kind of fascia in Mars, in the year 1656; but it was darker than the rest of the disc, and occupied its middle part.

FASCINES, in Fortification, are faggots made of the twigs and small branches of trees and brush-wood, bound up in bundles; these, being mixed with earth, serve to fill up ditches, and to make the parapets of trenches, batteries, &c.

FATHOM, an English measure of the length of 6 feet or 2 yards.

FATUUS Ignis. See IGNIS Fatuus.

FAUCON, and **FAUCONET**, the same as Falcon and Falconet; the old names of certain species of ordnance; which, as well as many others, are now no longer in use, as it has been for some time past the practice to denominate the several sizes of cannon from the weight of their ball, instead of calling them by those fanciful and unmeaning names.

FAUSSE-BRAYE, in Fortification, an elevation of earth, about three feet above the level ground; round the foot of the rampart on the outside, defended by a parapet about four or five fathoms distant from the upper parapet, which parts it from the berme, and the edge of the ditch. The fausse-braye is the same with what is otherwise called chemin des rondes, and basse enceinte; its use being for the defence of the ditch.

FEBRUARY, the 2d month of the year, containing 28 days for three years, and every fourth year 29 days. These years being called Bissextile, or Leap-years; and return every fourth year, except at the commencement of a new century, which are not bissextile, unless the number of the century be divisible by 4; so 1800 was not bissextile, nor will 1900 be so, but 2000 will, because 20 is divisible by 4. (See BISSEXTILE.) In the first ages of Rome, February was the last month of the year, and preceded January, till the Decemviri made an order that February should be the 2d month of the year, and come after January.

FELLOWSHIP, COMPANY, or PARTNERSHIP, is a rule in arithmetic, of great use in balancing accounts among merchants, and partners in trade, teaching how to assign to every one of them his due share of the gain or loss, in proportion to the stock he has contributed, and the time it has been employed, or according to any other conditions. Or, more generally, it is a method of dividing a given number, or quantity, into any number of parts, that shall have any assigned ratios to one another.

And hence comes this general rule : Having added into one sum the several numbers that express the proportions of the parts, it will be,

As the sum of the proportional numbers :

Is to the given quantity to be divided :

So is each proportional number :

To the corresponding share of the given quantity.

For Example. Suppose it be required to divide the number 120 into three parts that shall be in proportion to each other as the numbers 1, 2, 3.—Here 120 is the quantity to be divided, and 6 is the sum of the numbers 1, 2, and 3, which express the proportions of the parts ; therefore as

$$6 : 120 :: \begin{cases} 1 & : 20 \text{ the 1st part,} \\ 2 & : 40 \text{ the 2d part,} \\ 3 & : 60 \text{ the 3d part.} \end{cases}$$

This rule is usually distinguished into two cases, one in which time is concerned, or in which the stocks of partners are continued for different times ; and the other in which time is not considered ; the latter being called Single Fellowship, and the former Double Fellowship.

Single Fellowship, or Fellowship without Time, is the case in which the times of continuance of the shares of partners are not considered, being all the same ; and in this case, the rule will be as above, viz,

As the whole stock of the partners :

Is to the whole gain or loss ::

So is each one's particular stock :

To his share of the gain or loss.

Example. Two partners, A and B, form a joint stock, of which A contributed 75*l.*, and B 45*l.*; with which they gain 30*l.* how much of it must each person have ?

$$\text{As } 120 : 30 :: \begin{cases} 75 : 18\frac{1}{2}s. = A's \text{ share,} \\ 45 : 11\frac{1}{2}s. = B's \text{ share.} \end{cases}$$

Double Fellowship, or Fellowship with Time, is the case in which the times of the stocks continuing are considered, because they are not all the same. In this case, the shares of the gain or loss must be proportional, both to the several shares of the stock, and to the times of their continuance, and therefore proportional to the products of the two. Hence this rule: Multiply each particular share of the stock by the time of its continuance, and add all the products together into one sum ; then say,

As the sum of the products :

Is to the whole gain or loss ::

So is each several product :

To the corresponding share of the gain or loss.

For Example. A had in company 50*l.* for 4 months, and B 60*l.* for 5 months ; and their gain was 24*l.* how must it be divided between them ?

$$\begin{array}{r} 50 & 60 \\ 4 & 5 \\ \hline 200 & 300 \end{array}$$

$$\text{As } 500 : 24 :: \begin{cases} 200 : 9\frac{1}{2}s. = A's \text{ share,} \\ 300 : 14\frac{1}{2}s. = B's \text{ share.} \end{cases}$$

FERGUSON (JAMES), an ingenious experimental philosopher, mechanist, and astronomer, was born in Banffshire, in Scotland, 1710, of very poor parents. At the very earliest age his extraordinary genius began to unfold itself. He first learned to read, by overhearing his father teach his elder brother : and he had made this acquisition before any one suspected it. He soon discovered a peculiar taste for mechanics, which first arose on seeing his

father use a lever. He pursued his study to a considerable length, while he was yet very young ; and made a watch in wood-work, from having once seen one. As he had at first no instructor, nor any help from books, every thing he learned had all the merit of an original discovery ; and such, with inexpressible joy, he believed it to be.

As soon as his age would permit, he went to service ; in which he met with hardships, that rendered his constitution feeble through life. While he was servant to a farmer (whose goodness he acknowledges in the modest and humble account of himself which he prefixed to one of his publications), he contemplated and learned to know the stars, while he tended the sheep ; and began the study of astronomy, by laying down, from his own observations only, a celestial globe. His kind master, observing in him these marks of ingenuity, procured him the countenance and assistance of some neighbouring gentlemen, through whose help and instructions he gained farther knowledge, having by these means been taught arithmetic, with some algebra, and practical geometry. He had also obtained some notion of drawing, and being sent to Edinburgh, he there began to take portraits in miniature, at a small price ; an employment by which he supported himself and family for several years, both in Scotland and England, while he was pursuing more serious studies. In London he first published some curious astronomical tables and calculations ; and afterwards gave public lectures in experimental philosophy, both in London and most of the country towns in England, with the highest marks of general approbation. He was elected a fellow of the Royal Society, and was excused the payment of the admission fee and the usual annual contributions, on account of his supposed inability to pay them. He enjoyed from the king a pension of 50 pounds a year, besides other occasional presents, which he privately accepted and received from different quarters, till the time of his death ; through which, and the fruits of his own labours, he died worth about six thousand pounds, which astonished all his friends, who had always entertained an idea of his great poverty. His death happened in 1776, at 66 years of age, though he had the appearance of being much older.

Mr. Ferguson must be allowed to have been a very uncommon genius, especially in mechanical contrivances and executions, for he constructed many machines himself in a very neat manner. He had also a good taste in astronomy, as well as in natural and experimental philosophy, and was possessed of a happy manner of explaining himself in an easy, clear, and familiar way. His general mathematical knowledge, however, was little or nothing. Of algebra he understood but little more than the notation ; and he has often told me that he could never demonstrate one proposition in Euclid's Elements ; his constant method being to satisfy himself, as to the truth of any problem, with a measurement by scale and compasses. He was a man of a very clear judgment in any thing that he professed, and of unweary application to study : benevolent, meek, and innocent in his manners as a child : humble, courteous, and communicative : instead of pedantry, philosophy seemed to produce in him only diffidence and urbanity. The list of Mr. Ferguson's public works, is as follows :

1. Astronomical Tables and Precepts, for calculating the true times of New and Full Moons, &c ; 1763.—

2. Tables and Tracts, relative to several arts and sciences; 1767.—3. An Easy Introduction to Astronomy, for Young Gentlemen and Ladies; 2d edit. 1769.—4. Astronomy explained upon Sir Isaac Newton's Principles; 5th edit. 1772.—5. Lectures on Select Subjects in Mechanics, Hydrostatics, Pneumatics, and Optics; 4th edit. 1772.—6. Select Mechanical Exercises; with a short Account of the Life of the author, by himself; 1773.—7. The Art of Drawing in Perspective made easy; 1775.—8. An Introduction to Electricity; 1775.—9. Three Letters to the Rev. John Kennedy, on the Harvest Moon, 1763 and 1775.

FERMAT (PETER), a celebrated mathematician and philosopher, and counsellor of the parliament of Toulouse, where he was born towards the commencement of the seventeenth century, or just before; and notwithstanding he did not make the mathematics the whole, nor even the principal part of his study, he yet obtained considerable celebrity for his knowledge and discoveries in this science. He had also a perfect knowledge of the Greek and Latin languages, beside several of the modern languages of Europe, as the Italian, Spanish, and English. He also cultivated poetry, some of his works being still extant. At the same time he fulfilled the duties of his office as counsellor to the parliament of Toulouse, with assiduity and honour, enjoying the reputation of an enlightened judge.

It was the custom of the time in which Fermat flourished, for the mathematicians of different countries to propose problems to each other for solution, and in this kind of correspondence we find him deeply engaged, particularly in theorems relating to certain properties of numbers, the demonstrations of which he generally suppressed, if, as is doubtful, he was in possession of them: however this may be, many of them are even now without demonstrations, and several others which were left by him in this state, would perhaps still have remained so had it not been for the ingenuity and industry of Euler, Lagrange, and some other more modern mathematicians.

Fermat had a violent dispute with Descartes on the subject of Maxima and Minima of quantities, of which he was the author; as well as on the doctrine of refraction; and though a compromise at length took place between them, they were never good friends after; but in this Descartes was most to blame, as Fermat seems to have much wished for a complete reconciliation. He died in the beginning of the year 1665. Besides his new edition of Diophantus, Fermat was author of 1. A Method for the Quadrature of all sorts of Parabolas.—2. Another on Maxima and Minima: which serves not only for the determination of plane and solid problems; but also for drawing tangents to curve lines, finding the centres of gravity in solids, and the solution of questions concerning numbers: in short, a method very similar to the Fluxions of Newton.—3. An Introduction to Geometric Loci, plane and solid.—4. A Treatise on Spherical Tangencies: where he demonstrates in the solids, the same things as Vieta demonstrated in planes.—5. A Restoration of Apollonius's two books on Plane Loci.—6. A General Method for the dimension of Curve Lines. Besides a number of other smaller pieces, and many letters to learned men; several of which are to be found in his *Opera Varia Mathematica*, printed at Toulouse, in folio, 1679.

FERMENTATION, an intestine motion, arising spon-

taneously among the small and insensible particles of a mixed body, thus producing a new disposition, and a different combination of those parts. Fermentation differs from dissolution, as the cause from its effect, the latter being only the result or effect of the former.

FESTOON, in Architecture &c, a decoration in form of a garland or cluster of flowers.

FICHANT FLANK. See FLANK.

FICHANT Line of Defence. See FIXED Line of Defence.

FIELD-Book, in Surveying, a book used for setting down angles, distances, and other things, remarkable in taking surveys. The pages of the field-book may be conveniently divided into three columns. In the middle column are to be entered the angles taken at the several stations by the theodolite, with the distances measured from station to station. And the offsets, taken with the offset-staff, on either side of the station line, are to be entered in the columns on either side of the middle column, according to their position, on the right or left, with respect to that line: also on the right or left of these are to be set down the names and characters of the objects, with proper remarks, &c. See a specimen in my Treatise on Mensuration; pa. 386, ed. 4th. See also SURVEYING.

FIELD-FORT. See FORTINE.

FIELD-Pieces, are small cannon, usually carried along with an army in the field: such as, one-pounders, one-and-a-half; two-, three-, four-, six-, nine-, and 12-pounders; which, being light and small, are easily carried.

FIELD-Staff, is a staff carried by the gunners, in which they screw lighted matches, when they are on service; which is called arming the field-staffs. See LINSTOCK.

FIELD of View, or of Vision, is the whole space or extent within which objects can be seen through an optical machine, or at one view of the eye without turning it.

The precise limits of this space are not easily ascertained, for the natural view of the eye. In looking at a small distance, we have an imperfect glimpse of objects through almost the extent of a hemisphere, or at least for above 60 degrees each way from the optic axis; but towards the extremity of this space, objects are very imperfectly seen; and the diameter of the field of distinct vision does not subtend an angle of more than 5 degrees at most, so that the diameter of a distinct image on the retina is less than $\frac{1}{20}$ of an inch; but it is probably much less.

FIELD Works, in Fortification, are those that are thrown up by an army in besieging a fortress, or by the besieged to defend the place. Such are the fortifications of camps, highways, &c.

FIFTH, in Music, one of the harmonical intervals or concords; called by the ancients diapente.

The fifth is the 3d in order of the concords, and the ratio of the chords that produce it, is that of 3 to 2. It is called fifth, because it contains five terms, or sounds, between its extremes, and four degrees; so that in the natural scale of music it comes in the 5th place, or order, from the fundamental.—The imperfect, or defective fifth, by the ancients called semidiapente, is less than the fifth by a mean semitone.

FIGURATE Numbers, are those numbers which are formed from the addition of all the leading terms of successive series, beginning first with that of the natural numbers, as in the following table; where the law of continuation is manifest.

A	1, 2, 3, 4, 5, 6	- n.
B	1, 3, 6, 10, 15, 21	- $\frac{n \cdot (n+1)}{1 \cdot 2}$.
C	1, 4, 10, 20, 35, 56	- $\frac{n \cdot (n+1) \cdot (n+2)}{1 \cdot 2 \cdot 3}$.
D	1, 5, 15, 35, 70, 126	- $\frac{n \cdot (n+1) \cdot (n+2) \cdot (n+3)}{1 \cdot 2 \cdot 3 \cdot 4}$.

Here, the first series A is that of the natural numbers, of which the general term is n ; the second series B, is that of triangular numbers, of which the general term is $\frac{n \cdot (n+1)}{1 \cdot 2}$. If now from this general term, which is the n th term of the series B, there be subtracted the preceding term of the same series, which is $\frac{(n-1) \cdot n}{1 \cdot 2}$, the remainder will be n , which is the n th term of the series A. Hence we shall form the n th term of the series B, by adding to the $n-1$ term of the same series, the n th term of the series A.

The third series C is that of pyramidal numbers, the general term of which $\frac{n \cdot (n+1) \cdot (n+2)}{1 \cdot 2 \cdot 3}$, and if from this term we subtract the preceding one $\frac{(n-1) \cdot n \cdot (n+1)}{1 \cdot 2 \cdot 3}$, the difference will be $\frac{n \cdot (n+1)}{1 \cdot 2}$, which is the n th term of the series B. Whence we may form the series C by means of the series B, as this latter is formed from the series A. And exactly in the same manner the 4th series D, of which the general term is $\frac{n \cdot (n+1) \cdot (n+2) \cdot (n+3)}{1 \cdot 2 \cdot 3 \cdot 4}$, may be formed from the third C, and so on of others.

The general terms given above, as definitions, and from which the successive law of formation is deduced, contains the whole theory of figurate numbers, and presents, at one view, the demonstration of the general proportion mentioned by Fermat in his notes on Diaphantus, par 16, and which he considered as one of his principal discoveries.

So that the figurate numbers of any order may be found without computing those of the preceding orders; which is done by taking the successive products of as many of the terms of the arithmeticals 1, 2, 3, 4, 5, &c, in their natural order, as there are units in the number which denominates the order of figurates required, and dividing those products always by the first product: thus, the triangular numbers are found by dividing the products $1 \times 2, 2 \times 3, 3 \times 4, 4 \times 5, \&c$, each by the 1st pr. 1×2 ; the first pyramids by dividing the products $1 \times 2 \times 3, 2 \times 3 \times 4, 3 \times 4 \times 5, \&c$, by the first $1 \times 2 \times 3$. And, in general, the figurate numbers of any order n , are found by substituting successively 1, 2, 3, 4, 5, &c, instead of x in this general expression $x \cdot x + 1 \cdot x + 2 \cdot x + 3 \cdot \&c$.

$1 \cdot 2 \cdot 3 \cdot 4 \cdot \&c$; where the factors in the numerator and denominator are supposed to be multiplied together, and to be continued till the number in each be less by 1 than that which expresses the order of the figurates required. See Maclaurin's Fluxions, art. 351, in the notes; also Simpson's Algebra, pa. 213; or Malcolm's Arithmetic, pa. 396, where the subject of figurates is treated in a very extensive and perspicuous manner.

FICURE, in general, denotes the surface or terminating extremes of a body.—All finite bodies have some figure, form, or shape; whence, figurability is reckoned among the essential properties of body, or matter: a body without figure, would be an infinite body.

FIGURES, in Architecture and Sculpture, denote representations of things made in solid matter; as statues, &c.

FIGURES, in Arithmetic, are the numeral characters, by which numbers are expressed or written, as the ten digits, 1, 2, 3, 4, 5, 6, 7, 8, 9, 0. These are usually called the Arabic, and Indian figures, from which people it is supposed they were derived, being brought into Europe by the Moors of Spain, and into England about 1130, as Dr. Wallis conjectures: See his Algebra, pa. 9. However, from some ancient documents, supposed to consist wholly or in part of Arabian figures, some have concluded that these figures, originally Indian, were known and used in this country at least as early as the 10th century. The oldest date discovered by Dr. Wallis, was on a chimneypiece, at Helmdon, in Northamptonshire, thus M133, that is 1133. Other dates discovered since, are 1090, at Colchester, in Essex; M16 or 1016, at Wigdell-hall, near Buntingford, in Hertfordshire; 1011 on the north front of the parish church of Rumsey in Hampshire; and 975 over a gate-way at Worcester.

Dr. Ward, however, has urged several objections against the antiquity of these dates. As no example occurs of the use of such figures in any ancient manuscript, earlier than some copies of Johannes de Sacro Bosco, who died in 1256, he thinks it strange that these figures should have been used by artificers so long before they appear in the writings of the learned; and he also disputes the fact. The Helmdon date, according to him, should be 1233; the Colchester date 1490; that at Wigdell-hall has in it no Arabic figures, the 1 and 6 being I and G, the initial letters of a name; and the date at Worcester consists, he supposes, of Roman numerals, being really MXXV. See my Bridg. Philos. Trans. vol. 8, pa. 32, 39, &c.

Mr. Gibbon observes (in his History of the Decline and Fall of the Roman Empire, vol. v. pa. 321) that "under the reign of the caliph Waled, the Greek language and characters were excluded from the accounts of the public revenue. If this change was productive of the invention or familiar use of our present numerals, the Arabic characters or ciphers, as they are commonly styled, this regulation has promoted the most important discoveries of arithmetic, algebra, and the mathematical sciences."

On the other hand it may be observed that, "according to a new, though probable notion, maintained by M. de Villalson (Anecdota Graeca, tom. ii. pa. 152, 157), our ciphers are not of Indian or Arabic invention. They were used by the Greek and Latin arithmeticians long before the age of Boethius. After the extinction of science in the West, they were adopted in the Arabic versions from the original manuscripts, and restored to the Latins about the 11th century."

FIGURE of the Earth. See EARTH.

FIGURE of an Eclipse, in Astronomy, denotes a representation on paper &c, of the path or orbit of the sun or moon, during the time of the eclipse; with the different phases, the digits eclipsed, and the beginning, middle, and end of darkness, &c.

FIGURE, or Delineation, of the full moon, such as, viewed through a telescope with two convex glasses, is of considerable use in observations of eclipses, and conjunctions of the moon with other luminaries. In this figure are usually represented the maculae or spots of the moon, marked by numbers; beginning with those that usually enter first within the shade at the time of the eclipses, and also emerge the first.

FIGURE, in Conic Sections, according to Apollonius, is the rectangle contained under the latus-rectum and the transverse axis, in the ellipse and hyperbola.

FIGURE, in Fortification, is the plan of any fortified place; or the interior polygon, &c. When the sides, and the angles, are all equal, it is called a regular figure; but when unequal, an irregular one.

FIGURE, in Geometry, denotes a surface or space inclosed on all sides; and is either superficial or solid; superficial when it is inclosed by lines, and solid when it is inclosed or bounded by surfaces.

Figures are either straight, curved, or mixed, according as their bounds are straight, or curved, or both. The exterior bounds of a figure, are called its sides; the lowest side, its base; and the angular point opposite the base, the vertex of the figure; also its height, is the distance of the vertex from the base, or the perpendicular let fall upon it from the vertex.

For **Figures**, equal, equiangular, equilateral, circumscribed, inscribed, plane, regular, irregular, similar, &c; see the respective adjectives.

Apparent FIGURE, in Optics, that figure, or shape, under which an object appears, when viewed at a distance. This is often very different from the true figure; for a straight line viewed at a distance may appear but as a point; a surface as a line; a solid as a surface; and a crooked figure as a straight one. Also, each of these may appear of different magnitudes, and some of them of different shapes, according to their situation with regard to the eye. Thus, an arch of a circle may appear a straight line; a square or parallelogram, a trapezium, or even a triangle; a circle, an ellipsis; angular magnitudes, round; a sphere, a circle; &c.

Also any small light, as a candle, seen at a distance in the dark, will appear magnified, and farther off than it really is. Add to this, that when several objects are seen at a distance, under angles that are so small as to be insensible, as well as each of the angles subtended by any one of them, and that next to it; then all these objects appear not only as contiguous, but as constituting and seeming but one continued magnitude.

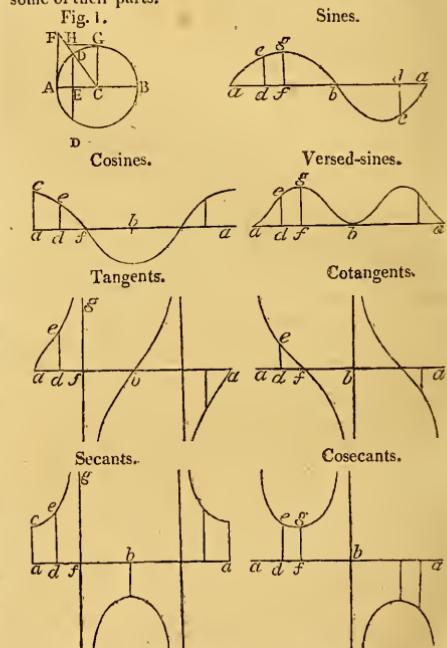

FIGURE of the Sines, Cosines, Versed-sines, Tangents, or Secants, &c. are figures made by conceiving the circumference of a circle extended out in a right line, upon every point of which are erected perpendicular ordinates equal to the sines, cosines, &c., of the corresponding arcs; and then drawing the curve line through the extremity of all these ordinates; which is called the figure of the sines, cosines, &c.

It is probable that these figures took their rise from the circumstance of the extension of the meridian line by Edward Wright, who computed that line by collecting the successive sums of the secants, which is the same thing as the area of the figure of the secants, being made up of all the ordinates, or secants, by the construction of the figure. And in imitation of this, the figures of the other lines have been invented; and by means of the figure of the secants, James Gregory showed how the logarithmic tangents may be constructed, in his *Exercitationes Geometricae*, 4to, 1668.

Construction of the Figures of Sines, Cosines, &c.

Let AB & AC (fig. 1) be the circle, AD an arc, DE its sine, CE its cosine, AE the versed-sine, AF the tangent, AG the cotangent, EF the secant, and EN the cosecant. Draw a right line aa' equal to the whole circumference

$ADBA$ of the circle, upon which lay off also the lengths of several arcs, as the arcs at every 10° , from 0 at a , to 360° at the other end at a ; upon these points draw perpendicular ordinates, upwards or downwards, according as the sine, cosine, &c., is affirmative or negative in that part of the circle, and equal to them; then drawing a curve line through the extremities of all these ordinates, it will form the figure of the sines, cosines, versed-sines, tangents, cotangents, secants, and cosecants, as in the annexed figures. Where it may be observed, that the following curves are the same, viz, those of the sines and cosines, those of the tangents and cotangents, and those of the secants and cosecants; except in the disposition of some of their parts.

It may be known when any of these lines, viz, the sines, cosines, &c., are affirmative or negative, i. e. to be set upwards or downwards, by observing the following general rules for those lines in the 1st, 2d, 3d, and 4th quadrants of the circle.

The sines	in the 1st and 2d are affirmative, in the 3d and 4th negative:
The cosines	in the 1st and 4th are affirmative, in the 2d and 3d negative:
The tangents	in the 1st and 3d are affirmative, in the 2d and 4th negative;
The cotangents	in the 1st and 3d are affirmative, in the 2d and 4th negative:
The secants	in the 1st and 4th are affirmative, in the 2d and 3d negative:
The cosecants	in the 1st and 2d are affirmative, in the 3d and 4th negative:

And all the versed-sines are affirmative.

To find the Equation and Area, &c, to each of these Curves.

Draw any ordinate de ; putting $r = AC$ the radius of the given circle, $x = ad$ or AD any absciss or arc, and $y = de$ its ordinate, which will be either the sine $DE = s$, cosine $CE = c$, versed-sine $AE = v$, tangent $AF = t$, cotangent $GH = \tau$, secant $CF = s$, or cosecant $CH = \sigma$, according to the nature of the particular construction. Now, from the property of the circle are obtained these following general equations, expressing the relations between the fluxions of a circular arc and its sine, or cosine, &c, viz,

$$\begin{aligned}\dot{x} &= \frac{\dot{s}}{\sqrt{(r^2 - s^2)}} = \frac{-\dot{c}}{\sqrt{(r^2 - c^2)}} = \frac{\dot{v}}{\sqrt{(2rv - v^2)}} = \frac{\dot{t}}{r^2 + t^2} \\ &= -\frac{\dot{\tau}}{r^2 - \tau^2} = \frac{\dot{\sigma}}{r^2 - \sigma^2} = \frac{\dot{s}}{r^2 + r^2} = \frac{\dot{v}}{s\sqrt{(s^2 - v^2)}} = \frac{\dot{t}}{s\sqrt{(s^2 - t^2)}}.\end{aligned}$$

And these also express the relation between the absciss and ordinate of the curves in question, each in the order in which it stands; where x is the common absciss to all of them, and the respective ordinates are s , c , v , t , τ , s , and σ . And hence the area &c, of any of these curves may be found, as follows:

1. In the FIGURE of Sines.—Here $x = ad$, and $s =$ the ordinate de ; and the equation of the curve, as above, is $\dot{x} = \frac{\dot{s}}{\sqrt{(r^2 - s^2)}}$. Hence $s\dot{x} = \frac{\dot{rs}}{\sqrt{(r^2 - s^2)}}$ is the fluxion of the area; the correct fluent of which is $r^2 \mp r\sqrt{(r^2 - s^2)} = r^2 - rc = rv$ the rectangle of radius and vers. i. e. $-$ or $+$ as s is increasing or decreasing; which is a general expression for the area ade in the figure of sines. When $s = 0$, as at a or b , this expression becomes 0 or $2r^2$; that is 0 at a , and $2r^2 =$ the area aeb ; or $r^2 =$ the area of afg when ad becomes a quadrant af .

2. In the FIGURE of Cosines.—Here $x = ad$ and $c = de$; and the equation of the curve is $\dot{x} =$

$\frac{-\dot{c}}{\sqrt{(r^2 - c^2)}}$. Hence $c\dot{x} = \frac{-\dot{rc}}{\sqrt{(r^2 - c^2)}}$ is the fluxion of the area; and the fluent of this is $r\sqrt{(r^2 - c^2)} = rs$, the rectangle of radius and sine, for the general area $adec$. When $s = r$, or $c = 0$, this becomes $r^2 =$ the area afc , whose absciss af is equal to a quadrant of the circumference; the same as in the figure of the sines, upon an equal absciss.

3. In the FIGURE of Versed-sines.—Here $x = ad$, and $v = de$; and the equation of the curve is

$\dot{x} = \frac{\dot{v}}{\sqrt{(2rv - v^2)}}$. Hence $v\dot{x} = \frac{\dot{rv}}{\sqrt{(2rv - v^2)}} = \frac{\dot{rv}\sqrt{v}}{v}$ is the fluxion of the area; and the fluent of this is $rx - rs = r \times (AD - DE)$ for the area ade in the figure of versed sines. When AD or ad is a quadrant AG or af , this becomes $3 \cdot 1416 \times \frac{1}{2}r^2 - r^2 = 5708r^2$ for the area afg . And when AD or ad is a semicircle ab , it becomes $3 \cdot 1416r^2$ the area abg = in the figure of versed-sines.

4. In the FIGURE of Tangents.—Here $x = ad$, and $t = de$; and the equation of the curve is $\dot{x} =$

$\frac{\dot{t}}{r^2 + t^2}$. Hence the fluxion of the area is $t\dot{x} = \frac{\dot{rt}}{r^2 + t^2}$; and the correct fluent of this is $\frac{1}{2}r^2 \times \text{hyp. log. of } \frac{r^2 + t^2}{r^2} = r^2 \times \text{hyp. log. of } \frac{s}{r}$.

And hence the figure of the tangents may be used for constructing the logarithmic secants; a property that was remarked by James Gregory at the end of his Exercit. Geomet.

When ad becomes a quadrant af , t being then infinite, this becomes infinite for the area afg . And the same for the figure of cotangents, beginning at f instead of a .

5. For the FIGURE of the Secants.—Here $x = ad$, and $s = de$; and the equation of the curve is $\dot{x} =$

$$\frac{r^2 s}{s\sqrt{(s^2 - r^2)}}. \text{ Hence } s\dot{x} = \frac{r^2 s}{\sqrt{(s^2 - r^2)}} \text{ is the fluxion of the area; the fluent of which is } r^2 \times \text{hyp. log. of } \frac{s + \sqrt{(s^2 - r^2)}}{r} \text{ for the general area } ade. \text{ And when } ad \text{ becomes the quadrant } af, \text{ this expression becomes infinite for the area } agf. \text{ The same process will serve for the figure of cosecants, beginning at } f \text{ instead of } a.$$

Hence the meridional parts in Mercator's chart may be calculated for any latitude AD or ad : For the merid. parts: are to the arc of latitude AD :: as the sum of the secants : to the sum of as many radii or :: as the area ade : to $ad \times$ radius ac or $A D \times AC$ in the first figure.

FILLET, in Architecture, any little square member or ornament used in crowning a larger moulding.

FINÆUS (ORONTIUS), in French, *Finé*, professor of mathematics in the Royal College of Paris, was the son of a physician, and was born at Briançon in Dauphiné in 1494. He went young to Paris, where his friends procured him a place in the college of Navarre. He applied himself there to the study of philosophy and polite literature; but more especially to mathematics, in which he made considerable progress, particularly in mechanics; for, having both a genius to invent instruments, and a skilful hand to execute them, he gained much reputation by the specimens he gave of his ingenuity.

Finæus first made himself publicly known by correcting and publishing Siliceus's Arithmetic, and the Margarita Philosophica. He afterwards read private lectures in mathematics, and then taught that science publicly in the college of Gervais; from the reputation he thus gained, he was recommended to Francis the 1st, as a proper person to teach mathematics in the new college which that prince had founded at Paris. And here, though he spared no pains to improve his pupils, he yet found time to publish a great many books on many of the principal parts of the mathematics. But neither his genius, his labours, his inventions, nor the esteem which numberless persons showed him, could secure him from that fate which so often befalls men of letters. He was obliged to struggle all his life-time with poverty; and when he died, left a numerous family deeply in debt. However, as merit must always be esteemed in secret, though it seldom has the fortune to be rewarded openly; his children found friends who for their father's sake assisted his family.—He died in 1555, at 61 years of age.

Like all other mathematicians and astronomers of those times, he was greatly addicted to astrology; and had the misfortune to be a long time imprisoned for having predicted some things, that were not acceptable to the court of France. He was also one of those, who vainly boasted of having found out the quadrature of the circle, with the solution of the problem of two mean proportionals, and that of the trisection of an angle; but he was vigorously refuted by Nonius, as well as by Butron and Borelli, two of his own pupils.—Several of his pieces were published separately; as, his Practical Arithmetic in 1555, and Practical Geometry in 1554, both in 4to. And an edition of his whole works, translated into the Italian language, was published in 4to, at Venice, 1587; consisting of Arithmetic, Practical Geometry, Cosmography, Astronomy, and Dialling.

FINITE, the property of any thing that is bounded

or limited, either in its power, or extent, or duration, &c; as distinguished from the property of infinite, or without bounds.

FIRE, is that subtle invisible fluid by which bodies are made hot to the touch, and expanded or enlarged in bulk; by which fluids are rarefied into vapour; or solid bodies become fluid, and at last are either dissipated and carried off in vapour, or else melted into glass. It seems also to be the chief agent in nature on which animal and vegetable life have an immediate dependence. See CALORIC and HEAT.

The disputes concerning fire, which long existed among philosophers, have now in a great measure subsided. Those celebrated philosophers of the 17th century, Bacon, Boyle, and Newton, were of opinion, that fire was not a substance distinct from other bodies, but that it entirely consisted in the violent motion of the parts of any body, which was produced by the mechanical force of impulsion, or of attrition. So Boyle says, when a piece of iron becomes hot by hammering, "there is nothing to make it so, except the forcible motion of the hammer impressing a vehement and variously determined agitation on the small parts of the iron." And Bacon defines heat, which he makes synonymous with fire, an "expansive undulatory motion in the minute particles of a body, whereby they tend with some rapidity from a centre towards a circumference, and at the same time a little upwards." And according to Newton, fire is a body heated so hot as to emit light copiously; for what else, says he, is red-hot iron, but fire? and what else is a fiery coal than red-hot wood? by which he suggests, that bodies which are not fire, may be changed and converted into it.

On the other hand, the chemists strenuously contended that fire was a fluid of a certain kind, distinct from all others, and universally present throughout the whole globe. Boerhaave particularly maintained this doctrine; and in support of it brought this argument, that flint and steel would strike fire, and produce the same degree of heat in Nova Zembla as they would do under the equator. Other arguments were drawn from the increased weight of metallic calces, which they thought proceeded from the fixing of the element of fire in the substance whose weight was thus increased. For a long time, however, the matter was most violently disputed; but the mechanical philosophers at last prevailed through the deference paid to the principles of Newton, though he himself had scarcely taken any active part in the contest.

The experiments of Dr. Black, however, seemed to bring the dispute to a decision, and that in favour of the chemists, concerning what he called latent heat. From these discoveries it appears, that fire may exist in bodies in such a manner, as not to discover itself in any other way than by its action on the minute parts of the body; but that suddenly this action may be changed so, as no longer to be directed on the particles of the body itself, but upon external objects; in which case we then perceive its action by our sense of feeling, or discover it by the thermometer, and call it heat, or sensible fire.

From this discovery, and others in electricity, it is now pretty generally allowed, that fire is a distinct fluid, capable of being transferred from one body to another. But when this was discovered, another question no less perplexing arose, viz, what kind of a fluid it was; or whether it bears any analogy to those with which we are better acquainted. Now there are found two fluids, viz,

the solar light, and the electric matter, both of which occasionally act as fire, and which therefore seem to indicate an original identity; and popularly the matter has been long since determined; the solar rays and the electric fluid having been indifferently accounted elementary fire. Some indeed have imagined both these fluids to be mere phlogiston itself, or at least containing a large portion of it; and Mr. Scheele went so far in this way as to form an hypothesis, which he endeavoured to support by experiments, that fire is composed of phlogiston and dephlogisticated air. But it is now ascertained beyond doubt, that the result of such a combination is not fire, but fixed air.

It was long since observed by Newton, that heat was certainly conveyed by a medium more subtle than the common air; for two thermometers, one included in the vacuum of an air-pump, the other placed in the open air, at an equal distance from the fire, would become equally hot in nearly the same time. This and other experiments show, that fire exists and acts where there is no other matter, and of consequence it is a fluid per se, independent of every terrestrial substance, without being generated or compounded of any thing we are yet acquainted with. To determine the nature of the fluid, we have only to consider whether any other can be discovered which will pass through the perfect vacuum just mentioned, and act there as fire. Such a fluid is found in the solar light, which is well known to act even in vacuo as the most violent fire. The solar light will likewise act in the very same manner in the most intense cold; for M. de Saussure has found, that on the cold mountain-top the sun-beams are equally powerful as on the plain below, if not more so. It appears therefore, that the solar light will produce heat independent of any other substance whatever; that is, where no other body is present, at least as far as we can judge, except the light itself, and the body to be acted on. We cannot therefore avoid concluding, that a certain modification of the solar light is the cause of heat, expansion, vapour, &c, and answers to the rest of the characters given in the foregoing definition of fire, and that independent of any other substance whatever.

It is very probable too, that the electric matter is no other than the solar light absorbed by the earth, and thus becoming subject to new laws, and assuming many properties apparently different from what it has when it acts as light. Even in this case it manifests its identity with fire or light, viz, by producing a most intense heat where a large quantity of it passes through a small space. So that at any rate, the experiments which have already been made, and the proofs drawn from the phenomena of nature, show such a strong affinity between the elements of fire, light, and electricity, that we may not only assert their identity on the most probable grounds, but lay it down as a position against which at present no argument of any weight has an existence.

FIRE Arrow, is a small iron dart, furnished with springs and bars, and also a match impregnated with sulphur and powder, which is wound about its shaft. It is chiefly used by privateers and pirates to fire the sails of the enemy's ship, and for this purpose it is discharged from a musketoon, or a swivel gun. The match being kindled by the explosion, it communicates the flame to the sail against which it is directed, where the arrow fastens itself by means of its bars and springs. This weapon is peculiar to hot climates, particularly the West Indies; the sails being

very dry, are quickly inflamed, and the fire is soon conveyed to the masts, rigging, and finally to the vessel itself.

FIRE-BALLS, in Artillery, are certain balls composed of combustible matters, such as fine or mealed powder, sulphur, saltpetre, rosin, pitch, &c. These are thrown into the enemy's works in the night-time, to discover where they are; or to set fire to houses, galleries, or blinds of the besiegers, &c. They are sometimes armed with spikes or hooks of iron, that they may not roll off, but stick or hang where they are to take effect.

FIRE-BALLS, or *Fiery Meteors*, in Meteorology, a kind of luminous bodies usually appearing at a great height above the earth, with a splendour surpassing that of the moon, and sometimes apparently as large. It has not been observed that they follow any regular course or motion, but, on the contrary, moving in all directions, and with very different degrees of celerity; frequently breaking into several smaller ones; sometimes making a strong hissing sound, sometimes bursting or vanishing with a loud report, and sometimes not.

These luminous appearances doubtless constitute one part of the ancient prodigies, blazing stars, or comets, which last they sometimes resemble in being attended with a train; but more often they appear round. The first of these of which we have any accurate account, was observed by Dr. Halley, and some other philosophers at different places, in the year 1719, the height of which above the surface of the earth was computed at more than 70 miles. Many others have been accurately observed since that time, and described by different philosophers. See French Memoirs, and Philos. Trans. vols. 30, 41, 42, 43, 46, 47, 48, 51, 53, 54, 63, 74, &c. The velocities, directions, appearances, and heights of all these were found to be very various; though the height of some of them was supposed above the limits assigned to our atmosphere, or where it loses its refractive power. The most remarkable phenomenon of this kind on record, appeared on the 18th of August 1783, about 9 o'clock in the evening. It was seen to the northward of Shetland, and took a south-easterly direction for an immense space, being observed as far as the southern provinces of France, and by some it was said to have been seen at Rome, passing over a space of 1000 miles in about half a minute of time, and at a very great height. During its course it appeared several times to change its shape; sometimes appearing in the form of one ball, sometimes of two or more; sometimes with a train, and sometimes without one.

There are divers opinions concerning the nature and origin of these meteors. The first thing that occurred to philosophers on this subject was, that they were burning bodies rising from the surface of the earth, and flying through the atmosphere with great rapidity. But this hypothesis was soon rejected, on considering that there was no power known by which such bodies could either be raised to a sufficient height, or projected with the velocity which they had by some means acquired. The next hypothesis was, that, instead of one single body, they consist of a train of sulphureous vapours, extending an immense way through the atmosphere, and being kindled at one end, display the luminous appearances in question by the fire running from one extremity of the train to the other. But it is not easy to conceive how such matters can exist and be disposed in such lines in so rare a part of the atmosphere, and even to burn there, in an almost perfect vacuum. For which reason this hypothesis was aban-

doned, for another, which was, that those meteors are permanent solid bodies, not rising from the earth, but revolving round it in very eccentric orbits, and thus in their perigee moving with vast rapidity. But as the various appearances of one and the same meteor, to observers at different places, are not compatible with the idea of a single body so revolving, this hypothesis has also been given up in its turn. Again it has been said, that these meteors are a kind of bodies that take fire as soon as they come within the atmosphere of the earth. But this cannot be supposed without implying a previous knowledge of the nature of these bodies, which it is impossible we can have. Another hypothesis is, that these fiery meteors are great bodies of electric matter, moving from one part of the heavens where, to our conception, it is superabundant, to another where it is deficient: a conclusion attended with some probability, from the analogy observed between electricity and the phenomena of these bodies: and hence they appear to be of the same origin with shooting-stars, lightning, the aurora-borealis, &c, being all referred to the same cause, viz, the electricity of the atmosphere. See AEROLITE.

FIRE-ENGINE, is a machine for extinguishing accidental fires by means of a stream or jet of water. The common squiring fire-engine consists of a lifting pump placed in a vessel of water, and wrought by two levers that act always together. During the stroke, the water raised by the piston of the pump spouts forcibly through a pipe joined to the pump-barrel, and made capable of any degree of elevation by means of a yielding leather pipe, or by a ball and socket turning every way, screwed on the top of the pump. The vessel containing the water is covered with a strainer, to prevent the mud, &c, which is poured into it with the water, from choking the pump-work. Between the strokes of this engine the stream is discontinued, for want of an air-vessel. However, in some cases, engines of this construction have their use, because the stream, though interrupted, is much smarter than when the engine is made to throw water in a continued stream. See these engines particularly described in Desaguliers's Exper. Philos. vol. 2, pa. 505; or Martin's Philos. Britan. vol. 2, pa. 69; O. G. Gregory's Mechanics. See also the figure of them, plate x. fig. 3.

It appears that in the year 1675, Sir Sam. Morland got a patent for a powerful engine of this kind. This machine, by the strength of 8 men, would force water in a continued stream, from the river Thames, to the top of Windsor castle, and 60 feet higher, at the rate of 60 barrels an hour, which experiment was repeated several times, in the year 1681, before the king, queen, and court; when his majesty presented Morland with a medal, with his effigy set round with diamonds, and appointed him his master of mechanics, &c.

FIRE-LOCK, or *Fusil*, a small gun or musket, which fires with a flint and steel; as distinguished from the old musket, or match-lock, which was fired with a match. The fire-lock is now in common use with the European armies, and carried by the foot-soldiers. It is usually about 3 feet 8 inches in the barrel; and, including the stock, 4 feet 8 inches, carrying a leaden bullet, of which 29 make 2lb. The diameter of the ball is .55, and that the barrel .56 parts of an inch. The time of the invention of fire-locks is uncertain; they were however used in 1690.

FIRE-PLACES, are contrivances for communicating heat

to rooms, and also for answering various purposes of art and manufacture.—The general properties of air and fire, on which their construction chiefly depends, are the following, viz, that air is rarefied by heat, and condensed by cold; or, in other words, the same quantity of air takes up more space when warm than when cold. Air rarefied and expanded by heat, is specifically lighter than it was before, and will rise in other air of greater density: so that a fire being made in any chimney, the air about and over the fire is rarefied by the heat, thence becomes lighter, and so rises in the funnel, and goes out at the top of the chimney: the other air in the room, flowing towards the chimney, supplies its place, is then rarefied in its turn, and rises likewise; and the place of the air thus carried out of the room, is supplied by fresh air coming in through doors and windows, or, if they be shut, through every crevice with violence; or if the avenues to the room be so closed up, that little or no fresh supply of air can be obtained, the current up the funnel must flag; and the smoke, no longer driven up, float about in the room.

On these principles, various contrivances and kinds of fire-grates and stoves have been devised, from the old very open and wide, chimney places, down to the present modish ones, which are much narrowed in the front, opening, by side and back jambs, and a low breast or mantle, besides the convenience of a flap, called a register, that covers the top of the fire-stove, but opening to any degree with a small winch, which lifts the back part sloping upwards, and so throws the smoke freely up the funnel, admitting as little air to pass as you please; by which simple means the warm air is kept more in the room, while the very narrow and sloping orifice promotes the brisk ascent of the smoke, and yet prevents its return down again, for the same reason.

Another ingenious, but more complex, apparatus, called the Pennsylvania fire-place, was invented by Dr. Franklin, which keeps a room very warm by a constant supply of fresh hot air, that passes into it through the stove itself. See the description in his Letters and Papers on Philosophical Subjects.

Many other forms of fire-grates, often of whimsical figures, have been recommended by different persons: but, after all, the common register-grate is far the best.

FIRE-POT, in the Military Art, is a small earthen pot, into which is put a grenade, filled with fine powder till the grenade be covered; the pot is then closed with a piece of parchment, and two pieces of match laid across and lighted. This pot being thrown where it is designed to do execution, breaks and fires the powder, and this again fires the powder in the grenade, which ought to have no fuse, that its operation may be the quicker.

Rasant, or Razant FIRE, is a fire from the artillery and small arms, directed parallel to the horizon, or to those parts of the works of a place that are defended.

Running FIRE, is when ranks of men fire one after another; or when the lines of an army are drawn out to fire on account of a victory; in which case each squadron or battalion takes the fire from that on its right, from the right of the first line to the left, and from the left to the right of the second line, &c. This is now commonly called a *feu-de-joue*.

FIRE-Ships, in the navy, are vessels charged with combustible materials or artificial fire-works: which having the wind of an enemy's ship, grapple her, and set her on

fire. Anderson, in his History of Commerce, vol. 1, pa. 432, ascribes the invention to the English, in this instance, viz, some vessels being filled with combustible matter, and sent among the Spanish ships composing the Invincible Armada in 1588; and hence arose, it is said, the terrible invention of fire-ships. But Livy informs us, that the Rhodians had invented a kind of fire-ships, which were used in junction with the Roman fleet in their engagement with the Syrians, in the year 190 before Christ: cauldrons of combustible and burning materials were hung out at their prows, so that none of the enemies' ships durst approach them: for these fell on the enemies' galleys, struck their beaks into them, and at the same time set them on fire. Livy, lib. 37, cap. 30.

Wild-FIRE, is a kind of artificial or factitious fire, that burns even under water, and that with greater violence than out of it. It is composed of sulphur, naphtha, pitch, gum, and bitumen, and it is only extinguishable by vinegar, mixed with sand and urine, or by covering it with raw hides. It is said its motion is contrary to that of natural fire, always following the direction in which it is thrown, whether it be downwards, sideways, or otherwise.

The French call it Greek fire, or Feu Gregeois, because first used by the Greeks about the year 660, as is observed by the Jesuit Petavius, on the authority of Nicetas, Theophanes, Cedrenus, &c. The inventor, according to the same author, was an engineer of Heliopolis, in Syria, named Callinicus, who first applied it in the sea-fight commanded by Constantine Pogonates, against the Saracens, near Cyzicus, in the Hellespont; and with such effect, that he burnt the whole fleet, which had on board 30,000 men. But others refer it to a much older date, and ascribe the invention to Marcus Gracchus; an opinion that is supported by several passages, both in the Greek and Roman writers; which shew that it was anciently used by each of these nations in their wars. See Scaliger against Cardan.

The successors of Constantine used it on several occasions, with great advantage: and it is said that they were able to keep the secret of the composition to themselves; so that no other nation knew it in the year 960.

It is recorded by Chorier, in his Hist. de Dauph. that Hugh, king of Burgundy, demanding ships of the emperor Leo for the siege of Fresne, desired also the Greek fire.—F. Daniel gives also a good description of the Greek fire, in his account of the siege of Damietta, under St. Louis. Every body, says he, was astonished with the Greek fire, which the Turks then prepared; and the secret of which is now lost. They threw it out of a kind of mortar, and sometimes shot it with an odd sort of cross-bow, which was strongly bent by means of a handle, or winch, with much greater force than the bare arm. That which was thrown from the mortar sometimes appeared in the air of the size of a tun, with a long tail, and a noise like that of thunder. The French, by degrees, got the secret of extinguishing it; in which they succeeded several times.

After all, perhaps the invention of the wild-fire is to be ascribed to other nations, and to a still older date, and that it was the same as that used among the Indians in Alexander's invasion, when it was said they fought with thunder and lightning, or shot fire with a terrible noise.

FIRE-Works, otherwise called Pyrotechnia, are artificial fires, or preparations made of gunpowder, sulphur, and other inflammable and combustible ingredients, which are

displayed at public rejoicings, and on other occasions. The principal of these are rockets, serpents, stars, hail, mines, bombs, garlands, letters, and other devices. The invention of fire-works is attributed, by M. Mahudel, to the Florentines and people of Sienna; who also discovered the method of adding to them decorations of statues, with fire issuing from their eyes and mouths.

FIRKIN, an English measure of capacity; being the 4th part of a barrel; or containing 9 gallons.

FIRLOT, a dry measure used in Scotland. The oat-firlot contains $21\frac{1}{4}$ pints of that country, or about 85 English pints; and the barley-firlot, 31 standard pints. The wheat-firlot contains about 2211 cubic inches; and therefore exceeds the English bushel by 60 cubic inches, or almost an English quart.

FIRMAMENT, by some old astronomers, is the orb of the fixed stars, or the highest of all the heavens. But in Scripture and common language it is used for the middle regions, or the space or expanse appearing like an arch quite around or above us in the heavens. Many ancients and moderns also accounted the firmament a fluid matter; but those who gave it the name of firmament must have taken it for a solid one.

FIRMNESS, is the consistence of a body; or that state in which its parts cohere, or are united together, so that the motion of one part induces a motion of the rest. And in this sense firmness stands opposed to fluidity. The firmness of bodies therefore depends on the connexion or cohesion of their particles; and the cause of cohesion the Newtonians hold to be an attractive force, inherent in bodies, which binds their small particles together; exerting itself only at the points of contact, or extremely near them, and vanishing at greater distances.

FISSURES, in the History of the Earth, are certain interruptions, mostly parallel to each other, that divide or separate its strata from one another, in nearly horizontal directions; and the parts of the same stratum in nearly vertical directions.

FIXED Line of Defence, a line drawn along the face of the bastion, and terminating in the curtain.

FIXED Signs of the Zodiac, according to some, are the four signs Taurus, Leo, Scorpio, Aquarius. They are so called because the sun passes them respectively in the middle of each quarter, when that season is more settled and fixed than under the signs which begin and end it.

FIXED Stars, are such as constantly retain the same position and distance with respect to each other; by which they are contradistinguished from erratic or wandering stars, which are continually varying their situation and distance.—The fixed stars only are properly and absolutely called stars; the other celestial bodies falling under the denomination of planets or comets.

FIXITY, or **FIXEDNESS**, the quality of a body which determines it fixed; or a property which enables it to endure the fire and other violent agents. A body may be said to be fixed in two respects: 1st, When on being exposed to the fire, or a corrosive menstruum, its particles are indeed separated, and the body rendered fluid, but without being resolved into its first elements. The 2d, when the body sustains the active force of the fire or menstruum while its integral parts are not carried off in fumes. Each kind of fixity is the result of a strong or intimate cohesion between the particles.

FLAME, the subtlest and brightest part of the fuel, ascending above it in a pyramidal figure, and heated red-

hot. Sir Isaac Newton defines flame as only red-hot smoke, or the vapour of any substance raised from it by fire, and heated to such a degree as to emit light copiously. Is not flame, says he, a vapour, fume, or exhalation, heated red-hot; that is, so hot as to shine? For bodies do not flame without emitting a copious fume; and this fume burns in the flame. The ignis fatuus is a vapour shining without heat; and is there not the same difference between this vapour and flame, as between rotten wood shining without heat, and burning coals of fire? In distilling hot spirits, if the head of the still be taken off, the vapour which ascends will take fire at the flame of a candle, and turns into flame. Some bodies, heated by motion or fermentation, if the heat grow intense, fume copiously; and if the heat be great enough, the fumes will shine, and become flame. Metals in fusion do not flame, for want of a copious fume. All flaming bodies, as oil, tallow, wax, wood, fossil coal, pitch, sulphur, &c, by burning, waste in smoke, which at first is lucid; but at a little distance from the body ceases to be so, and only continues hot. When the flame is put out, the smoke is thick, and frequently smells strongly: but in the flame it loses its smell; and, according to the nature of the fuel, the flame is of divers colours. That of sulphur and spirit of wine is blue; that of copper opened with sublimate, green; that of tallow, yellow; of camphire, white; &c. Newton's Optics, pa. 318.

FLAMSTEED (JOHN), an eminent English astronomer, being indeed the first astronomer-royal, for whose use the royal observatory was built at Greenwich, thence called Flamsteed House. He was born at Denby in Derbyshire the 19th of August 1646; and was educated at the free-school of Derby, where his father lived. At 14 years of age he was afflicted with a severe illness, which rendered his constitution tender ever after, and prevented him then from going to the university, for which he was intended. He nevertheless prosecuted his school education with the best effect; and, in 1662, on quitting the grammar-school, he pursued the natural bent of his genius, which led him to the study of astronomy, and closely pursued Sacrobosco's book *De Sphaera*, which fell in his way, and thus laid the foundation of all that mathematical and astronomical knowledge, for which he became afterward so justly celebrated. He next procured more modern books on the same subject, and among them Streete's *Astronomia Carolina*, then lately published, from which he learned to calculate eclipses and the planets' places. Some of these being shewn to Mr. Halton, a considerable mathematician, he lent him Riccioli's *Almagestum Novum*, and Kepler's *Tabulæ Rudolphinae*, from which he gained much information. In 1669, having calculated some remarkable eclipses of the moon, he sent them to lord Brouncker, president of the Royal Society, which were greatly approved by that learned body, and procured him a letter of thanks from Mr. Oldenburg their secretary, and another from Mr. John Collins, with whom, and other learned men, Mr. Flamsteed for a long time afterwards kept up a correspondence by letters on literary subjects. In 1670, his father, observing that he held correspondence with these ingenious persons, advised him to take a journey to London, to make himself personally acquainted with them; an offer which he gladly embraced, and visited Mr. Oldenburg and Mr. Collins, who introduced him to Sir Jonas Moore, which proved the means of his greatest honour and preferment. He here got the knowledge and

practice of astronomical instruments, as telescopes, micrometers, &c: and on his return, he called at Cambridge, and visited Dr. Barrow, Newton, and other learned men there, and entered himself a student of Jesus-college. In 1672 he made many celestial observations, which, with calculations of appulses of the moon and planets to fixed stars for the year following, he sent to Mr. Oldenburg, who published them in the *Philos. Trans.*

In 1673, Mr. Flamsteed wrote a small tract on the true diameters of all the planets, when at their greatest, and least distances from the earth; which he lent to Newton in 1685, who made some use of it in the 4th book of his *Principia*.—In 1674 he wrote an ephemeris, to show the falsity of astrology, and the ignorance of those who pretended to it: with calculations of the moon's rising and setting; also occultations and appulses of the moon and planets to the fixed stars. To which, at Sir Jonas Moore's request, he added a table of the moon's southings for that year; from which, and from Philips's theory of the tides, the high-waters being computed, he found the times come very near. In 1674 he also drew up an account of the tides, for the use of the king. Sir Jonas also showed the king, and the duke of York, some barometers and thermometers that Mr. Flamsteed had given him, with the necessary rules for judging of the weather; and otherwise took every opportunity of speaking favourably of Flamsteed to them, till at length he brought him a warrant to be the king's astronomer, with a salary of 100*l.* per annum, to be paid out of the office of Ordnance, because Sir Jonas was then surveyor general of the Ordnance. This however did not abate our author's propensity for holy orders, and he was accordingly ordained at Ely by bishop Gunning.

On the 10th of August 1675, the foundation of the royal observatory at Greenwich was laid; and during the building of it, Mr. Flamsteed's temporary observatory was in the queen's house, where he made his observations of the appulses of the moon and planets to the fixed stars, and wrote his *Doctrine of the Sphere*, which was afterwards published by Sir Jonas Moore, in his *System of the Mathematics*.

About the year 1684 he was presented to the living of Burslow in Surrey, which he held as long as he lived. Mr. Flamsteed was equally respected by the great men his contemporaries, and by those who succeeded him. Dr. Wotton, in his *Reflections upon Ancient and Modern Learning*, styles our author one of the most accurate observers of the heavens, and says he calculated tables of the eclipses of the several satellites, which proved very useful to the astronomers. And Mr. Molyneaux, in his *Dioptrica Nova*, speaks very highly of his abilities; and, in the admonition to the reader prefixed to the work, observes, that the geometrical method of calculating a ray's progress is quite new, and never before published; but for the first hint of it, says he, I must acknowledge myself obliged to my worthy friend Mr. Flamsteed. He wrote several small tracts, and had many papers inserted in the *Philosophical Transactions*, in almost every volume, from the 4th to the 29th, which are too numerous to be particularly mentioned in this place.

But his great work, and that which contained the principal operations of his life, was the *Historia Cœlestis Britannica*, published in 1725, in 3 large folio volumes. The first of which contains the observations of Mr. William Gascoigne, the original inventor of the method of measuring angles in a telescope by means of screws, and

the first who applied telescopic sights to astronomical instruments, in observations made at Middleton, near Leeds in Yorkshire, between the years 1638 and 1643; extracted from his letters by Mr. Crabtree; with some of Mr. Crabtree's observations about the same time; and also those of Mr. Flamsteed himself, made at Derby between the years 1670 and 1675; besides a multitude of curious observations, and necessary tables to be used with them, made at the royal observatory, between the years 1675 and 1689.—The 2d volume contains his observations, made with a mural arch of near 7 feet radius, and 140 degrees on the limb, of the meridional zenith distances of the fixed stars, sun, moon, and planets, with their transits over the meridian; also observations of the diameters of the sun and moon, with their eclipses, and those of Jupiter's satellites, and variations of the compass, from 1689 to 1719: also tables showing how to render the calculation of the places of the stars and planets easy and expeditious. To which are added, the moon's place at her oppositions, quadratures, &c; also the planets' places, derived from the observations.—The 3d volume contains a catalogue of the right-ascensions, polar-distances, longitudes, and magnitudes of near 3000 fixed stars, with the corresponding variations of the same. To this volume is prefixed a preface, at considerable length, containing an account of all the astronomical observations made before his time, with a description of the instruments employed; as also of his own observations and instruments; a new Latin version of Ptolemy's catalogue of 1026 fixed stars; and Ulegh-beig's places annexed on the Latin page, with the corrections: a small catalogue of the Arabs: Tycho Brahe's of about 780 fixed stars: the Landgrave of Hesse's of 386: Hevelius's of 1534: and a catalogue of some of the southern fixed stars not visible in our hemisphere, calculated from the observations made by Dr. Halley at St. Helena, adapted to the year 1726.

This work he prepared in a great measure for the press, with much care and accuracy: but through a natural weakness of constitution, and the advance of age, he died of a strangury before he had completed it, December the 19th, 1719, at 73 years of age; leaving the care of finishing and publishing his work to his friend Mr. Hodgson. A less perfect edition of the *Historia Cœlestis* had before been published, but without his consent, viz, in 1712, in one volume folio, containing his observations to the year 1705.

FLANK, in Fortification, is that part of the bastion reaching from the curtain to the face; and it defends the curtain, with the opposite face and flank.

Oblique or Second FLANK, or FLANE of the Curtain, is that part of the curtain from which the face of the opposite bastion can be seen, being contained between the lines rasant and fichant, or the greater and less lines of defence; or the part of the curtain between the flank and the point where the ficheant line of defence terminates.

Covered, Low, or Retired FLANK, is the platform of the casemate, which lies hid in the bastion; and is otherwise called the orillon.

Fichant FLANK, is that from which a cannon playing, fires directly on the face of the opposite bastion.

Rasant or Razant FLANK, is the point from which the line of defence begins, from the conjunction of which with the curtain, the shot only raseth the face of the next bastion, which happens when the face cannot be discovered but from the flank alone.

Simple Flanks, are lines going from the angle of the shoulder to the curtain; the chief office of which is for the defence of the moat and place.

Flank, is also a term of war, used by way of analogy for the side of a battalion, army, &c, in contradistinction to the front and rear. So, to attack the enemy in flank, is to discover and fire upon them on one side.

Flanked, is used of something that has flanks, or may be approached on the flank. As

Flanked Angle, or that formed by the two faces of the bastion, and forming its point or angle.

Flanked Line of Defence, *Flanked Tenaille*, &c.

Flanking, in general, is the discovering and firing upon the side of a place, body, battalion, &c. To flank a place, or other work, is to dispose it in such a manner as that every part of it may be played upon both in front and rear.

Flat Bastion, is that which is built on a right line, as on the middle of the curtain, &c.

Fletcher (ABRAHAM), an ingenious mathematician, was born at Little Broughton, in Cumberland, in 1714, and brought up in his father's business, husbandry and tobacco-pipe making. He learned to read and write by his own endeavours, and afterwards taught himself arithmetic, and gradually the several branches of mathematics, with botany, touching the medicinal qualities of herbs. At the age of 30 he turned schoolmaster, to which profession was added those of astrologer and country doctor; in which, by means of industry and economy, the two handmaids of fortune, he was enabled to leave his family in possession of 4000*l.* at his death, which happened in 1793, in the 79th year of his age. Mr. Fletcher published, in 1752, an ingenious treatise, entitled *The Universal Measurer*, in one vol. 8vo; which was afterwards (1762) much enlarged and improved, under the title of *The Universal Measurer and Mechanic*, being a general collection of exercises in most of the mathematical sciences.

Flexible, is the property or quality of a body that may be bent.

Flexion, the same as Flexure.

Flexure, or *Flexion*, is the bending or curving of a line or figure. When a line first bends one way, and then gradually changes to a bend the contrary way, the point where the two parts join, or where the bending changes to the other side, is called the point of inflexion, or of contrary flexure.

Flie, or *Fly*, that part of the mariner's compass on which the 32 points of the wind are drawn, and over which the needle is placed, and fastened underneath.

FLOAT-Boards, the boards fixed to the outer rim of undershot water-wheels, serving to receive the impulse of the stream, by which the wheel is carried round.—There may be too many of these boards on a wheel. It is thought to be the best rule, to have their distance asunder such, that each of them may come out of the water as soon as possible, after it has received and acted with its full impulse; or, which comes to the same thing, when the succeeding one is in a direction perpendicular to the surface of the water.

Floating Bridge, is a bridge of boats, casks, &c, covered with planks, firmly bound together for the passage of men, horses, or carriages, &c.

Flood, a deluge or inundation of water.

Flood, is also used in speaking of the tide, when it is rising or flowing up; in contradistinction to the ebb, which is when it is decreasing or running out.

Flooring, in *Carpentry*, is commonly understood of the boarding of the floors. The measurement of flooring is estimated in squares, of 100 square feet each, or of 10 feet on each side every way; 10 times 10 being 100. Hence, the length of the floor being multiplied by its breadth, in feet, and two figures cut off on the right-hand, gives the squares, and feet, or decimals cut off. Thus, a floor being 22 feet long, and 16 wide; then $22 \times 16 = 352$ square feet, or 3*52* squares, the content.

Fluent, or *Flowing Quantity*, in the *Doctrine of Fluxions*, is the variable quantity which is considered as increasing or decreasing; or the fluent of a given fluxion, is that quantity whose fluxion being taken, according to the rules of that calculus, shall be the same with the given fluxion. See *Fluxions*.

Contemporary Fluents, are such as flow together or for the same time. And the same is to be understood of contemporary fluxions.—When contemporary fluents are always equal, or in any constant ratio; then also are their fluxions respectively either equal, or in that same constant ratio. That is, if $x = y$, then is $\dot{x} = \dot{y}$; or if $x : y :: n : 1$, then is $\dot{x} : \dot{y} :: n : 1$; or if $x = ny$, then is $\dot{x} = ny$.

It is easy to find the fluxions to all the given forms of fluents; but, on the contrary, it is difficult to find the fluents of many given fluxions; and indeed there are numberless cases in which this cannot be effected, except it be by the quadrature and rectification of curve lines, or by logarithms, or infinite series.

This doctrine, first invented by Sir Isaac Newton, was carried by him to a considerable degree of perfection, at least as to the most frequent, and most useful forms of fluents; as may be seen in his *Fluxions*, and in his *Quadrature of Curves*. Maclaurin, in his *Treatise of Fluxions*, has made several inquiries into fluents, reducible to the rectification of the ellipse and hyperbola; and Dalemberg has pursued the same subject, and carried it farther, in the *Memoires de l'Acad. de Berlin*, tom. 2. p. 200. To the celebrated M. Euler this doctrine is greatly indebted, in many parts of his various writings, as well as in the *Institutio Calculi Integralis*, in 3 vols 4to, Petr. 1768. The ingenious Mr. Cotes contributed very much to this doctrine, in his *Harmonia Mensuraria*, concerning the measures of ratios and angles, in a large collection of different forms of fluxions, with their corresponding fluents; which was farther prosecuted in the same way by Walmesley, in his *Analyse des Mesures des Rapports et des Angles*, a large vol. in 4to, 1749. Besides many other authors who, by their ingenious labours, have greatly contributed to facilitate and extend the doctrine of fluents; as Emerson, Simpson, Landen, Waring, &c, in this country; l'Hôpital, and many other learned foreigners. Lastly, in 1785 was published at Vienna, by M. Paccassi, a German nobleman, *Udhandlung über eine neue Methode zu Integrieren*, being a method of integrating, or finding the fluents of given fluxions, by the rules of the direct method, or by taking again the fluxion of the given fluxion, or the 2d fluxion of the fluent sought; and then making every flowing quantity, its fluxion, and 2d fluxion, in geometrical progression; a method however, which, it seems, only holds true in the easiest cases or forms, whose

fluent are easily had by the most common methods: and which nearly resembles the method employed by Clairaut, in treating what he called Equations of Condition.

As it is only in certain particular forms and cases that the fluents of given fluxions can be found; there being no method of performing this universally a priori, by a direct investigation, like finding the fluxion of a given fluent quantity; we can do little more than lay down a few rules for such forms of fluxions as are known, from the direct method, to belong to such and such kinds of fluents or flowing quantities: and these rules, it is evident, must chiefly consist in performing such operations as are the reverse of those by which the fluxions are found to given flowing quantities. The principal cases of which are as follow:

I. To find the Fluent of a simple fluxion; or that in which there is no variable quantity, and only one fluxional quantity. This is done by barely substituting the variable or flowing quantity instead of its fluxion, and is the result or reverse of the notation only. Thus,

The fluent of $a\dot{x}$ is ax .

The fluent of $ay + \dot{y}$ is $ay + y$.

II. When any power of a flowing quantity is multiplied by the fluxion of the root. Then, having substituted, as before, the flowing quantity for its fluxion, divide the result by the new index of the power. Or, which is the same thing, take out, or divide by, the fluxion of the root; add 1 to the index of the power; and divide by the index so increased.

So if the fluxion proposed be $-3x^5\dot{x}$;

Strike out \dot{x} , then it is $-3x^5$;

add 1 to the index, and it is $-3x^6$;

divide by the index 6, and it is $-\frac{1}{6}x^6$ or $\frac{1}{6}x^6$; which is the fluent of the proposed fluxion $3x^5\dot{x}$.

In like manner, the fluent of $4ax\dot{x}$ is $2ax^2$;

of $3x^{\frac{1}{2}}\dot{x}$ is $2x^{\frac{3}{2}}$;

of $ax^n\dot{x}$ is $\frac{a}{n+1}x^{n+1}$;

of \dot{z} or $z^{\frac{1}{2}}\dot{z}$ is $-z^{-1}$ or $-\frac{1}{z}$.

of $(a^2 + z^2)^{\frac{1}{2}}\dot{z}$ is $\frac{1}{z}(a^2 + z^2)^{\frac{1}{2}}$.

III. When the root under a vinculum is a compound quantity; and the index of the part or factor without the vinculum increased by 1, is some multiple of that under the vinculum: Put a single variable letter for the compound root; and substitute its powers and fluxion instead of those, of the same value, in the given quantity; so will it be reduced to a simpler form, to which the preceding rule can then be applied.

Thus, if the given fluxion be $\dot{r} = (a^2 + x^2)^{\frac{3}{2}}x^3\dot{x}$; where 3, the index of the quantity without the vinculum, increased by 1, makes 4, which is double of 2, the exponent of x^2 within the same; therefore putting $z = a^2 + x^2$, thence $x^2 = z - a^2$, and its fluxion is $2x\dot{x} = \dot{z}$; hence then $x^3\dot{x} = \frac{1}{2}x^2\dot{z} = \frac{1}{2}\dot{z}(z - a^2)$, and the given quantity \dot{r} or $(a^2 + x^2)^{\frac{3}{2}}x^3\dot{x}$ is $= \frac{1}{2}z^{\frac{5}{2}}\dot{z}(z - a^2)$ or $= \frac{1}{2}z^{\frac{5}{2}}\dot{z} - \frac{1}{2}z^{\frac{3}{2}}\dot{z}^2$; and the fluent of each term gives

$\dot{r} = \frac{3}{2}az^{\frac{3}{2}} - \frac{3}{2}a^2z^{\frac{5}{2}} = 3z^{\frac{5}{2}}(\frac{1}{2}z - \frac{1}{2}a)$; or, by substituting the value of z instead of it, the same fluent is

$3(a^2 + x^2)^{\frac{3}{2}} \times (\frac{1}{2}x^2 - \frac{1}{2}a^2)$, or $\frac{3}{2}(a^2 + x^2)^{\frac{3}{2}}(x^2 - \frac{1}{2}a^2)$.

IV. When there are several terms involving two or more

variable quantities, having the fluxion of each multiplied by the other quantity or quantities: Take the fluent of each term, as if there was only one variable quantity in it, namely that whose fluxion is contained in it, supposing all the others to be constant in that term; then if the fluents of all the terms so found, be the very same quantity, that quantity will be the fluent of the whole.—Thus, if the given fluxion be $\dot{xy} + x\dot{y}$. Then, the fluent of xy is xy , supposing y constant; and the fluent of $x\dot{y}$ is also xy , when x is constant; therefore the common resulting quantity xy is the required fluent of the given fluxion $\dot{xy} + x\dot{y}$.

And, in like manner, the fluent of $\dot{xy} + x\dot{y} + xy\dot{z}$ is xyz .

V. When the given fluxional expression is in this form $\frac{\dot{xy} - x\dot{y}}{y^2}$, viz, a fraction including two quantities, being the fluxion of the former drawn into the latter, minus the fluxion of the latter drawn into the former, and divided by the square of the latter: then the fluent is the fraction $\frac{x}{y}$, or of the former quantity divided by the latter. That is,

The fluent of $\frac{\dot{xy} - x\dot{y}}{y^2}$ is $\frac{x}{y}$;

and the fluent of $\frac{2x\dot{xy} - 2x^2\dot{y}}{y^3}$ is $\frac{x^2}{y}$.

Though the examples of this case may be performed by the foregoing one. Thus the given fluxion

$\frac{\dot{xy} - x\dot{y}}{y^2}$ reduces to $\frac{\dot{xy}}{y^2} - \frac{x\dot{y}}{y^2}$ or $\frac{x}{y} - xy^{-2}$;

of which the fluent of $\frac{x}{y}$ is $\frac{x}{y}$ when y is constant; and

the fluent of xy^{-2} is $+xy^{-1}$ or $\frac{x}{y}$ when x is constant; and therefore, by that case,

$\frac{x}{y}$ is the fluent of the whole $\frac{\dot{xy} - x\dot{y}}{y^2}$.

VI. When the fluxion of a quantity is divided by the quantity itself: Then the fluent is equal to the hyperbolic logarithm of that quantity; or, which is the same thing, the fluent is equal to 2.30258509 &c, multiplied by the common log. of the same quantity.

So the fluent

of $\frac{\dot{x}}{x}$ or $x^{-1}\dot{x}$ is the hyp. log. of x ;

of $\frac{2\dot{x}}{x}$ is $2 \times$ hyp. log. of x , or = h. l. of x^2 ;

of $\frac{ax}{x}$ is $a \times$ h. l. of x , or h. l. of x^a ;

of $\frac{\dot{x}}{a+x}$ is the h. l. of $a+x$;

of $\frac{3x^2\dot{x}}{a+x^3}$ is the h. l. of $a+x^3$.

VII. Many fluents may be found by the direct method of fluxions, thus: Take the fluxion again of the given fluxional expression, or the 2d fluxion of the fluent sought; into which substitute $\frac{\dot{x}}{x}$ for \dot{x} , and $\frac{\dot{y}}{y}$ for \dot{y} , &c, that is, make x, \dot{x}, \ddot{x} , as also y, \dot{y}, \ddot{y} , &c, in continual proportion, or $x : \dot{x} : \ddot{x} : \dddot{x}$; $y : \dot{y} : \ddot{y} : \dddot{y}$, &c; then divide the square of the given fluxional expression by the 2d fluxion, just found, and the quotient will be the fluent sought in many cases.

Or the same rule may be otherwise delivered thus: In the given fluxion \dot{r} , write x for \dot{x} , y for \dot{y} , &c, and call the result c , taking also the fluxion of this quantity, \dot{c} ; then

make $\dot{G} : F :: G : f$, so shall the 4th proportional f be the fluent as before. And this is the rule of M. Pacassi.

It may be proved whether this be the true fluent, by taking the fluxion of it again, which, if it agree with the proposed fluxion, will show that the fluent is right; otherwise, it is not.

Thus, if it be proposed to find the fluent of $nx^{n-1}\dot{x}$. Here $F = nx^{n-1}\dot{x}$; write first x for \dot{x} , and it is $nx^{n-1}x$ or $nx^n = g$; the fluxion of this is $\dot{g} = n^2x^{n-1}\dot{x}$; therefore $G : F :: G : f$ becomes $n^2x^{n-1}\dot{x} : nx^{n-1}x : nx^n = f$, the fluent sought.

Again, suppose it be proposed to find the fluent of $xy + x\dot{y}$. Here $F = xy + x\dot{y}$; then, writing x for \dot{x} , and y for \dot{y} , it is $xy + x\dot{y}$ or $2x\dot{y} = g$; the fluxion of which is $2\dot{y} + 2x\ddot{y} = \dot{g}$; then $G : F :: G : f$ becomes $2\dot{y} + 2x\ddot{y} : xy + x\dot{y} : nx^n = f$.

$: \dot{xy} + x\ddot{y} : : 2xy : xy = f$, the fluent sought. See also CONDITION, Equations of.

VIII. To find Fluxions by means of a table of forms of Fluxions and Fluxents.

In the following table are contained the most usual forms of fluxions that occur in the practical solution of problems, with their corresponding fluents set opposite to them; by means of which, viz, comparing any proposed fluxion with the corresponding form here, the fluent of it will be found.

Where it is to be noted, that the logarithms in the said forms, are the hyperbolic ones, which are found by multiplying the common logs. by 2³⁰²⁵⁸⁵⁰⁹²⁹⁹⁴⁰ &c. Also the arcs whose sine, or tangent, &c, are mentioned, have the radius 1, and are those in the common tables of sines, tangents, &c.—And the numbers m , n , &c. are to be some quantities, as the forms fail when $n = 0$, or $m = 0$, &c.

Forms.	Fluxions.	Fluents.
I	$x^{\frac{n-1}{n}}\dot{x}$	$\frac{1}{n}x^n$
II	$(a \pm x^n)^{m-1}x^{\frac{n-1}{n}}$	$\pm \frac{1}{mn}(a \pm x^n)^m$
III	$\frac{x^{\frac{mn-1}{m}}\dot{x}}{(a \pm x^n)^{m+1}}$	$\frac{1}{mna} \times \frac{x^{mn}}{(a \pm x^n)^m}$
IV	$\frac{(a \pm x^n)^{\frac{m-1}{m}}\dot{x}}{x^{\frac{mn+1}{m}}}$	$\frac{-1}{mna} \times \frac{(a \pm x^n)^m}{x^{mn}}$
V	$(m\dot{xy} + n\dot{y})x^{\frac{m-1}{m}}y^{\frac{n-1}{n}}$, or $(\frac{m\dot{x}}{x} + \frac{ny}{y})x^m y^n$	$x^m y^n$
VI	$mx^{\frac{m-1}{m}}\dot{xy}^{n-1}z^r + nx^m y^{\frac{n-1}{n}}\dot{yz}^r + rx^m y^{\frac{n-1}{n}}z^{r-1}\dot{z}$, or $(m\dot{xyz} + n\dot{yz} + r\dot{xz})x^{\frac{m-1}{m}}y^{\frac{n-1}{n}}z^{r-1}$, or $(\frac{m\dot{x}}{x} + \frac{ny}{y} + \frac{rz}{z})x^m y^n z^r$	$x^m y^n z^r$
VII	$\frac{\dot{x}}{x}$ or $x^{-1}\dot{x}$	log. of x
VIII	$\frac{x^{n-1}\dot{x}}{a \pm x^n}$	$\pm \frac{1}{n} \log. \text{ of } a \pm x^n$

XIV	$\frac{x^{-1}\dot{x}}{\sqrt{(a \pm x^n)}}$	$\frac{1}{n\sqrt{a}} \log. \text{ of } \frac{\sqrt{a} - \sqrt{(a \pm x^n)}}{\sqrt{a} + \sqrt{(a \pm x^n)}}$
XV	$\frac{x^{-1}\dot{x}}{\sqrt{(-a + x^n)}}$	$\frac{2}{n\sqrt{a}} \times \text{arc to secant } \sqrt{\frac{x^n}{a}}, \text{ or } \frac{2}{n\sqrt{a}} \times \text{arc to cosine } \frac{a}{x^n}$ or $\frac{1}{n\sqrt{a}} \times \text{arc to cosine } \frac{2a - x^n}{x^n}$
XVI	$\frac{\dot{x}}{\sqrt{(dx - x^2)}}$	$\frac{2}{d} \times \text{arc to diam. } d, \text{ and vers. } x$
XVII	$\dot{x}\sqrt{(dx - x^2)}$ $\dot{x}\sqrt{(a^2 - x^2)}$	$\frac{1}{2} \text{ circ. seg. to diam. } d \text{ and vers. } x$ $\frac{1}{2} \text{ circ. zone, rad. } a, \text{ and height from centre } x$
XVIII	$c^{nx}\dot{x}$	$\frac{c^{nx}}{n \log. c}$
XIX	$\dot{x}y^x \log. y + xy^{x-1}\dot{y}$	y^x
XX	$(a + x^n)^m x^{m-1}\dot{x}$ Putting $s = m + r$	$\frac{(a + x^n)^{m+1} x^{m-n}}{ns} \times \left(\frac{1}{1} - \frac{r - 1.a}{s - 1.x^n} + \frac{r - 1.r - 2.a^2}{s - 1.s - 2.x^{2n}} - \frac{r - 1.r - 2.r - 3.a^3}{s - 1.s - 2.s - 3.x^{3n}} &c. \right)$ or $\frac{(a + x^n)^{m+1} x^{rn}}{rna} \times \left(\frac{1}{1} - \frac{s + 1.x^n}{r + 1.a} + \frac{s + 1.s + 2.x^{2n}}{r + 1.r + 2.a^2} - \frac{s + 1.s + 2.s + 3.x^{3n}}{r + 1.r + 2.r + 3.a^3} &c. \right)$

The Use of the foregoing Table of Forms of Fluxions and Fluents.—In the use of this table, it is to be observed, that the first column serves only to show the number of the form, as a mark of reference; in the 2d column are the several forms of fluxions, which are of different kinds or classes; and in the 3d or last column are the corresponding fluents.

The method of using the table is this. Having any fluxion given, whose fluent it is proposed to find: First, compare the given fluxion with the several forms of fluxions in the 2d column of the table, till one of the forms be found that agrees with it; which is done by comparing the terms of the given fluxion with the like parts of the tabular fluxion, viz, the radical quantity of the one, with that of the other; and the exponents of the variable quantities of each, both within and without the vinculum; all which, being found to agree or correspond, will give the particular values of the general quantities in the tabular form. Then substitute these particular values, for the same quantities in the general or tabular form of the fluent, and the result will be the particular fluent sought; after it is multiplied by any coefficient the proposed fluxion may have.

For Example. To find the fluent of the fluxional expression $3x^3\dot{x}$. This agrees with the first form; and by comparing the fluxions, it appears that $x = x$, and $n - 1 = \frac{2}{3}$; or

$n = \frac{8}{3}$; which being substituted in the tabular fluent, or $\frac{1}{n}x^n$, gives, after multiplying by 3 the coefficient, $3 \times \frac{2}{3}x^{\frac{8}{3}}$ or $\frac{2}{3}x^{\frac{8}{3}}$ for the fluent sought.

Again, To find the fluent of $5x^2\dot{x}\sqrt{c^3 - x^3}$, or $5x^2\dot{x}(c^3 - x^3)^{\frac{1}{2}}$. This belongs to the 2d form; for $a = c^3$, and $-x^n = -x^3$, $n = 3$ under the vinculum, and $m - 1 = \frac{1}{2}$, or $m = \frac{3}{2}$, also the exponent $n - 1$ of x^{n-1} without the vinculum, by using $\frac{3}{2}$ for n , is $n - 1 = 2$, which agrees with x^2 in the fluxion given; and therefore all the parts of the form are found to answer. Then, substituting these values into the general fluent, $-\frac{1}{mn}(a - x^n)^m$, gives

$$-\frac{5}{3} \times \frac{2}{3} (c^3 - x^3)^{\frac{1}{2}} = -\frac{10}{9} (c^3 - x^3)^{\frac{1}{2}}.$$

Thirdly, To find the fluent of $\frac{1}{1+x^3}$. This agrees with the 8th form; where $\pm x^n = +x^3$ in the denominator, or $n = 3$; and the numerator x^{n-1} then becomes x^2 , which agrees with the numerator in the given fluxion, also $a = 1$. Hence then, by substituting in the general form of the fluent $\frac{1}{n} \logarithm of a + x^n$, it becomes $\frac{1}{3} \logarithm of 1 + x^3$.

IX. To find Fluents by means of Infinite Series.—When a finite form cannot be found to agree with a proposed

fluxion, it is then usual to throw it into an infinite series, either by division, or extraction of roots, or by the binomial theorem, &c; after which, the fluents of all the terms are taken separately.

For Example. To find the fluent of $\frac{1-x}{1+x-x^2}\dot{x}$. Here, by dividing the numerator by the denominator, this becomes $\dot{x} - 2x\dot{x} + 3x^2\dot{x} - 5x^3\dot{x} + 8x^4\dot{x}$ &c; and, the fluents of all the terms being taken, give $x - x^2 + x^3 - \frac{5}{4}x^4 + \frac{8}{5}x^5$ &c, for the fluent sought.

To Correct a FLUENT.—The fluent of a given fluxion, found as above, sometimes wants a correction, to make it contemporary with that required by the problem under consideration, &c: for the fluent of any given fluxion, as \dot{x} , may be either x (which is found by the rule) or it may be $x \pm c$, that is x plus or minus some constant quantity c ; because both x and $x \pm c$ have the same fluxion \dot{x} : and the finding of this constant quantity c , is called correcting the fluent. Now this correction is to be determined from the nature of the problem in hand, by which means to know the relation which the fluent quantities have to each other at some certain point or time. Reduce therefore the general fluent equation, found by the rules above, to that point or time; then if the equation be true at that point, it is correct; but if not, it wants a correction, and the quantity of that correction is the difference between the two general sides of the equation when reduced to that particular state. Hence the general rule for the correction is this:

Connect the constant, but indeterminate, quantity c , with one side of the fluent equation, as determined by the foregoing rules; and, in this equation, substitute for the variable quantities such values as they are known to have at any particular state, place, or time; and then from that particular state of the equation find the value of c , the constant quantity of the correction.

Example. To find the correct fluent of $\dot{z} = ax^3\dot{x}$. First the general fluent of this is $z = \frac{1}{4}ax^4$, or $z = \frac{1}{4}ax^4 + c$, taking in the correction c .—Now if it be known that z and x begin together, or that $z = 0$, when $x = 0$; then writing 0 both for x and z , the general equation becomes $0 = 0 + c$, or $c = 0$; so that, the value of c being 0, the correct fluents are $z = \frac{1}{4}ax^4$.

But if when $z = 0$, $x = b$, any known quantity; then substituting 0 for z , and b for x , in the general equation, it becomes $0 = \frac{1}{4}ab^4 + c$, from which is found $c = -\frac{1}{4}ab^4$; and this being written for it in the general equation, this becomes $z = \frac{1}{4}a(x^4 - b^4)$, for the correct, or contemporary fluents.

Or lastly, if it be known that when $z = d$, $x = b$; then substituting d for z , and b for x , in the general fluent equation $z = \frac{1}{4}ax^4 + c$, it becomes $d = \frac{1}{4}ab^4 + c$; and hence is deduced the value of the correction, viz, $c = d - \frac{1}{4}ab^4$; consequently, writing this value for c in the general equation, it becomes $z = \frac{1}{4}a(x^4 - b^4) + d$, for the correct equation of the fluents in this case.

And hence arises another easy and general way of correcting the fluents, which is this: In the general equation of the fluents, write the particular values of the quantities which they are known to have at any certain time; then subtract the sides of the resulting particular equation, from the corresponding sides of the general one, and the remainders will give the correct equation of the fluents sought. So, as above, the general equation being $- - - z = ax^4$; write d for z , and b for x , then $- - - d = ab^4$;

hence by subtraction $- - - z - d = ax^4 - ab^4$, or $- - - z = ax^4 - ab^4 + d$, the correct fluents as before.—See other methods of finding or transforming fluents, in my Course of Mathematics.

FLUID, or **FLUID Body**, according to Newton, is that whose parts yield to the smallest force impressed, and by yielding are easily moved among each other; in which sense it stands opposed to a solid. This is the definition of a perfect fluid: if the fluid require some sensible force to move its parts, it is imperfect in proportion to that force; and such perhaps are all the fluids we know of in nature. See **FLUIDITY**.

That fluids have vacuities in their substance is evident, because certain bodies may be dissolved in them without increasing their bulk. Thus, water will dissolve a certain quantity of salt; after which it will receive a little sugar, and after that a little alum; and all this without increasing its first dimensions. Which shows that the particles of these solids are so far separated as to become smaller than those of the fluid, and to be received and contained in the interstices between them.

Fluids are either elastic, such as air; or non-elastic, as water, mercury, &c. These latter occupy the same space, or are of the same bulk, under all pressures or forces; but the former dilate and expand themselves continually by taking off the external pressure from them; for which reason it is that the density and elasticity of such fluids, are proportional to the force or weight that compresses them. The doctrine and laws of fluids are of the greatest extent and importance in philosophy: the properties of elastic fluids constituting the doctrine of Pneumatics; those of the non-elastic fluids, that of Hydrostatics; and the laws of their motions, Hydraulics. For which see these respective articles.—For the laws of the pressure and gravitation in fluids specifically heavier or lighter than the bodies immersed, see **SPECIFIC GRAVITY**.—For the laws of the resistance of fluids, or the retardation of solid bodies moving in fluids, see **RESISTANCE**.—For the ascent of fluids in capillary tubes, or between glass planes, &c, see **ASCENT, and CAPILLARY TUBES**.

FLUTES, or FLUTINGS, are certain channels or cavities cut along the shaft of a column, or pilaster.

FLUIDITY, that state or affection of bodies, which dominates or renders them fluid; or that property by which they yield to the smallest force impressed: in contradistinction to solidity or firmness. Fluidity is to be carefully distinguished from liquidity or humidity, which latter implies wetting or adhering. Thus, air, ether, mercury, and other melted metals, and even smoke and flame itself, are fluid bodies, but not liquid ones; while water, beer, milk, urine, &c, are both fluids and liquids at the same time.

The nature and causes of fluidity have been variously assigned. The Gassendists, and ancient corpuscularians, require only three conditions as necessary to it; viz, a smallness and smoothness of the particles of the body, vacuities between these particles, each of which being a spherical figure. The Cartesians, and after them Dr. Hooke, Mr. Boyle, &c, besides these circumstances, require also a certain internal or intestine motion of the particles, as chiefly contributing to fluidity. Thus, Mr. Boyle, in his History of Fluidity, argues from various experiments: for example, a little dry powder of alabaster, or plaster of Paris, finely sifted, being put into a vessel over the fire, soon begins to boil like water; exhibiting all

the motions and phenomena of a boiling liquor: it tumbles variously in great waves; will bear stirring with a stick or ladle, without resisting; and if strongly stirred near the side of the vessel, its waves will apparently dash against it, thus resembling the boiling of water: yet it is all the while a dry parched powder.

The same is observed in sand; a dish of which being set on a drum-head, briskly beaten by the sticks, or on the upper stone of a mill, it in all respects emulates the properties of a fluid body. A heavy body, ex. gr. will immediately sink in it to the bottom, and a light one emerge to the top: each grain of sand has a constant vibratory and dancing motion; and if a hole be made in the side of the dish, the sand will spin out like water.

The Cartesians bring divers considerations to prove that the parts of fluids are in continual motion: as 1st, The change of solids into fluids, ex. gr. ice into water, and vice versa; the chief difference between the body in those two states consisting in this, that the parts, being fixed and at rest in the one, resist the touch; whereas in the other, being already in motion, they give way to the slightest impulse. 2dly, The effects of fluids, which commonly proceed from motion: such are the insinuation of fluids among the pores of bodies; the softening and dissolving hard bodies; the actions of corrosive menstruums; &c: to which they add, that no solid can be brought to a state of fluidity, without the intervention of some moving or moveable body, as fire, air, or water. Air, these philosophers hold to be the first spring of the causes of fluidity, it being this that gives motion to fire and water, though itself receives its motion and action from the ether, or subtle medium.

But Boerhaave pleads strenuously that fire is the first mover, and the great cause of all fluidity in other bodies, as air, water, &c: without this, he says, that the atmosphere itself would fix into one solid mass. And in like manner, Dr. Black, of Edinburgh, mentions fluidity as an effect of heat. The different degrees of heat which are required to bring different bodies into a state of fluidity, he supposes may depend on some particulars in the mixture and composition of the bodies themselves: which is rendered farther probable from considering that the natural state of bodies in this respect is changed by certain mixtures; thus, when two metals are compounded, the mixture is commonly more fusible than either of them separately.

Newton's idea of the cause of fluidity is different: he considers it to be the great principle of attraction. The various intestine motion and agitation among the particles of fluid bodies, he thinks is naturally accounted for, by supposing it a primary law of nature, that as all the particles of matter attract each other when within a certain distance; so at all greater distances, they avoid and fly from one another. For then, though their common gravity, together with the pressure of other bodies upon them, may keep them together in a mass, yet their continual endeavour to avoid one another singly, and the adventitious impulses of heat and light, or other external causes, may make the particles of fluids continually move round each other, and so produce this quality. As therefore the cause of cohesion of the parts of solid bodies appears to be their mutual attraction; so, on this principle, the chief cause of fluidity seems to be a contrary motion, impressed on the particles of fluids; by which they avoid and fly from each other, as soon as they come at, and as long as they keep at, a certain distance. It is observed also in

all fluids, that the direction of their pressure against the vessels which contain them, is in lines perpendicular to the sides of such vessels; which property, being the necessary result of the spherical figure of the particles of any fluid, shows that the parts of all fluids are so, or of a figure very nearly approaching to it.

FLUX, in Hydrography, a regular and periodical motion of the sea, happening twice in 24 hours and 48 minutes, nearly. The flux, or flow, is one of the motions of the tide: the other, by which the water sinks and retires, being called the reflux, or ebb. See TIDE.

Between the flux and reflux there is a kind of rest or cessation, of about half an hour; during which time the water is at its greatest height, called high-water.

The flux of the sea follows chiefly the course of the moon; and is always highest and greatest at new and full moons, particularly near the time of the equinoxes. In some parts, as at Mount St. Michael, the water rises 18 or 20 feet, though in the open sea it never rises above a foot or two; and in some places, as about the Morea, there is no flux at all. It runs up some rivers above 120 miles: though up the river Thames it goes only about 80, viz, near to Kingston in Surrey. Above London-bridge, the water flows 4 hours, and ebbs 8; and below the bridge, it flows 5 hours, and ebbs 7.

FLUXION, in the Newtonian analysis, denotes the rate or proportion at which a flowing or varying quantity increases its magnitude or quantity; and it is proportional to the magnitude by which the flowing quantity would be uniformly increased, in a given time, by the generating quantity continuing of the invariable magnitude it has at the moment of time for which the fluxion is taken: by which it stands contradistinguished from fluent, or the flowing quantity, which is gradually, and indefinitely increasing, after the manner of a space which a body in motion describes.

Mr. Simpson observes, that there is an advantage in thus considering fluxions, not as mere velocities of increase at a certain point, but as the magnitudes which would be uniformly generated in a given finite time: the imagination is not here confined to a single point, and the higher orders of fluxions are rendered much more easy and intelligible. And though Sir Isaac Newton defines fluxions to be the velocities of motions, yet he has recourse to the moments or increments, generated in equal particles of time, to determine those velocities, which he afterwards directs to expound by finite magnitudes of other kinds. As to the illustration of this definition, and the rules for finding the fluxions of all sorts of flowing quantities, see the following article, or the Method of Fluxions.

Method of Fluxions, is the algorithm and analysis of fluxions and fluents, or flowing quantities. Most foreigners define this as the method of differences or differentials, being the analysis of indefinitely small quantities. But Newton, and other English authors call these infinitely small quantities, moments; considering them as the momentary increments of variable quantities; us of a line considered as generated by the flux or motion of a point, or of a surface generated by the flux of a line. Accordingly, the variable quantities are called fluents, or flowing quantities; and the method of finding either the fluxion, or the fluent, the method of fluxions. But M. Leibnitz considers the same infinitely small quantities as the differences, or differentials, of quantities; and the method of finding those differences, he calls the Differential Calculus. Besides

this difference in the name, there is another in the notation. Newton expresses the fluxion of a quantity, as of x , by a point placed over it, thus \dot{x} ; while Leibnitz expresses his differential of the same x , by prefixing the initial letter d , as dx . And except in these circumstances, the two methods may be considered as the same.

The Method of Fluxions is probably one of the greatest, most subtle, and sublime discoveries of any age: it opens a new world to our view, and extends our knowledge, as it were, to infinity; carrying us beyond the bounds that seemed to have been prescribed to the human mind, at least infinitely beyond those to which the ancient geometry was confined.

The history of this important discovery, recent as it is, is a little dark and embroiled. Two of the greatest men of the last age have both of them claimed the invention, Sir I. Newton, and M. Leibnitz; and nothing can be more glorious for the method itself, than the zeal with which the partisans of either side have asserted their title.

To exhibit a just view of this dispute; and of the pretensions of each party, we may here advert to the origin of the discovery, and mark where each claim commenced, and how it was supported.

The principles on which the Method of Fluxions is founded, or which conducted to it, had been laying, and gradually developing, from the beginning of the 17th century, by Fermat, Napier, Barrow, Wallis, Slusius, &c, who had methods of drawing tangents, of maxima and minima, of quadratures, &c, in certain particular cases, as of rational quantities, on nearly the same principles. And it was not wonderful that such a genius as Newton should soon after raise those faint beginnings into a regular and general system of science, which he did about the year 1665, or sooner.

The first time however that the method appeared in print, was in 1684, when M. Leibnitz gave the rules of it in the Leipsic Acts of that year: but without the demonstrations. The two brothers however, John and James Bernoulli, being struck with this new method, applied themselves diligently to it, found out the demonstrations, and applied the calculus with great success.

But before this, M. Leibnitz had proposed his Differential Method, viz, in a letter, dated Jan. 21, 1677, in which he exactly pursues Dr. Barrow's method of tangents, that had been published in 1670; and Newton communicated his method of drawing tangents to Mr. Collins, in a letter dated Dec. 10, 1672; which letter, together with another dated June 13, 1676, were sent to M. Leibnitz by Mr. Oldenburgh, in 1676. So that there is a strong presumption that he might avail himself of the information contained in these letters, and other papers transmitted with them, and also in 1675, before the publication of his own letter, containing the first hint of his differential method. Indeed it sufficiently appears that Newton had invented his method before the year 1669, and that he actually made use of it in his Compendium of Analysis and Quadrature of Curves before that time. His attention seems to have been directed this way, even before the time of the plague which happened in London in 1665 and 1666, when he was about 28 years of age.

This is all that is heard of the method, till the year 1687, when Newton's great work the Principia appeared, which is almost wholly founded on the same calculus. The common opinion then was, that Newton and Leibnitz had each invented it about the same time: and what

seemed to confirm it was, that neither of them made any mention of the other; and that, though they agreed in the substance of the thing, yet they differed in their ways of conceiving it, calling it by different names, and using different characters. However, foreigners having first learned the method through the medium of Leibnitz's publication, which spread the method through Europe, they were insensibly accustomed to consider him as the sole, or principal inventor, and became ever after strongly prejudiced in favour of his notation and mode of conceiving it.

The two great authors themselves, without any seeming concern, or dispute, as to the property of the invention, enjoyed the glorious prospect of the progresses continually making under their auspices, till the year 1699, when the peace began to be disturbed.

M. Facio, in a treatise on the Line of Swiftest Descent, declared, that he was obliged to own Newton as the first inventor of the differential calculus, and the first by many years; and that he left the world to judge, whether Leibnitz, the second inventor, had taken any thing from him. This precise distinction between first and second inventor, with the suspicion it insinuated, raised a controversy between M. Leibnitz, supported by the editors of the Leipsic Acts, and the English mathematicians, who declared for Newton. Sir Isaac himself never appeared on the scene; his glory was become that of the nation; and his adherents, warm in the cause of their country, needed not his assistance to animate them.

Writings succeeded each other but slowly, on either side; probably on account of the distance of places; but the controversy grew still stronger and stronger: till at length M. Leibnitz, in the year 1711, complained to the Royal Society, that Dr. Keil had accused him of publishing the Method of Fluxions invented by Sir I. Newton, under other names and characters. He insisted that nobody knew better than Sir Isaac himself, that he had taken nothing from him; and required that Dr. Keil should disavow the ill construction which might be put upon his words.

The Society, thus appealed to as a judge, appointed a committee to examine all the old letters, papers, and documents, that had passed among the several mathematicians, relating to this subject; who, after a strict examination of all the evidence that could be procured, gave in their report as follows: "That M. Leibnitz was in London in 1673, and kept a correspondence with Mr. Collins by means of Mr. Oldenburgh, till Sept. 1676, when he returned from Paris to Hanover, by way of London and Amsterdam: that it did not appear that M. Leibnitz knew any thing of the differential calculus before his letter of the 21st of June, 1677, which was a year after a copy of a letter, written by Newton in the year 1672, had been sent to Paris to be communicated to him, and above 4 years after Mr. Collins began to communicate that letter to his correspondents; in which the Method of Fluxions was sufficiently explained, to let a man of his sagacity into the whole matter: and that Sir I. Newton had even invented his method before the year 1669, and consequently 15 years before M. Leibnitz had given any thing on the subject in the Leipsic Acts." From which they concluded that Dr. Keil had not at all injured M. Leibnitz in what he had said.

The Society printed this their determination, together with all the pieces and materials relating to it, under the

title of *Commercium Epistoliticum de Analyti Promota*, 8vo, Lond. 1712. This book was carefully distributed through Europe, to vindicate the title of the English nation to the discovery; for Newton himself, as already hinted, never appeared in the affair: whether it was that he trusted his honour with his compatriots, who were zealous enough in the cause; or whether he felt himself even superior to the glory of it.

M. Leibnitz and his friends however could not show the same indifference: he was accused of a plagiarism; and the whole *Commercium Epistoliticum* either expresses it in terms, or insinuates it. Soon after the publication therefore, a loose sheet was printed at Paris, in behalf of M. Leibnitz, then at Vienna. It is written with great zeal and spirit; and it boldly maintains that the Method of Fluxions had not preceeded the Method of Differences; and even insinuates that it might have arisen from it. The detail of the proofs however, on each side, would be too long, and could not be understood without a large comment, which must enter into the deepest geometry: M. Leibnitz had begun to work upon a *Commercium Epistoliticum*, in opposition to that of the Royal Society; but he died before it was completed.

A second edition of the *Commercium Epistoliticum* was printed at London in 1722; when Newton, in the preface, account, and annotations, which were added to that edition, particularly answered all the objections which Leibnitz and Bernoulli were able to make since the *Commercium* first appeared in 1712; and from the last edition of the *Commercium*, with the various original papers contained in it, it evidently appears that Newton had discovered his Method of Fluxions many years before the pretensions of Leibnitz. See also Raphson's History of Fluxions.

There are however, according to the opinion of some, strong presumptions in favour of Leibnitz; i.e. that he was no plagiarist: for that Newton was at least the first inventor, is past all dispute; his glory is secure; the reasonable part, even among the foreigners, allow it; and the question is only, whether Leibnitz took it from him, or fell upon the same thing with him; for, in his theory of abstract notions, which he dedicated to the Royal Academy in 1671, before he had seen any thing of Newton's, he already supposed infinitely small quantities, some greater than others; which is one of the great principles of his system. But, before prosecuting farther the history and improvements of this science, it will be proper to premise somewhat of the principles and practice of it, according to the ideas of the inventor.

Principles of the Method of FLUXIONS.

1. In the doctrine of fluxions, magnitudes or quantities, of all kinds, are considered, not as made up of a number of small parts, but as generated by continued motion, by means of which they increase or decrease: as a line by the motion of a point; a surface by the motion of a line; and a solid by the motion of a surface: which is no new principle in geometry; having been used by Archimedes, &c. So likewise, time may be considered as represented by a line, increasing uniformly by the motion of a point. And quantities of all kinds whatever, which are capable of increase and decrease, may thus be represented by lines, surfaces, or solids, considered as generated by motion.

2. Any quantity, in this manner generated, and variable, is called a Fluent, or flowing quantity. And the

rate or proportion according to which any flowing quantity increases, at any position or instant, is the fluxion of the said quantity, at that position or instant: and it is proportional to the magnitude by which the flowing quantity would be uniformly increased, in a given time, with the generating celerity uniformly continued during that time.

3. The small quantities thus generated or described, in any given small portion of time, and by any continued motion, either uniform or variable, are called Increments.

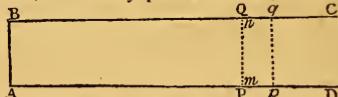

4. Hence, if the motion of increase be uniform, by which increments are generated, the increments will in that case be proportional, or equal, to the measures of the fluxions: but if the motion of increase be accelerated, the increments so generated, in a given finite time, will exceed the fluxion; and if it be a decreasing motion, the increments so generated, will be less than the fluxion. But if the time be indefinitely small, so that the motion be considered as uniform for that instant; then these nascent increments will always be proportional or equal to the fluxions, and may be substituted for them; in any calculation.

5. To illustrate these definitions: Suppose a point m be conceived to move from the position A , and to generate a

A ————— P P

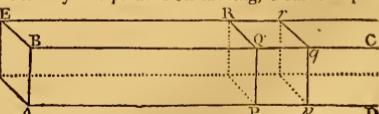

line AP , with a motion any-how regulated; and suppose the celerity of the point m , at any position P , to be such, as would, if from thence it should become, or continue, uniform, be sufficient to describe, or pass uniformly over, the distance PP' , in the given time allowed for the fluxion: then will the said line PP' represent the fluxion of the said fluent or flowing line AP , at that position.

6. Again, suppose the right line mn to move, from the position AB , continually parallel to itself, with any con-

tinued motion, so as to generate the fluent, or flowing rectangle $ABQP$, whilst the point m describes the line AP ; also let the distance PP' be taken, as above, to express the fluxion of the line or base AP ; and complete the rectangle $PP'Q'P$. Then, in the same manner as PP' is the fluxion of the line AP , so the small parallelogram PQ is the fluxion of the flowing parallelogram, AQ ; both these fluxions or increments being uniformly described in the same time.

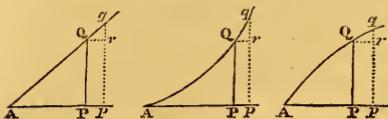

7. In like manner, if the solid $AERP$ be conceived as generated by the plane PQR moving, from the position

AD , always parallel to itself, along the line AD ; and if PP' denote the fluxion of the line AP . Then, as the parallelogram PQ , or $PP' \times PQ$, expresses the fluxion of the flowing rectangle AQ , so likewise shall the fluxion of the variable solid or prism AR be expressed by the prism PR , or $PP' \times$ the plane PR . And in both these last two cases, it appears that the fluxion of the generated rectangle, or prism, is equal to the product of the generated rectangle, whether

line or plane, drawn into the fluxion of the line along which it moves.

S. Hitherto the generant, or generating line or plane, has been considered as of a constant or invariable magnitude; in which case the fluent, or quantity generated, is a parallelogram, or a prism, the former being described by the motion of a line, and the latter by the motion of a plane. In like manner are other figures, whether plane or solid, conceived to be described, by the motion of a variable magnitude, whether it be a line or a plane. Thus, let a variable line PQ be carried with a parallel motion along AP , or while a point P is carried along, and describes, the line AP , suppose another point Q to be car-

ried by a motion perpendicular to the former, and to describe the line PQ : let pq be another position of PQ , indefinitely near the former; and draw qr parallel to AP . Now in this case there are several fluents or flowing quantities, with their respective fluxions: viz, the line or fluent AP , the fluxion of which is ep , or qr ; the line or fluent PQ , the fluxion of which is qr ; the curve, or oblique line AQ , described by the oblique motion of the point, the fluxion of which is qg ; and lastly the surface APQ , described by the variable line PQ , and the fluxion of which is the rectangle $pqrp$, or $pq \times pp$. And in the same manner may any solid be conceived to be described, by the motion of a variable plane parallel to itself, substituting the variable plane for the variable line; in which case, the fluxion of the solid, at any position, is represented by the variable plane, at that position, drawn into the fluxion of the line along which it is carried.

9. Hence then it follows generally, that the fluxion of any figure, whether plane or solid, at any position, is equal to the section of it, at that position, drawn into the fluxion of the axis, or line along which the variable section is supposed to be perpendicularly carried; i. e. the fluxion of the figure AQp , is equal the plane $PQ \times ep$ when that figure is a solid, or to the ordinate $PQ \times pp$ when the figure is a surface.

10. It also follows, from the same premises, that, in any curve, or oblique line, AQ , whose absciss is AP , and ordinate is PQ , the fluxions of these three form a small right-angled plane triangle qpr ; for $qr = pp$ is the fluxion of the absciss AP , gr the fluxion of the ordinate PQ , and qg the fluxion of the curve or right line AQ . And consequently that, in any curve, the square of the fluxion of the curve, is equal to the sum of the squares of the fluxions of the absciss and ordinate, when these two lines are at right angles to each other.

11. From the premises it also appears, that contemporaneous fluents, or quantities that flow or increase together, which are always in a constant ratio to each other, have their fluxions also in the same constant ratio at every position. For, let AP and BQ be two contemporaneous

points P and Q , the contemporaneous positions being p , q , and P, Q ; and let AP be to BQ , or ap to bq , in the constant ratio of n to 1. Then is

$$\frac{AP}{BQ} = \frac{n}{1}$$

and

$$\frac{AP}{BQ} = \frac{n}{1}$$

therefore by subtraction,

$$\frac{AP - ap}{BQ - bq} = \frac{n - n}{1}$$

that is, the fluxion pp : fluxion qq :: $n : 1$,
the same as fluent AP : fluent BQ :: $n : 1$; or
the fluxions and fluents are in the same constant ratio.

But if the ratio of the fluents be variable, so will that of the fluxions, be also, though not in the same variable ratio with the former, at every position.

The Notation, &c, in Fluxions.

12. To apply the foregoing principles to the determination of the fluxions of algebraic quantities, by means of which those of all other kinds are determined, it will be necessary first to premise the notation used in this science, with some observations. As, first, that the final letters of the alphabet $z, y, x, w, &c$, are used to denote variable or flowing quantities; and the initial letters $a, b, c, d, &c$, constant or invariable ones: thus, the variable base AP of the flowing rectangular figure $ABQP$, at art. 6, may be represented by x ; and the invariable altitude PQ , by a : also the variable base or absciss AP , of the figures in art. 8, may be represented by x ; the variable ordinate PQ , by y ; and the variable curve or line AQ , by z .

Secondly, that the fluxion of a quantity denoted by a single letter, is represented by the same letter with a point over it: Thus, the fluxion of x is expressed by \dot{x} , that of y by \dot{y} , and that of z by \dot{z} . As to the fluxions of constant or invariable quantities, as of $a, b, c, &c$, they are equal to 0 or nothing, because they do not flow, or change their magnitude.

Thirdly, that the increments of variable or flowing quantities, are also denoted by the same letters with a small ('') over them: So the increments of x, y, z , are $\dot{x}, \dot{y}, \dot{z}$.

13. From these notations, and the foregoing principles, the quantities and their fluxions, there considered, will be denoted as below.

In all the foregoing figures, put
the variable or flowing line - - - $AP = x$,
in art. 6, the constant line - - - $PQ = a$,
in art. 8, the variable ordinate - - - $PQ = y$,
the variable curve or right line - - - $AQ = z$;
Then shall the several fluxions be thus represented, viz,

$$\begin{aligned}\dot{x} &= pp \text{ the fluxion of the line } AP, \\ \dot{a}x &= pqp \text{ the fluxion of } ABQP \text{ in art. 6,} \\ \dot{y}x &= pqrp \text{ the fluxion of } APQ \text{ in art. 8,} \\ \dot{z}x &= qg = \sqrt{(\dot{x}^2 + \dot{y}^2)} \text{ the fluxion of } AQ, \\ \text{and } \dot{ax} &= pr \text{ the flux. of the solid in art. 7, if} \\ a &\text{ denote the constant generating plane } PQR.\end{aligned}$$

Also $nx = BQ$ in the figure to art. 11,
and $\dot{nx} = qg$ the fluxion of the same.

14. The principles and notation being thus laid down, we may proceed to the practice and rules of this doctrine, which consists of two principal parts, called the direct and inverse method of fluxions; viz, the direct method, which consists in finding the fluxion of any proposed fluent or flowing quantity; and the inverse method, which consists in finding the fluent of any proposed fluxion. As to the former of these two problems, it can always be determined, and that in finite algebraic terms; but the latter, or finding of fluents, only in some certain cases, except by means of infinite series.—First then, of

A P P B Q Q

fluents, described in the same time by the motion of the

The Direct Method of Fluxions.

15. To find the fluxion of the product or rectangle of two variable quantities; let $\Delta RQ = xy$ be the flowing or variable rectangle, generated by two lines RQ and PQ moving always perpendicular to each other, from the positions AP and AQ ; denoting the one by x , and the other by y ; and suppose x and y to be so related, that the curve AQ may always pass through their intersection Q , or the opposite angle of the rectangle.

Now this rectangle consists of the two trilineal spaces APQ , and ARQ , of which the fluxion of the former is $RQ \times PQ$ or xy , and that of the latter is $RQ \times BR$ or $x\dot{y}$; therefore the sum of the two, $\dot{xy} + xy$, is the fluxion of the whole rectangle xy or ΔRQ .

The same otherwise.—Let the sides of the rectangle, x and y , by flowing, become $x + \dot{x}$ and $y + \dot{y}$: then the product of the two, or $xy + x\dot{y} + y\dot{x} + \dot{x}\dot{y}$ will be the new or contemporaneous value of the flowing rectangle PR or xy ; subtract the one value from the other, and the remainder $x\dot{y} + \dot{x}y + \dot{x}\dot{y}$, will be the increment generated in the same time as x or y ; of which the last term $\dot{x}\dot{y}$ is nothing, or indefinitely small in respect of the other two terms, because x and y are indefinitely small in respect of x and y ; which term being therefore omitted, there remains $x\dot{y} + \dot{x}y$ for the value of that increment: and hence, by substituting x and \dot{y} for x and y , to which they are proportional, there arises $\dot{xy} + xy$ for the value of the fluxion of xy ; the same as before.

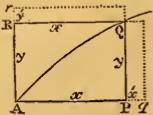

17. Hence may be derived the fluxions of all powers and products, and of all other forms of algebraic quantities whatever. And first for the continual products of any number of quantities, as xyz , or $wxyz$, or $vwxyz$, &c. For xyz put q or pz , so that $p = xy$, and $xyz = pz = q$. Now, taking the fluxion of $q = pz$, by the last article, it is $\dot{q} = p\dot{z} + p\dot{z}$; but $p = xy$, and so $\dot{p} = xy + \dot{x}y$ by the same article; substituting therefore these values of p and \dot{p} instead of them, in the value of \dot{q} , this becomes $\dot{q} = xyz + x\dot{yz} + xy\dot{z}$, the fluxion of xyz required; which is therefore equal to the sum of the products arising from the fluxion of each letter or quantity multiplied by the product of the other two.

Again, to determine the fluxion of $wxyz$, the continual product of four variable quantities; put this product, viz, $wxyz$ or $qw = r$, where $q = xyz$ as above; then, taking the fluxion by the last article, $\dot{r} = qw + qw$; and this, by substituting for q and \dot{q} their values as above, becomes $\dot{r} = wxyz + wxyz + wxyz + wxyz$, the fluxion of $wxyz$ as required; consisting of the fluxion of each quantity drawn into the products of the other three.

In the very same manner it is discovered that the fluxion of $vwxyz$ is

$vwxyz + vwxyz + vwxyz + vwxyz + vwxyz$; and so on, for any number of quantities whatever; in which it is always found that there are as many terms as variable quantities in the proposed fluent, and that these terms consist of the fluxion of each variable quantity multiplied by the product of all the rest of the quantities.

18. From hence is easily derived the fluxion of any power of a variable quantity, as of x^2 , or x^3 , or x^4 , &c.

For, in the rectangle or product xy , if $x = y$, then is the product $xy = xx$ or x^2 , and also its fluxion $\dot{xy} + xy = \dot{xx} + xx = 2x\dot{x}$, the fluxion x^2 .

Again, if all the three x , y , z be equal; then is the product of the three $xyz = xxx$ or x^3 ; and its fluxion $\dot{xyz} + xyz = \dot{xxx} + xxx + x\dot{x}$ or $3x^2\dot{x}$, the fluxion of x^3 .

And in the same manner it will appear that the fluxion of x^4 is $= 4x^3\dot{x}$,
that of x^5 is $= 5x^4\dot{x}$,
that of x^n is $= nx^{n-1}\dot{x}$;

where n is any positive whole number. That is, the fluxion of any positive integral power, is equal to the exponent of the power (n), multiplied by the next less power of the same quantity (x^{n-1}), and by the fluxion of the root (\dot{x}).

19. Next, for the fluxion of any fraction, as $\frac{x}{y}$, of one variable quantity divided by another; put the proposed fraction $\frac{x}{y} = q$; then, multiplying by the denominator, $x = qy$; and taking the fluxions, $\dot{x} = \dot{q}y + q\dot{y}$, or $\dot{q}y = \dot{x} - q\dot{y}$; and, by division, $\dot{q} = \frac{\dot{x}}{y} - \frac{q\dot{y}}{y} = (\text{by substituting the value of } q, \text{ or } \frac{x}{y}) \frac{\dot{x}}{y} - \frac{\dot{y}}{y^2} = \frac{\dot{x} - q\dot{y}}{y^2}$ the fluxion of $\frac{x}{y}$ as required. That is, the fluxion of any fraction, is equal to the fluxion of the numerator drawn into the denominator, minus the fluxion of the denominator drawn into the numerator, and the remainder divided by the square of the denominator.

20. Hence too is easily derived the fluxion of any negative integer power of a variable quantity, as of x^{-n} or $\frac{1}{x^n}$ which is the same thing. For here the numerator of the fraction is 1, whose fluxion is nothing; and therefore, by the last article, the fluxion of such a fraction, or negative power, is barely-equal to minus the fluxion of the denominator, divided by the square of the said denominator. That is, the fluxion of x^{-n} , or $\frac{1}{x^n}$,

is $= -\frac{nx^{-n-1}\dot{x}}{x^{2n}}$ or $= -\frac{n\dot{x}}{x^{n+1}}$ or $= nx^{-(n+1)}\dot{x}$; which is the same rule as before for integral powers.

Or, the same thing is otherwise derived immediately from the fluxion of a rectangle or product, thus: put the proposed fraction, or quotient, $\frac{1}{x^n} = q$; then is $qx^n = 1$; and, taking the fluxions, $\dot{q}x^n + qx^{n-1}\dot{x} = 0$; hence $\dot{q}x^n = -qx^{n-1}\dot{x}$, and then dividing by x^n we have $\dot{q} = -\frac{qx^n}{x^n} = (\text{by substituting } \frac{1}{x^n} \text{ for } q) \frac{-n\dot{x}}{x^n}$ or $= nx^{-n-1}\dot{x}$; the same as before.

21. Much in the same manner is obtained the fluxion of any surd, or fractional power of a fluent quantity, as of $x^{\frac{m}{n}}$ or $\sqrt[n]{x^m}$. For, putting the proposed quantity $x^{\frac{m}{n}} = q$, then, raising each to the n power, $-mx^{m-1}\dot{x} = q^n$; take the fluxions, $-mx^{m-1}\dot{x} = nq^{n-1}q\dot{x}$; divide by nq^{n-1} , $\dot{q} = \frac{mx^{m-1}\dot{x}}{nq^{n-1}} = \frac{mx^{m-1}\dot{x}}{nx^{m-\frac{m}{n}}} = \frac{m}{n}x^{m-\frac{m}{n}}\dot{x}$; which is still the same rule as before, for finding the fluxion of any power of a fluent quantity, and which is therefore general, whether the exponent be positive or negative, integral or fractional.

22. For the Fluxions of Logarithms: Let a be the principal vertex of an hyperbola, having its asymptotes CD , CP , with the ordinates DA , BA , PQ , &c, parallel to them. Then, from the nature of the hyperbola, and of logarithms, it is known that any space $ABPQ$ is the log. of the ratio of CB to CP , or the modulus $ACBD$. Now put $CB = BA = 1$ the side of the square or rhombus DB ; $m =$ the modulus, or area of DB , or sine of the angle c to the radius 1; also the absciss $CP = x$, and the ordinate $PQ = y$. Then, by the nature of the hyperbola, $CP \times PQ$ is always equal to DB , that is, $xy = m$; hence $y = \frac{m}{x}$, and the fluxion of the space, or dy is $\frac{m\dot{x}}{x} = \frac{m}{x^2}y$ the fluxion of the log. of x , to the modulus m . And in the ordinary hyp. logarithms the modulus m being 1, therefore $\frac{\dot{x}}{x}$ is the fluxion of the hyp. log. of x ; which is therefore equal to the fluxion of the quantity, divided by the quantity itself. And the same might be shown in several other ways, independent of the figure of the hyperbola.

23. By means of the fluxions of logarithms, are determined those of exponential quantities, i. e. quantities which have their exponent also a flowing or variable quantity. These exponentials are of two kinds, viz, when the root is a constant quantity, as e^x ; and when the root is variable, as y^x .

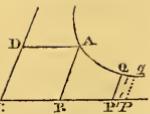

In the former case, put the proposed exponential $e^x = z$, a single variable quantity; then take the logarithm of each, so shall log. of $z = x \cdot \log. e$; take the fluxions of these, so shall $\frac{\dot{z}}{z} = \dot{x} \cdot \log. e$; hence $\dot{z} = \dot{x}z \cdot \log. e = e^x \dot{x} \cdot \log. e$, the fluxion of the proposed exponential e^x ; and which therefore is equal to the said proposed quantity, drawn into the fluxion of the exponent, and also into the log. of the root.

24. And in the 2d case, put the exponential $y^x = z$; then the logarithms give log. $z = x \times \log. y$, and the fluxions give $\frac{\dot{z}}{z} = \dot{x} \cdot \log. y + x \cdot \frac{\dot{y}}{y}$; hence $\dot{z} = \dot{x}z \cdot \log. y + \frac{xy\dot{y}}{y}$,

$y + \frac{xy\dot{y}}{y} =$ (by substituting y^x for z) $y^x \dot{x} \cdot \log. y + xy^{x-1}\dot{y}$, is the fluxion of the proposed exponential y^x ; which therefore consists of two terms, of which the one is the fluxion of the proposed quantity considering the exponent only as constant, and the other is the fluxion of the same quantity considering the root as constant.

Of Second, Third, &c. FLUXIONS.—Having explained the manner of considering and determining the first fluxions of flowing or variable quantities; it remains now to consider those of the higher orders, as 2d, 3d, 4th, &c, fluxions.

25. If the rate or celerity with which any flowing quantity changes its magnitude, be constant, or the same, at every position; then is the fluxion of it also constantly the same. But if the variation of magnitude be continually changing, either increasing or decreasing; then will there be a certain degree of fluxion peculiar to every point or position; and the rate of variation or change in the fluxion, is called the fluxion of the fluxion, or the second fluxion of the given fluent quantity. In like manner, the variation or fluxion of this 2d fluxion is called the third fluxion of the first proposed fluent quantity; and so on. And these orders of fluxions are denoted by the fluent let-

ter or quantity, with the corresponding number of points over it; viz, 2 points for the 2d fluxion, 3 for the 3d fluxion, 4 for the 4th fluxion, and so on. So the different orders of the fluxions of x , are \dot{x} , \ddot{x} , \dddot{x} , &c; where each is the fluxion of the one next before it.

26. This description of the higher orders of fluxions may be illustrated by the three figures at the 8th article; where, if x denote the absciss AP , and y the ordinate PQ ; and if the ordinate PQ or y flow along the absciss AP or x , with an uniform motion; then the fluxion of x , viz, $\dot{x} = y$ or qr is a constant quantity, or $\ddot{x} = 0$, in all the figures. Also, in fig. 1, in which AQ is a right line, $\dot{y} = -rq$, or the fluxion of rq , is a constant quantity, or $\ddot{y} = 0$; for the angle q , = the angle α , being constant, or is to rq , or x to j , in a constant ratio. But in the 2d figure, rq , or the fluxion of rq , continually increases more and more; and in fig. 3 it continually decreases more and more; and therefore in both these cases y has a 2d fluxion, being positive in fig. 2, but negative in fig. 3: and so on for the other orders of fluxions.

27. Thus if, for instance, the nature of the curve be such, that x^3 is wherever equal to $3y^2$; then, taking the fluxions, it is $3\dot{y}^2 = 3x^2\dot{x}$; and, considering \dot{x} as a constant quantity, and taking the fluxions again, the equations of the several orders of fluxions will be as below; viz,

the 1st fluxions $\dot{a}^2y = 3x^2\dot{x}$,
 the 2d fluxions $\dot{a}^2y = 6x\dot{x}^2$,
 the 3d fluxions $\dot{a}^2y = 6x^2\dot{x}$,
 the 4th fluxions $\dot{a}^2y = 0$,

and all the higher fluxions = 0 or nothing.

Also the higher orders of fluxions are found in the same manner as the lower ones. Thus,
 The 1st flux. of $y^3 = -3y^2\dot{y}$;
 its 2d flux. or flux. of $3y^2 =$ considered as the rect- } $3y^2\dot{y} + 6yy^2$,
 angle of $3y^2$ and \dot{y} , is - and the flux. of this again, or } $3y^2\dot{y} + 18yy\dot{y} + 6\dot{y}^2$.
 the 3d flux. of y^3 , is }

28. In the foregoing articles, it has been supposed that the fluents increase; or that their fluxions are positive; but it often happens that some fluents decrease, and that therefore their fluxions are negative: and whenever this is the case, the sign of the fluxion must be changed, or made contrary to that of the fluent. So, of the rectangle xy , when both x and y increase together, the fluxion is $xy + \dot{xy}$: but if one of them, as y , decrease, while the other, x , increases; then the fluxion of y being $-j$, the fluxion of xy will in that case be $xy - \dot{xy}$. This may be illustrated by the annexed rectangle $APQy = xy$, supposed to be generated by the motion of the line PQ from A towards C , and by the motion of the line RQ from B towards A : for, by the motion of PQ , from A towards C , the rectangle is increased, and its fluxion is $+xy$; but by the motion of RQ , from B towards A , the rectangle is decreased, and the fluxion of the decrease is $-\dot{xy}$; therefore, taking the fluxion of the decrease from that of the increase, the fluxion of the rectangle xy , when x increases and y decreases, is $xy - \dot{xy}$.

For the Inverse Method, or the finding of fluents, see FLUENT. And for the several applications of this science to MAXIMA and MINIMA, the drawing of TANGENTS, &c, see the respective articles.

Since the first invention of this calculus by Sir I. Newton, it has received various improvements from many eminent authors, particularly John Bernoulli, who treated of the fluents belonging to the fluxions of exponential expressions; James Bernoulli, Craig, Cheyne, Cotes, Mandfredi, Riccati, Taylor, Fagnanus, Clairaut, Dalembert, Euler, Maclaurin, Condorcet, Leseur and Jacquier, Bougainville, Walmesley, Lagrange, Emerson, Simpson, Landen, Waring, &c. There are several other treatises also on the principles of fluxions, by Hayes, Newentyt, L'Hôpital, Hodson, Rowe, Lyons, Deatly, &c, &c, delivering the elements of this science in an easy and familiar manner.

FLY, in Mechanics, a heavy weight applied to certain machines, to regulate their motions, as in a jack; or to increase their effect, as in the coining engine, &c; by means of which the force of the power is not only preserved, but equally distributed throughout the revolution.

The fly is either like a cross with heavy weights at the ends of its arms; or like a heavy wheel at right-angles to the axis of motion. It may be applied to various kinds of engines, whether they be moved by men, horses, wind, or water; and it is of great use in those parts of an engine which have a quick circular motion, and where the power or resistance acts unequally in the different parts of a revolution. In this case the fly becomes a moderator, making the motion of revolution almost everywhere equal.

FLYERS, in Architecture, such stairs as go straight, and do not wind round, nor have the steps made tapering, but equally broad at both ends. Hence, if one flight do not rise to the top of the story, &c, there is a broad half pace, and then commonly another set of flyers.

FLYING, the progressive motion of a bird, or other winged animal, through the air. The parts of birds chiefly concerned in flying, are the wings and tail: by the former, the bird sustains and wafts himself along; and by the latter he is assisted in ascending and descending, to keep his body poised upright and steady. The wings are extended or stretched quite out, and then struck forcibly downwards against the air, which by its resistance raises the bird upwards; then, to make another stroke, the wing, by means of its joints, readily closes in some degree, presenting the sharp edge of the pinion foremost to cut the air, and drawing the collapsed feathers after it like a flag, to diminish the resistance to the ascent as much as possible; the wing and feathers are then stretched out horizontally again, and another downward stroke is given, which raises the bird still higher; and so on as far as he pleases, or at least as far as the density of the air will sustain him; performing those motions of the wings very rapidly, that the flight may be the quicker.

Artificial Flying, is that attempted by men, &c, by the assistance of mechanics. The art of flying has been attempted by several persons in all ages. Friar Bacon, about 500 years ago, not only asserts the possibility of flying, but affirms that he himself knew how to make a machine with which a man might be able to convey himself through the air like a bird; and further adds, that it had been tried with success. Though the fact is to be doubted, if, as it was said, it consisted in the following method; viz, in a couple of large thin hollow copper globes, exhausted of air; which, being much lighter than air, would sustain a chair on which a person might sit. Father Franciso Lana, in his Prodrino, proposes the same thing, as his own idea. He computes, that a round vessel of plate-brass, 14 feet in diameter, weighing 3 ounces

the square foot, will only weigh 1848 ounces; whereas a quantity of air of the same bulk will weigh near 2156 ounces; so that the globe will not only be sustained in the air, but will carry with it a weight of 304 ounces; and by increasing the size of the globe, the thickness of the metal remaining the same, he adds, a vessel might be made to carry a much greater weight. But the fallacy is obvious: a globe of the dimensions he describes, as Dr. Hooke observes, would not sustain the pressure of the air, but be crushed inwards. Indeed it is not even probable that a globe can be made sufficiently thin to float in the atmosphere after it is exhausted of air, and yet be strong enough to sustain the compressing force of the atmosphere. But for this purpose it seems that the globe should be filled with an air as elastic or strong as the atmosphere, and yet be very much lighter; such as is used in the mongolfiers and balloons; the former of which is filled with common air heated, so as to be more elastic, and less heavy; and the latter with inflammable air, which is as elastic as the common air, with only about one-tenth of its weight. And thus the idea of flying, or rather floating, in the air, has been realized by the moderns, using however a different kind of air. See AEROSTATION.

The same author describes a machine for flying, invented by the Sieur Besnier, a smith of Sable, in the county of Maine. See Philos. Collect. No. 1.

By the foregoing method however, at best, only a method of floating can be obtained, like a log floating in a current; but not of flying, which consists in moving through the air, independent of any current; and which must be effected by something in the nature of wings. Attempts of this latter kind also have indeed been made by several persons; but it does not appear that any of them have been attended with such success as to induce the authors of those attempts to make them public. The philosophers in the reign of King Charles the 2d were much employed on this subject; and the celebrated Bishop Wilkins was so confident of success in it, that he says, he does not question but in future ages it will be as usual to hear a man call for his wings, when he is going a journey, as it is now to call for his boots.

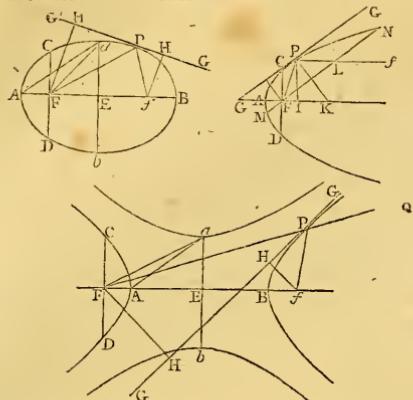

The story of the flight of Daedalus is well known.

Flying Pinion, is part of a clock, having a fly or fan with which to gather the air, and so check the rapidity of the clock's motion, when the weight descends in the striking part.

FOCAL Distance, the distance of the focus, which is sometimes understood as its distance from the vertex, as in the parabola; and sometimes its distance from the centre, as in the ellipse or hyperbola.

FOCUS, in Geometry and the Conic Sections, is applied to certain points in the ellipse, hyperbola, and parabola, where the rays reflected from all parts of these curves concur or meet; that is, rays issuing from a luminous point in the one focus, and falling on all parts of the curves, are reflected into the other focus, or into the line directed to the other focus, viz, into the other focus in the ellipse and parabola, and directly from it in the hyperbola: which is the reason of the name Focus, or Burning-point. Hence, as the one focus of the parabola is at an infinite distance; and consequently all rays drawn from it, to any finite part of the curve about the vertex, are parallel to one another; therefore, if rays from the sun, or any other object so distant that the rays may be considered as parallel, fall upon the curve of a parabola,

or concave surface of a paraboloidal figure, those rays will all be reflected into its focus.

Thus, the rays of PF , from the focus F , are reflected in the direction PF , into the other focus E , in the ellipse and parabola, and form the focus F into PQ , in the hyperbola.—In all the three curves, the double ordinate CP drawn through the focus F , is the parameter of the axis, or a 3d proportional to AB and ab , the transverse and conjugate axes.—In the ellipse and parabola, the transverse axis is equal to the sum of the two lines $PF + PF'$, drawn from the foci to any point P in the curve; but in the hyperbola, the transverse is equal to the difference of those two lines. That is,

$$AB = PF + PF' \text{ in the ellipse and parabola,}$$

$$AB = PF - PF' \text{ in the hyperbola.}$$

In the ellipse and parabola, the square of the distance between the foci, is equal to the difference of the squares of the two axes; and in the hyperbola, it is equal to the sum of their squares: that is

$$f^2 = AB^2 - ab^2 \text{ in the ellipse and parabola.}$$

$$f^2 = AB^2 + ab^2 \text{ in the hyperbola.}$$

Therefore the two semi-axes, with the distance of the focus from the centre, form always a right-angled triangle FAE , or AEE .

In all the curves, the conjugate semi-axis is a mean proportional between the distances of either focus from either end of the transverse axis: that is,

$$\frac{AF}{AE} : \frac{EA}{EG} : \frac{EG}{FB},$$

$$\text{or } EA^2 = AF \cdot FB.$$

If there be any tangent to these curves, and two lines drawn from the foci to the point of contact; these two lines will make equal angles with that tangent.

So, if GPG touch the curve at P ;
then is the angle $FPG = \angle F'PG$.

If a line be drawn from either focus, perpendicularly upon a tangent; the distance of their intersection from the centre will be equal to the semi-transverse axis. So; if FH or FH' be perpendicular to the tangent PH ; then is $EH = EA$ or EB . Consequently, the circle described on the diameter AB , will pass through all the points H , H' .

The foregoing are the principal properties that are common to the foci of all the three comic sections. To which may be added the following properties which are peculiar to the parabola: viz, In the parabola, the distance from

the focus to the vertex, is equal to $\frac{1}{2}$ of the parameter, or half the ordinate at the focus: viz, $AF = \frac{1}{2}FC$. Also, a line drawn from the focus to any point in the curve, is equal to the sum of the focal distance from the vertex and the absciss of the ordinate to that point: i.e. $FP = AF + AI = 2AF \pm FI = CF \pm FI$. If from any point of a parabola there be drawn a tangent, and a perpendicular to it PK , both to meet the axis produced; then the focus will be equally distant from the two intersections and the point of contact: i.e. $FG = FP = FK$. Also the $\angle KPF = KPF$.

Hence also the subnormal IK is $= 2AF = FC$ the semi-parameter.—The line drawn from the focus to any point of the curve, is equal to $\frac{1}{4}$ the parameter of the diameter PF .—If an ordinate to any diameter pass through the focus, it will be equal to half its parameter; and its absciss equal to $\frac{1}{2}$ of the same parameter; or the absciss equal to half the ordinate: i.e. $PL = \frac{1}{2}MN = \frac{1}{2}LM$ or $\frac{1}{2}LN$.

Focus, in Optics, is a point in which several rays meet, and are collected, after being either reflected or refracted. It is so called, because the rays being here brought together and united, their force and effect are increased, insomuch as to be able to burn; and therefore it is that bodies are placed in this point to be burnt, or to show the effect of burning-glasses, or mirrors.—It is to be observed, however, that in practice, the focus is not an absolute point, but a space of some small breadth, over which the rays are scattered; owing to the different nature and refrangibility of the rays of light, and to the imperfections in the figure of the lens, &c. However, the smaller this space is, the better, or the nearer to perfection the instrument approaches. Huygens shows that the focus of a lens convex on both sides, has its breadth equal to $\frac{1}{8}$ of the thickness of the lens.

Virtual Focus, or **Point of Divergence**, so called by Mr. Molyneux, is the point from which rays tend, after refraction or reflection; being in this respect opposed to the ordinary focus, or point of concurrence, where rays are made to meet after refraction or reflection. Thus, the foci of an hyperbola are mutually virtual foci to each other; but, in an ellipse, they are common foci to each other; for the rays are reflected from the other focus in the hyperbola, but towards it in the ellipse; as appears by the figures at the beginning of this article.

In Dioptrics, let ΔABC be the concavity of a glass, whose centre is D , and axis DE : Let FG be a ray of light falling on the glass, parallel to the axis DE ; this ray FG , after it has passed through the glass, at its emersion at G will not proceed directly to H , but be refracted from the perpendicular DG , and will become the ray GK , which being produced to meet the axis in E , this point E is the virtual focus, as the ray is refracted directly from this point.

Rules for the Foci of Lenses and Mirrors.

I. In Catoptrics, or Lenses.

1. The focus of a convex glass, i.e. the point where parallel rays unite when transmitted through a convex glass whose surface is the segment of a sphere, is distant from the pole or vertex of the glass, nearly a diameter and half of the convexity.—2. In a plano-convex glass, the focus of parallel rays is distant from the pole of the glass a diameter of the convexity, if the segment do not

exceed 30 degrees. Or the rule in plano-convex glasses is, As 107 : 193 :: so is the radius of convexity : to the refracted ray taken to its concourse with the axis; which in glasses of large spheres is nearly equal to the distance of the focus taken in the axis.—3. In double-convex glasses of the same sphere, the focus is distant from the pole of the glass about the radius of the convexity, if the segment be but 30 degrees. But when the two convexities are unequal, or segments of different spheres, then the rule is, As the sum of the radii of both convexities : is to the radius of either convexity alone :: so is double the radius of the other convexity : to the distance of the focus. But here it must be observed, that the rays which fall nearer the axis of any glass, are not united with it so near the pole of the glass as those farther off: nor will the focal distance be so great in plano-convex glass, when the convex side is towards the object, as when the plane side is towards it. And hence it is truly concluded, that, in viewing any object by a plano-convex glass, the convex side should always be turned outwards; as also in burning by such a glass.

II. For the Virtual Focus.

1. In concave glasses, when a ray passes through air parallel to the axis, the virtual focus, by its first refraction, becomes at the distance of a diameter and a half of the concavity.—2. In plano-concave glasses, when the rays fall parallel to the axis, the virtual focus is distant from the glass, the diameter of the concavity.—3. In planocconcave glasses, as 107 : 193 :: so is the radius of the concavity : to the distance of the virtual focus.—4. In double concaves of the same sphere, the virtual focus of parallel rays is at the distance of the radius of the concavity. But, whether the concavities be equal or unequal, the virtual focus, or point of divergency of the parallel rays, is determined by this rule; As the sum of the radii of both concavities : is to the radius of either concavity :: so is double the radius of the other concavity : to the distance of the virtual focus.—5. In concave glasses, exposed to converging rays, if the point to which the incident ray converges, be farther distant from the glass than the virtual focus of parallel rays, the rule for finding the virtual focus of this ray, is this; As the difference between the distance of this point from the glass, and the distance of the virtual focus from the glass: is to the distance of the virtual focus :: so is the distance of this point of convergence from the glass : to the distance of the virtual focus of this converging ray.—6. In concave glasses, if the point to which the incident ray converges, be nearer to the glass than the virtual focus of parallel rays, the rule to find where it crosses the axis, is this; As the excess of the virtual focus, above this point of convergency : is to the virtual focus :: so is the distance of this point of convergency from the glass : to the distance of the point where this ray crosses the axis.

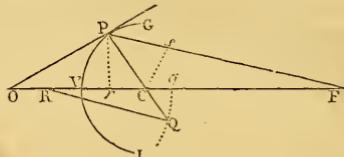

III. Practical Rules for finding the Foci of Glasses.

1. To find, by experiment, the focus of a convex spherical glass, being of a small sphere. Apply it to the end of a scale of inches and decimal parts, and expose it to the sun; then on the scale may be seen the bright intersection of the rays measured out: or, fix it in the hole of a dark chamber; and where a white paper receives the distinct representation of distant objects, there is the focus of the glass.—2. For a glass of a pretty long focus, observe some distant object through it, and recede from the glass till the eye perceives all in confusion, or the object begins to appear inverted; then the eye is in the focus.—

3. For a plano-convex glass: make it reflect the sun against the wall; then on the wall will be seen two sorts of light, a brighter within another more obscure: withdraw the glass from the wall, till the bright image be in its least dimensions; then is the glass distant from the wall about a fourth part of its focal length.—4. For a double convex: expose each side to the sun in like manner; and observe both the distances of the glass from the wall: then is the first distance about half the radius of the convexity turned from the sun; and the second is about half the radius of the other convexity. The radii of the two convexities being thus known, the focus is then found by this rule; As the sum of the radii of both convexities : is to the radius of either convexity :: so is double the radius of the other convexity : to the distance of the focus.

IV. To find the Foci of all Glasses Geometrically.

Dr. Halley has given a general method for finding the foci of spherical glasses of all kinds, both concave and convex; exposed to any kind of rays, either parallel, converging, or diverging; as follows: To find the focus of any parcel of rays diverging from, or converging to, a given point in the axis of a spherical lens, and making the same angle with it; the ratio of the sines of refraction being given.

Suppose GL a lens; P a point in its surface; V its pole; C the centre of the spherical segment; O the object, or point in the axis, to or from which the rays proceed; and R a given ray: and suppose the ratio of refraction to be as r to s . Then making CR to CO , as s to r for the immersion of a ray, or as r to s for the emersion (i.e. as the sines of the angles in the medium which the ray enters, to the corresponding sines in the medium out of which it comes); and laying CR from C towards O , the point U will be the same for all the rays of the point O . Lastly, drawing the radius PC , continued if necessary; with the centre C , and distance OP , describe an arc intersecting PC in Q . Then the line QR , being drawn, it will be parallel to the reflected ray; and RF , being drawn parallel to it, will intersect the axis in the point F , the focus sought.—Or, say as $CQ : CR :: CR : CF$, which will be the distance of the focus from the centre of the sphere.—And from this general construction, he advertises to a number of particular simple cases.—Dr. Halley gave also a universal algebraical theorem to find the focus of all sorts of optic glasses, or lenses. See also the Philos. Trans. No. 205, or my Abr. vol. 3, pa. 593.

V. In Catoptrics, or Foci by Reflection.

These are easily found for any known curve, from this principle, that the angle of incidence is always equal to the angle of reflection. The same are also easily found by experiment, being exposed to any object.

The increase of heat from collecting the sun's rays into a focus, has been found in many cases of burning-glasses, to be astonishingly great; the effect being increased as the square of the diameter of the glass exceeds that of the focus. If, for instance, there be a burning-glass of 12

inches diameter; this will collect or crowd together all the rays of the sun which fall upon the glass into the compass of about $\frac{1}{6}$ part of an inch: then, the areas of the two spaces being as the square of 12 to the square of $\frac{1}{6}$, or as the square of 96 to the square of 1, that is, as 9216 to 1; it follows, that the heat in the focus will be 9216 times greater than the sun's common heat. And this will have an effect as great as the direct rays of the sun would have on a body placed at the 96th part of the earth's distance from the sun; or the same as on a planet that should move round the sun at but a very little more than a diameter of the sun's distance from him, or that would never appear farther from him than about 36 minutes.

Besides Dr. Halley's method for finding the foci, several other authors have written upon this subject; as Mr. Dutton, in his Fluxions; Dr. Gregory, in his Elements of Dioptrics; M. Carré, and Guisnée, in the Mémoires de l'Acad.; Dr. Barrow and Sir I. Newton have also neat and elegant ways of finding geometrically the foci of spherical glasses; which may be seen in Barrow's Optical Lectures.

FOLIATE, a name given by some to a curve of the 2d order, expressed by the equation $x^3 + y^3 = axy$, being one species of defective hyperbolas, with one asymptote, and consisting of two infinite legs crossing each other, forming a kind of leaf. It is the 42d species of Newton's Lines of the 3d order.

FOLKES (MARTIN), an English mathematician, philosopher, and antiquary, was born at Westminster, about 1690; and was greatly distinguished as a member of the Royal Society in London, and of the Academy of Sciences at Paris. He was admitted into the former at 24 years of age; made one of their council two years after; named vice-president by Sir Isaac Newton himself; and, after Sir Hans Sloane, became president. Coins, ancient and modern, were a great object with him; and his last production was a book upon the English Silver Coin, from the Conquest to his own times. He died at London in 1754. Dr. Birch had drawn up materials for a life of Mr. Folkes, which are preserved at large in the Anecdotes of Bowyer, pa. 562. There are many memoirs of Mr. Folkes's in the Philos. Trans. from vol. 30 to vol. 46, both inclusive; viz, 1. Account of an Aurora Borealis, vol. 30.—2. Of Leeuwenhoek's curious Microscope, vol. 32.—3. On the Standard Measures in the Capitol at Rome, vol. 39.—4. Observations of three Mock-suns, vol. 40.—5. On the Fresh-water Polypus, vol. 42.—6. On human bones petrified, vol. 43.—7. On a passage in Pliny's Natural History, vol. 44.—8. On an Earthquake at London, vol. 46.—9. Ditto at Kensington, vol. 46.—10. Ditto at Newton, vol. 46.

FOMAHAUT, or FONAHAUT, a star of the first magnitude in the water of the constellation Aquarius, or in the mouth of the southern fish. Its latitude is $21^{\circ} 6' 28''$ south, and mean longitude to the beginning of 1760, $11^{\circ} 0' 28'' 55''$.

FONTENELLE (BERNARD DE), a celebrated French author, was born at Rouen in 1657, and died in 1736, having nearly attained his 100th year. He was a universal genius; at a very early age he wrote several comedies and tragedies of considerable merit; and he did the same at a very advanced age. Voltaire declares him the most universal genius the age of Lewis the 14th produced; and compares him to lands situated in so happy a climate, as to produce all sorts of fruits. His last comedies, though they showed the elegance of Fontenelle, were, however, little fitted for the stage; he then also produced an Apology

for the Vortices of Descartes; on which Voltaire says, "We must excuse his comedies, on account of his great age; and his Cartesian opinions, as they were those of his youth, when they were universally received all over Europe."

In his poetical performances and Dialogues of the Dead, the spirit of Voiture was discerned, though more extended and more philosophical. His Plurality of Worlds is a work singular in its kind: his design in this was, to present that part of philosophy to view in a gay and pleasing dress.

Fontenelle applied himself also to mathematics and natural philosophy; in which he proved not less successful than he had been in polite literature. Having been appointed perpetual secretary to the Academy of Sciences, he discharged that trust above 40 years with universal applause: his History of the Academy often throws great light on their Memoirs, which are sometimes obscure; and it has been said, he was the first who introduced elegance into the sciences. The Eloges, which he pronounced on the deceased members of the Academy, have this peculiar merit, that they excite a respect for the sciences as well as for the authors.

On the whole, Fontenelle must be considered as the great master of the new art of treating abstract sciences, in a manner that make their study at once easy and agreeable: nor are any of his works of other kinds void of merit. All those talents which he possessed from nature, were assisted by a good knowledge of history and languages: and he perhaps surpasses all men of learning who have not had the gift of invention.

Besides his poetical and theatrical works, with those belles-lettres, &c., he published Éléments de Géométrie de l'Infini, in 4to, 1727; also the Théorie des Tourbillons Cartésiens; and Discours Moraux et Philosophiques. All his different works were collected in eleven volumes 12mo, under the title of *Oeuvres Diverses*.

FOOT, a measure of length, divided into 12 inches, and each inch supposed to contain 3 barley-corns in length. Geometricians divide the foot into 10 digits, and the digit into 10 lines, &c.

It seems this measure has been taken from the length of the human foot; but it is of different lengths in different countries. The Paris royal foot is to the English foot, as 4263 to 4000, or nearly 16 to 15, and exceeds the English by $9\frac{1}{2}$ lines. The ancient Roman foot of the Capitol consisted of 4 palms; equal to 11 inches and $\frac{7}{15}$ English; the Rhinland, or Leyden foot, used by the northern nations, is to the Roman foot, as 19 to 20. For the proportions of the foot of several nations, compared with the English, see the article MEASURE.

Square Foot, is a square whose side is 1 foot, or 12 inches, and consequently its area is 144 square inches.

Cubic Foot, is a cube whose side is one foot, or 12 inches, and consequently it contains 12³ or 1728 cubic inches.

Foot-bank, or Foot-step, in Fortifi. See BANQUETTE.

FORCE, *Vis*, or *Power*, in Mechanics, Philosophy, &c., denotes the cause of the change in the state of a body, with respect to motion, rest, pressure, &c.; as well as its endeavour to oppose or resist any such change. Thus, whenever a body, which was at rest, begins to move; or when its motion is either not uniform, or not direct; the cause of this change in the state of the body, is what is called Force, and is an external cause. Or, while a body remains in the same state, either of rest, or of uniform and rectilinear motion, the cause of its remaining in such state,

is in the nature of the body, being an innate internal force, and is called its *inertia*.

Mechanical forces may be reduced to two sorts; one of a body at rest, the other of a body in motion.

The force, &c, of a body at rest, is that which we conceive to be in it when lying on a plane, or hanging by a rope, or supported by a spring, &c; and this is called Pressure, Tension, Force, or Vis Mortua, Solicitatio, Conatus Movendi, Conamen, &c; which kind of force may be always measured by a weight, viz, the weight that sustains it. To this class of forces may also be referred centripetal and centrifugal forces, though they reside in a body in motion; because these forces are homogeneous to weights, pressures, or tensions of any kind. The pressure, or force of gravity in any body, is proportional to the quantity of matter contained in it.

The force of a body in motion, is a power residing in that body, so long as it continues its motion; by means of which, it is able to remove those obstacles which are opposed to it; or to lessen, destroy, or overcome the force of any other moving body, which meets it in an opposite direction; or to surmount any the largest dead pressure or resistance, as tension, gravity, friction, &c, for some time; but which will be lessened or destroyed by such resistance as lessens or destroys the motion of the body. This is called Vis Motrix, Moving Force, or Motive Force, and by some late writers Vis Viva, to distinguish it from the Vis Mortua before mentioned; and by these appellations, however different, the same thing is understood by all mathematicians; namely, that power which is inherent in a moving body, and which accompanies it in whole, or in part, as long as the body is in motion; so as to displace, or to withstand opposite moving forces, or by which it overcomes any dead resistance, &c, which force is otherwise called Percussion, or Percussive Force, or Momentum.

But concerning the measure of this kind of force, mathematicians have been divided into two parties. It is allowed on both sides, that the measure of this force depends partly on the mass of matter in the body, or its weight, and partly on the velocity of its motion; so that on any increase of either weight or velocity, the moving force becomes greater. It is also agreed, that the velocity being given, or being the same in two moving bodies, their forces are in proportion to their masses or weights. But, when two bodies are equal, and the velocities with which they move are different, they no longer agree about the measure of the moving force.

The Cartesians and Newtonians maintain, that, in this case, the moving force is in proportion simply as the velocity with which a body moves; so that with a double velocity it has a double force, &c: But the Leibnitians assert, that the moving force is proportional to the square of the velocity; so that, with a double velocity a quadruple force will be produced, &c. Or, when the bodies are different, the former hold, that the momentum or moving force of bodies, is in the compound ratio of their weights and velocities: while the latter maintain, that it is in the compound ratio of the weights and squares of the velocities.

Though Leibnitz was the first who expressly asserted, that the force of a body in motion is as the square of its velocity, which was in a paper inserted in the Leipsic Acts for the year 1686, yet it is thought that Huygens led him into that notion, by some demonstrations in the 4th part of his book De Horologio Oscillatorio, relating to the

centre of oscillation, and by his dissertations, in answer to the objections of the abbot Catalan, one of which was published in 1684. This eminent mathematician had demonstrated, that in the collision of two bodies that are perfectly elastic, the sum of the products of each body multiplied by the square of its velocity, was the same after the shock as before (though the same thing is true of the sums of the products of the bodies multiplied simply by their velocities). Now that proposition is so far general as to obtain in all collisions of bodies that are perfectly elastic: and it is also true, when bodies of a perfect elasticity strike any immovable obstacle, as well as when they strike one another; or when they are constrained by any power or resistance to move in directions different from those in which they impel one another. These considerations might have induced Huygens to lay it down as a general rule, that bodies constantly preserve their ascensional force, i.e. the product of their mass by the height to which their centre of gravity can ascend, which is as the square of the velocity; and therefore, in a given system of bodies, the sum of the squares of their velocities will remain the same, and not be altered by the action of the bodies among themselves, nor against immovable obstacles. Leibnitz's metaphysical system led him to think that the same quantity of action or force subsisted in the universe; and finding this impossible, if force were estimated by the quantity of motion, he adopted Huygens's principle of the preservation of the ascensional force, and made it the measure of moving forces. But it is to be observed that Huygens's principle, above-mentioned, is general only when bodies are perfectly elastic: and in some other cases, which Maclaurin has endeavoured to distinguish: showing at the same time that no useful conclusion in mechanics is affected by the disputes concerning the measure of the force of bodies in motion, which have been objected to mathematicians. Analyst, Query 9. See Maclaurin's Fluxions, vol. 2, art. 533; Huygens, Oper. tom. 1, pa. 248; &c.

Leibnitz's principle was adopted by several persons; as Wolfius, the Bernoullis, &c. Mr. Dan. Bernoulli, in his Treatise, has assumed the preservation of the vis ascendentis of Huygens, or, as others express it, the conservatio virium vivarum; and, in Bernoulli's own expression, *aequalitas inter descensum actualem ascensumque potentiale*, as an hypothesis of wonderful use in mechanics. But Dr. Jurin contends, that the conclusions drawn from this principle are often false than true. See De Conservat. Virium Vivarum Dissert: Lond: 1744.

Catalan and Papin answered Leibnitz's paper published in 1686; and from that time the controversy became more general, and was carried on for several years by Leibnitz, John and Daniel Bernoulli, Poleni, Wolfius, Gravescande, Camus, Muschenbroek, &c, on one side; and Pemberton, Eanes, Desaguliers, Dr. S. Clark, M. de Maran, Jurin, Maclaurin, Robins, &c, on the other. See Act. Erud. 1686, 1690, 1691, 1695; Nouv. de la Rep. des Let. Sept. 1686, 1687, art. 2; Comm. Epist. inter Leibn. et Bern. Ep. 24, p. 143; Discours sur les Loix de la Comm. du Mouvement, Oper. tom. 3, & Diss. de vera Notione Virium Vivarum, ib; Act. Petropol. tom. 1, pa. 131, &c; Hydrodynamica, sect. 1; Herman, in Act. Petrop. tom. 1, p. 217, &c, and in Cosmol. Gener.; Graves, in Journ. Lit. et Phys. Elem. Math. 1742, lib. 2, cap. 2 and 3; Memoir. de l'Acad. des Sciences, 1728;

Muschenbr. Int. ad Phil. Nat. 1762, vol. 1, p. 83 &c; &c., in Phil. Trans. No. 371, 375, 376, 396, 400, 401, or my Abridg. vol. 6, p. 570 &c. Mairan in Mem. de l'Acad. des Sc. 1728, Phil. Trans. No. 439, or Abridg. vol. 7, p. 637, Philos. Trans. vol. 43, p. 423 &c.; MacLaurin's Acc. of Newton's Discoveries, p. 117 &c. Flux. ubi supr. and Recueil des Pièces qui ont emporté le Prix &c. tom. 1; Desagul. Course Exp. Philos. vol. 1, p. 393 &c. vol. 2, p. 49 &c.; and Robins's Tracts, vol. 2, p. 135.

The nature and limits of this work will not admit of a full account of the arguments and experiments that have been urged on both sides of the question; but they may be found chiefly in the preceding references. A few of them however may be considered, as follows.

The defenders of Leibnitz's principle, besides the arguments above-mentioned, refer to the spaces that bodies ascend to, when thrown upwards, or the penetrations of bodies let fall into soft wax, tallow, clay, snow, and other soft substances, which spaces are always as the squares of the velocities of the bodies. On the other hand, their opponents retort, that such spaces are not the measures of the force in question, which is rather percussive and momentary, as those above are passed over in unequal times, and are indeed the joint effect of the forces and times.

Desaguilers brings an argument from the familiar experiment of the balance, and the other simple mechanic powers, showing that the effect is in proportion to the velocity multiplied by the weight; for example, 4 pounds being placed at the distance of 6 inches from the centre of motion of a balance, and 2 pounds at the distance of 12 inches; these will have a *vis viva* if the balance be put into a swinging motion. Now it appears that these forces are equal, because, with contrary directions, they soon destroy each other; and they are to each other in the simple ratio of the velocity multiplied by the mass, viz $4 \times 6 = 24$, and $2 \times 12 = 24$ also.

Mr. Robins, in his remarks on J. Bernoulli's treatise, entitled, Discours sur les Loix de la Communication du Mouvement, informs us, that Leibnitz adopted this opinion through mistake; for though he maintained that the quantity of force is always the same in the universe, he endeavours to expose the error of Descartes, who also asserted, that the quantity of motion is always the same; and in his discourse on this subject in the Acta Eruditorum for 1686, he says that it is agreed on by the Cartesians, and all other philosophers and mathematicians, that there is the same force requisite to raise a body of 1 pound to the height of 4 yards, as to raise a body of 4 pounds to the height of 1 yard; but being shown how much he was mistaken in taking that for the common opinion, which would, if allowed, prove the force of the body to be as the square of the velocity it moved with, he afterwards, rather than own himself capable of such a mistake, endeavoured to defend it as true; since he found it was the necessary consequence of what he had once asserted; and he maintained, that the force of a body in motion was proportional to the height from which it must fall, to acquire that velocity; and the heights being as the square of the velocities, the forces would be as the masses multiplied by them; whereas, when a body descends by its gravity, or is projected perpendicularly upwards, its motion may be considered as the sum of the uniform and continual impulses of the power of gravity, during its falling in the former case, and till they extinguish it in the latter.

Thus when a body is projected upwards with a double velocity, these uniform impulses must be continued for a double time, in order to destroy the motion of the body; and hence it follows, that the body, by setting out with a double velocity, and ascending for a double time, must arise to a quadruple height, before its motion is exhausted. But this proves that a body with a double velocity moves with a double force, because it is produced or destroyed by the same uniform power continued for a double time, and not with a quadruple force, though it rises to a quadruple height; so that the error of Leibnitz consisted in his not considering the time, since the velocities alone are not the causes of the spaces described, but the times and the velocities together; yet this is the fallacious argument on which he first built his new doctrine; and those which have been since much insisted on, and derived from the indentings or hollows produced in soft bodies by others falling into them, are much of the same kind. Robins's Tracts, vol. 2, p. 178.

But many of the experiments and reasonings, that have been urged on both sides of this controversy, have been founded in the different senses applied to the term Force. The English and French philosophers, by the word Force, mean the same thing as they do by momentum, motion, quantity of motion, percussion, or instantaneous pressure, which is measured by the mass drawn into the velocity, and may be known by its effect; and when they consider bodies as moving through a certain space, they allow for the time in which that space is described: whereas the Dutch, Italian, and German philosophers, who have espoused the new opinion, mean by the word Force, or Force inherent in a body in motion, that which it is able to produce; or, in other words, the force is always measured by the whole effect produced by the body in motion, until its whole force be entirely communicated or destroyed, without any regard to the time employed in producing this total effect. Thus, say they, if a point runs through a determinate space, and presses with a certain given force, or intensity of pressure, it will perform the same action whether it move fast or slow, and therefore the time of the action in this case ought not to be regarded. Gravesande, Phys. El. Math. § 723—728.

Euler observes, with regard to this dispute concerning the measure of vivid force, or living force, as it is sometimes called, that we cannot absolutely ascribe any force to a body in motion, whether we suppose this force proportional to the velocity, or to the square of the velocity: for the force exerted by a body, striking another at rest, is different from that which it exerts in striking the same body in motion; so that this force cannot be ascribed to any body considered in itself, but only relatively to the other bodies it meets with. There is no force in a body absolutely considered, but its inertia, which is always the same, whether the body be in motion or at rest. But if this body be forced by others to change its state, its inertia then exerts itself as a force, properly so called, which is not absolutely determinable; because it depends on the changes that happen in the state of the body.

A second observation which has been made by some eminent writers, is, that the effect of a shock of two or more bodies, is not produced in an instant, but requires a certain interval of time. Admitting this to be the case, the heterogeneity between the *vis viva* and *morta*, or living and dead force, will vanish; since a pressure may always be assigned, which in the same time, however little,

shall produce the same effect. If then the vis viva be homogeneous to the vis mortua, and having a perfect measure and knowledge of the latter, we need require no other measure of the former than that which is derived from the vis mortua equivalent to it.

Now that the change in the state of two bodies, by their shock, does not happen in an instant, appears evidently from the experiments made on soft bodies: in these, percussion forms a small cavity, visible after the shock, if the bodies have no elasticity. Such a cavity cannot certainly be made in an instant. And if the shock of soft bodies require a determinate time, we must certainly say as much of the hardest, though this time may be so small as to be beyond all our ideas. Neither can an instantaneous shock agree with that constant law of nature, by virtue of which nothing is performed per saltum. But it is needless to insist farther upon this, since the duration of any shock may be determined from the most certain principles.

The force of percussion, resulting from the pressures that bodies exert on each other, while the collision lasts, may be perfectly known, if these pressures be determined for every instant of the shock. The mutual action of the bodies begins the first moment of their contact; and is then least; after which this action increases, and becomes greatest when the reciprocal impressions are strongest. If the bodies have no elasticity, and the impressions they have received remain, the forces will then cease. But if the bodies be elastic, and the parts compressed restore themselves to their former state, then will the bodies continue to press each other till they separate. To comprehend therefore perfectly the force of percussion, it is requisite first to define the time the shock lasts, and then to assign the pressure corresponding to each instant of this time; and as the effect of pressures in changing the state of any body may be known, we may thence come at the true cause of the change of motion arising from collision. The force of percussion therefore is no more than the operation of a variable pressure during a given time; and to measure this force, we must have regard to the time, and to the variations according to which the pressure increases and decreases.

Euler has given some calculations relative to these particulars; and he illustrates their tendency by this instance: Suppose that the hardness of the two bodies, A and B , is equal; and such, that being pressed together with the force of 100lb, the impression made on each is of the depth of $\frac{1}{700}$ th part of a foot. Suppose also that B is fixed, and that A strikes it with the velocity of 100 feet in a second; then, according to this author, the greatest force of compression will be equivalent to 400lb, and this force will produce in each of these bodies an impression equal to $\frac{1}{5}$ of a foot; and the duration of the collision, that is, till the bodies arrive at their greatest compression, will be about $\frac{1}{200}$ of a second. M. Euler, in his calculations, supposes the hardness of a body to be proportional to the force of pressure requisite to make a given impression on it; so that the force by which a given impression is made on a body, is in a compound ratio of the hardness of the body and of the quantity of the impression. But he observes, that regard must be had to the magnitude of the bodies, as the same impression cannot be made on the least bodies as on the greatest, from the defect of space through which their component particles must be driven: he considers therefore only the least impressions, and supposes the bodies of such magnitudes, that the impressions with

respect to them may be considered as nothing. What he supposes concerning the hardness of bodies, neither implies elasticity nor the want of it, as elasticity only produces a restitution of figure and impression when the pressing force ceases; but this restitution need not be here considered. It is also supposed, that the bodies which strike each other, have plane and equal bases, by which they touch each other in the collision; so that the impression hereby made diminishes the length of each body. It is farther to be observed, that in M. Euler's calculations, bodies are supposed so constituted, that they may not only receive impressions from the forces pressing them, but that a greater force is requisite to make a greater impression. This excludes all bodies, fluid or solid, in which the same force may penetrate farther and farther, provided it has time, without ever being in equilibrio with the resistance: thus a body may continually penetrate farther into soft wax, though the force impelling it be not increased: in these, and the like cases, nothing is required but to surmount the first obstacles; which being once done, and the connexion of parts broken, the penetrating body always advances, meeting with the same obstacles as before, and destroying them by an equal force. But this celebrated genius only considers the first obstacles which exist before any separation of parts, and which are doubtless such, that a greater impression requires a greater force. Indeed this chiefly takes place in elastic bodies; but it seems likewise to obtain in all bodies when the impressions made on them are small, and the contexture of their parts is not altered.

These things being premised, let the mass or weight of the body A be expressed in general by a , and let its velocity before the shock be that which it might acquire by falling from the height a . Further, let the hardness of A be expressed by m , and that of B by n , and let the area of the base, on which the impression is made, be cc ; then will the greatest compression be made with the force $\sqrt{\left(\frac{mncc}{m+n}\right) \times aa}$. Therefore, if the hardness of the two bodies, and the plane of their contact during the whole time of their collision be the same, this force will be as \sqrt{aa} , that is, as the square root of the vis viva of the striking body A . And as \sqrt{a} is proportional to the velocity of the body A , the force of percussion will be in a compound ratio of the velocity and of the subduplicate ratio of the mass of the body striking; so that in this case neither the Leibnitzian nor the Cartesian propositions take place. But this force of percussion depends chiefly on the hardness of the bodies; the greater this is, the greater will the force of percussion be. If $m = n$, this force will be as $\sqrt{(acc \times aa)}$, that is, in a compound subduplicate ratio of the vis viva of the striking body, of the hardness, and of the plane of contact. But if m , the hardness of one of the bodies, be infinite, the force of percussion will be as $\sqrt{(acc \times aa)}$; at the same time, if $m = n$, this force will be as $\sqrt{(\frac{1}{2}acc \times aa)}$. Therefore, all other things being equal, the force of percussion, if the striking body be infinitely hard, will be to the force of percussion when both the bodies are equally hard, as $\sqrt{2}$ to 1.

Euler further deduces from his calculation, that the impression received by the bodies A and B will be as follows; viz, as $\sqrt{\frac{n \times aa}{(m+n) \times acc}}$ and $\sqrt{\frac{m \times aa}{(m+n) \times acc}}$ respectively. If therefore the hardness of A , that is m , be infinite, it will suffer no impression; whereas that on B will extend to the

depth of $\sqrt{\frac{Aa}{Ncc}}$. But if the hardness of the two bodies be the same, or $M = N$, they will each receive equal impressions of the depth $\sqrt{\frac{Aa}{2Ncc}}$. So that the impression received by the body B in this case, will be to the impression it receives in the former, as 1 to $\sqrt{2}$.

Euler has likewise considered and computed the case where the striking body has its anterior surface convex, with which it strikes an immovable body whose surface is plane. He has also examined the case when both bodies are supposed immovable; and from his formulæ he deduces the known laws of the collision of elastic and non-elastic bodies. He has also determined the greatest pressures the bodies receive in these cases; and likewise the impressions made on them. In particular he shows, that the impressions received by the body struck, or B , if movable, is to the impression received by the same body when fixed, as \sqrt{B} to $\sqrt{(A+B)}$.

There are several curious, as well as useful observations, in Desaguliers's Experimental Philosophy, concerning the comparative forces of men and horses, and the best way of applying them. A horse draws with the greatest advantage when the line of direction is level with his breast; in such a situation, he is able to draw 200lb for 8 hours a day, walking about $2\frac{1}{2}$ miles an hour. But if the same horse be made to draw 240lb, he can work only 6 hours a day, and cannot go quite so fast. On a carriage indeed, where friction alone is to be overcome, a middling horse will draw 1000lb. But the best way to try the force of a horse, is to make him draw up out of a well, over a single pulley or roller; and in that case, an ordinary horse will draw about 200lb, as before observed.

It is found that 5 men are of equal force with one horse, and can with equal ease push round the horizontal beam of a mill, in a walk 40 feet wide; whereas 3 men will do it in a walk only 19 feet wide.

The worst way of applying the force of a horse is to make him carry or draw up hill: for if the hill be steep, 3 men will do more than a horse, each man climbing up faster with a burden of 100lb weight, than a horse that is loaded with 300lb: a difference which is owing to the position of the parts of the human body being better adapted to climb, than those of a horse.

On the other hand, the best way of applying the force of a horse, is the horizontal direction, in which a man can exert the least force: thus, a man that weighs 140lb, when drawing a boat along by means of a rope coming over his shoulders, cannot draw above 27lb, or exert above 1-7th part of the force of a horse employed to the same purpose; so that in this way the force of a horse is equal to that of 7 men.

The best and most effectual posture in a man, is that of rowing; when he not only acts with more muscles at once for overcoming the resistance, than in any other position; but also as he pulls backwards, the weight of his body assists by way of lever. See Desaguliers's Exp. Philos. vol. 1, pa. 241, where several other observations are made relative to force acquired by certain positions of the body; from which that author accounts for most feats of strength and activity. See also a memoir on this subject by M. Lahire, in the Mem. Roy. Acad. 1729; or in Desaguliers's Exp. &c. pa. 267 &c, who has published a translation of part of it with remarks.

VOL. I.

FORCE is distinguished into motive and accelerative or retardative.

Motive Force, otherwise called Momentum, or Force of Percussion, is the absolute force of a body in motion, &c; and is expressed by the product of the weight or mass of matter in the body multiplied by the velocity with which it moves. But

Accelerative Force, or **Retardive Force**, is that which respects the velocity of the motion only, accelerating or retarding it; and it is denoted by the quotient of the motive force divided by the mass or weight of the body. So, if m denote the motive force, and b the body, or its weight, and f the accelerating or retarding force, then is $f = \frac{m}{b}$.

Again, forces are either constant or variable.

Constant Forces are such as remain and act continually the same for some determinate time. Such, for example, is the force of gravity, which acts constantly the same upon a body while it continues at the same distance from the centre of the earth, or from the centre of force, wherever that may be. In the case of a constant force F acting upon a body b , for any time t , we have these following theorems;

$$f = \text{the constant accelerating force} = F \div b,$$

$$v = \text{the velocity at the end of the time } t,$$

$$s = \text{the space passed over in that time, by the constant action of that force on the body:}$$

and $g = 16\frac{1}{2}$ feet, the space generated by gravity in 1 second, and calling the accelerating force of gravity 1;

$$\text{then is } s = \frac{1}{2}vt = gft^2 = \frac{v^2}{4gf};$$

$$v = 2gft = \frac{2s}{t} = \sqrt{4gs};$$

$$t = \frac{v}{2gf} = \frac{2s}{v} = \sqrt{\frac{s}{gf}};$$

$$f = \frac{v}{2gt} = \frac{s}{gt^2} = \frac{v^2}{4gs}.$$

Variable Forces are such as are continually changing in their effect and intensity; such as the force of gravity at different distances from the centre of the earth, which decreases in proportion as the square of the distance increases. In variable forces, theorems similar to those above may be exhibited by using the fluxions of quantities, and afterwards taking the fluents of the given fluxional equations. And herein consists one of the great excellencies of the Newtonian or modern analysis, by which we are enabled to manage, and compute the effects of all kinds of variable forces, whether accelerating or retarding. Thus, using the same notation as above for constant forces, viz. f the accelerating force at any instant, t the time a body has been in motion by the action of the variable force, v the velocity generated in that time, s the space run over in that time, and $g = 16\frac{1}{2}$ feet; then is

$$s = \frac{v\dot{v}}{2gf} = vt; \quad \dot{v} = \frac{2gfs}{v} = 2gft;$$

$$t = \frac{s}{v} = \frac{v}{2gf}; \quad f = \frac{v\dot{v}}{2gs} = \frac{\dot{v}}{2gi}.$$

In these four theorems, the force f , though variable, is supposed to be constant for the indefinitely small time i ; and they are to be used in all cases of variable forces, as the former ones in constant forces; viz., from the circumstances of the problem under consideration, deduce a general expression for the value of the force f , at any indefinite time t ; then substitute it in one of these theorems,

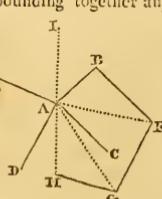

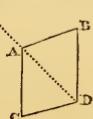

which shall be proper to the case in hand; and the equation thence resulting will determine the corresponding values of the other quantities in the problem. It is also to be observed, that the foregoing theorems equally hold good for the destruction of motion and velocity, by means of retarding or resisting forces, as for the generation of the same by means of accelerating forces. Many applications of these theorems may be seen in my Mathematics, vol. 2.

There are many other denominations and kinds of forces; such as attractive, central, centrifugal, &c, &c; for which see the respective words.

FORCES, *the Equilibrium of*, or *the Composition and Resolution of*, is the conspiring and opposing of two or more forces, so as to balance one another, or to keep in equilibrium the body or point against which they all mutually act.—This equilibrium may be of two, or of three, or of any other number of forces. In the case of two forces only, it is manifest that they must be both equal in quantity, and in directions exactly opposite. For, if they be not directly opposite, the body or point of meeting must move towards one side; and if they be not equal, the greater will prevail over the less, and carry this along with it, with the difference of the two forces. Hence, in all the cases of equilibrium and compositions of three or more forces, the practice must be to compose and reduce all the given forces into one, of a given quantity, and having a given direction; for then taking another, of an equal quantity, and giving it the opposite direction, it will be in equilibrium with all the former given forces, so compounded together.—This will divide into two or three or any other number of forces, as below.

Parallelogram or Triangle of Forces, is when two oblique forces are given, to compound them, in order to find a third force to balance them. So, if \overline{AB} , \overline{AC} be the two given forces, acting at the common point A : draw \overline{BD} parallel and equal to \overline{AC} , and join \overline{AD} ; then is \overline{AD} a force compounded of, and equivalent to, the two given forces \overline{AB} , \overline{AC} . Hence if, in \overline{AD} produced, there be taken $\overline{AE} = \overline{AD}$; then \overline{AE} will be the equivalent balancing force to \overline{AD} , and consequently to the two given forces \overline{AB} , \overline{AC} .—From the circumstance of the two given forces \overline{AB} and \overline{AC} , or \overline{AB} and \overline{BD} , forming, with their equivalent compound \overline{AD} , a triangle $\triangle ABD$, arises the phrase *Triangle of Forces*. And from the circumstance of a parallelogram $\triangle ADC$ being formed by joining \overline{CD} , that the expression *Parallelogram of Forces* has arisen.—From the foregoing method of compounding two forces into one, will easily follow the composition of any number whatever of forces into one; viz, first compound two together, then that and a 3d, next that and a 4th, and so on to the last, whatever their number may be; which may be symmetrically called the *Polygon of Forces*, as below.

Polygon of Forces, is the compounding together any number of forces into one. As, the four forces \overline{AB} , \overline{AC} , \overline{AD} , \overline{AE} , all acting at the point A . From the extremity B of the first, draw \overline{BF} parallel and equal to the 2d \overline{AC} ; then \overline{IG} parallel and equal to the 3d \overline{AD} ; lastly \overline{GH} parallel and equal to the 4th \overline{AE} ; then \overline{AH} , being joined, is the quantity and direction of a single force, which is

compounded of, and equivalent to, the four first given forces; and consequently, taking \overline{AI} opposite and equal to \overline{AB} , then \overline{AI} , balancing \overline{AB} , will also balance all the four given forces. For, by the principle of the Triangle of forces, \overline{AI} and \overline{AC} , or \overline{ER} , are compounded into \overline{AR} ; then \overline{AR} and \overline{AD} , or \overline{FG} , are compounded into \overline{AG} ; lastly \overline{AG} and \overline{AE} , or \overline{GH} , are compounded into \overline{AH} ; and so on, if there be ever so many forces.

Force of Running Water. This must be as the square of its velocity, or as the height from which a heavy body must fall, to acquire that velocity; because the effect is first as the velocity of each particle, and also as the number of them, which is as the velocity again.

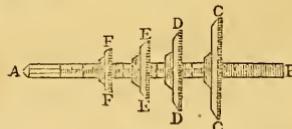

FORCER, in Mechanics, is properly a piston without a valve. For, by drawing up such a piston, the air is drawn up, and the water follows; then pushing the piston down again, the water being prevented from descending by the lower valve, is forced up to any height above, by means of a side branch between the two.—See the ways of making these in Desagulier's Exper. Philos. vol. 2, pa. 161 &c. See also Clare's Motion of Fluids, pa. 60.

FORCING PUMP, one that acts, or raises water, by a forcing piston. See above.

FORELAND, or FORENESS, in Navigation, a point of land jutting out into the sea.

FORELAND, in Fortification, is a small piece of ground between the wall of a place and the moat; called also Berme and Liziere.

FORE-STAFF, an instrument formerly used at sea, for taking the altitudes of the heavenly bodies. It is so called, because the observer, in using it, turns his face forward or towards the object, in contradistinction to the back-staff, with which he turns his back to the object. It is also called the cross-staff, because it consists of several pieces set across a staff. See *Cross-Staff*.

The fore-staff is formed of a straight square staff AB , of about 3 feet long, having each of its four sides graduated like a line of tangents, and four crosses, or vane, FF , EE , DD , CC , sliding upon it, of unequal lengths, the halves of which represent the radii to the lines of tangents on the different sides of the staff. The first or shortest of these vanes, FF , is called the ten cross, or ten vane, and belongs to the 10 scale, or that side of the instrument on which the divisions begin at 3 degrees, and end at 10. The next longer cross, EE , is called the 30 cross, belonging to that side of the staff where the divisions begin at 10 degrees, and end at 30, called the 30 scale. The third vane DD , is termed the 60 cross, and belongs to that side where the divisions begin at 20 degrees, and end at 60. The last or longest vane CC , called the 90 cross, belongs to the side where the divisions begin at 30 degrees, and end at 90.

The chief use of this instrument, is to take the height of the sun, and stars, or the distance between two stars; and the 10, 30, 60, or 90 cross is to be used, according as the altitude is more or less; that is, if the altitude be less than 10 degrees, the 10 cross is to be used; if above 10, but less than 30, the 30 cross is to be used; and so on.

To observe an Altitude with a Fore-staff. Apply the flat end of the staff to the eye, and slide one of the crosses backwards and forwards upon it, till over the upper end of the cross be just seen the centre of the sun or star, and over the under end the extreme horizon; then the degrees and minutes cut by the cross on the side of the staff proper to the vane in use, gives the altitude above the horizon.

In like manner, for the Distance between two luminaries; the staff being set to the eye, bring the cross just to subtend or cover that distance, by having the one luminary just at the one end of it, and the other luminary at the other end of it; and the degrees and minutes, in the distance, will be cut on the proper side of the staff, as before.

FORMULA, a theorem or general rule, or expression, for resolving certain particular cases of some problem, &c. So $s + \frac{1}{2}d$ is a general formula for the greater of two quantities whose sum is s and difference d ; and $\frac{1}{2}s - \frac{1}{2}d$ is the formula, or general value, for the less quantity. Also $\sqrt{(dx - x^2)}$ is the formula, or general value, of the ordinate to a circle, whose diameter is d , and abscissa x .

FORT, a small castle or fortress; or a place of inconsiderable extent, fortified either by nature or art. The fort is usually encompassed with a moat, rampart, and parapet, to secure some high ground, or passage of a river; to make good or strengthen an advantageous post; or to fortify the lines and quarters of a siege.

Field **F**ort, otherwise called Fortin, or Fortlet, and sometimes Sconce, is a small fort, built in haste, for the defence of a pass or post; but particularly constructed for the defence of a camp in the time of a siege, where the principal quarters are usually joined, or made to communicate with each other, by lines defended by fortins and redoubts. Their figure and size are various, according to the nature of the situation, and the importance of the service for which they are intended; but they are most commonly made square, each side about 100 toises, the perpendicular 10, and the faces 25; the ditch about this fort may be 10 or 12 toises wide; the parapet is made of turf, and braised, and the ditch pallisadoed when dry. There may be made a covert-way about this fort, or else a row of pallisades might be placed on the outside of the ditch. Some of these are fortified with bastions, and some with demi-bastions. —A fort differs from a citadel, as this last is erected to command and guard some town; and from a redoubt, as it is closed on all sides, while the redoubt is open on one side.

Royal **F**ort, is one whose line of defence is at least 26 fathoms long.

Star **F**ort, is a sconce or redoubt, constituted by re-entering and salient angles, having commonly five to eight points, and the sides flanking each other.

Forts are sometimes made triangular, only with half bastions; or of various other figures, regular or irregular, and sometimes in the form of a semicircle, especially when they are situated near a river, or the sea, as at the entrance of a harbour, for the convenience of firing at ships quite around them on that side. In the construction of all forts, it should be remembered, that the figure of fewest sides and bastions, that can possibly answer the proposed defence, is always to be preferred; as works on such a plan are sooner executed, and with less expense; besides, fewer troops will serve, and they are more readily brought together in case of necessity.

FORTIFICATION, called also Military Architecture, is the art of fortifying or strengthening a town or other place,

by making certain works around it, to secure and defend it from the attacks of enemies. Fortification has doubtless been practised by all nations, and in all ages; being at first very rude and simple, and varying in its nature and manner, according to the mode of attack, and the weapons made use of. Thus, when villages and towns were first formed, it was found necessary, for the common safety, to encompass them with walls and ditches, to prevent any violence or sudden surprises from their neighbours. When offensive and missile weapons came to be used, walls were raised as a defence against the assailants, and loop-holes or loop-holes made through the same to annoy the enemy, by shooting arrows, &c, through them. But finding that as soon as the enemy got close to the walls, they could no longer be seen or discomfited by the besieged, these added square towers along the wall, at proper distances from each other, so that all the intervening parts of the wall might be seen and defended from the adjacent sides of the towers. However, this manner of inclosing towns was found to be rather imperfect, because there remained still the outer face of the towers which fronted the field, that could not be seen and defended from any other part. To remedy this imperfection, they next made the towers round instead of square, as seeming better adapted both for strength to resist the battering engines, and for being defended from the other parts of the wall. Nevertheless, a small part of these towers still remained unseen, and incapable of being defended; for which reason they were again changed for square ones, as before, but with this difference, that now they presented an angle of the square outwards to the field, instead of a face or side; and thus such a disposition of the works was obtained, as that no part could be approached by the enemy without being seen and attacked.

Since the use of gunpowder, it has been found necessary to add thick ramparts of earth to the walls, and the towers have been enlarged into bastions, as well as many other things added, that have given a new appearance to the whole art of defence, and the name of fortification, on account of the strength afforded by it, which was about the year 1500, when the round towers were changed into bastions.

But notwithstanding all the improvements made in this art since the invention of gunpowder, that of attacking is still superior to it: the superiority of the besiegers' fire, together with the greater number of men, sooner or later compels the besieged to submit. A special advantage was added to the art of attacking by M. Vauban, at the siege of Ath, in the year 1697, viz, in the use of ricochet firing, or at a low elevation of the gun, by which the shot was made to run and roll a great way along the inside of the works, to the great annoyance of the besieged.

The chief authors who have treated of fortification, since it has been considered as a particular art, are the following, and mostly in the order of time: viz, La Treille, Alghisi, Marchi, Pasino, Rainelli, Cataneo, and Speckle, who, as Mr. Robins says, was one of the greatest geniuses that has applied to this art: he was architect to the city of Strasburgh, and died in the year 1589: he published a treatise on fortification in the German language, which was reprinted at Leipsc in 1736. Afterwards, Errard, who was engineer to Henry the Great of France; Stevinus, engineer to the prince of Orange; with Marolais, the chevalier de Ville, Lorini, Cochorn, the count de Pagan, and the marshal de Vauban; which last two noble

authors have contributed greatly to the perfection of the art; besides Scheiter, Mallet, Belidor, Blondel, Muller, Montalambert, &c. Also a list of several works on the art of fortification may be added, as follows: viz. Melder's *Praxis Fortificatoria*: *Les Fortifications du Comte de Pagan*: *L'Ingénieur Parfait du Sieur de Ville*: Sturmy's *Architectura Militaris Hypothetical*: Blondel's *Nouvelle Manière de Fortifier les Places*; the Abbé de Fay's *Véritable Manière de Bien Fortifier*: Vauban's *Ingénieur François*: Cochorn's *Nouvelle Fortification tant pour un Terrain bas et humide, que sec et élevé*: Alexander de Grotte's *Fortification*: Donatus Roselli's *Fortification*: Medrano's *Ingénieur François*: the Chevalier de St. Julian's *Architecture Militaire*: Lansberg's *Nouvelle Manière de Fortifier les Places*: an anonymous treatise in French, called *Nouvelle Manière de Fortifier les Places*, tirée des Méthodes du Chevalier de Ville, &c: Ozanam's *Traité de Fortification*: *Mémoires de l'Artillerie de Surrey de St. Remy*: Muller's treatises of Elementary and Practical Fortification: Rio's *Elem. of Fortification*, printed anonymously: and Montalambert's *Fortification Perpendiculaire*.

Maxims in FORTIFICATION. From the nature and circumstances of this art, certain general rules, or maxims, have been drawn, and laid down. These may indeed be multiplied to any extent, but the principal of them are the following: viz,

1. That the manner of fortifying should be accommodated to that of attacking. So that no one manner can be assured always to hold, unless it be assured that the manner of besieging is incapable of being altered. Also, to judge of the perfection of a fortification, the method of besieging at the time when it was built must be considered.

2. All the parts of a fortification should be equally strong on all sides, where there is equal danger; and they should be able to resist the most powerful machines used in besieging.

3. A fortification should be so contrived, as to be defended with the fewest men possible: which consideration, when well attended to, saves a great deal of expense.

4. That the defendants may be in the better condition, they must not be exposed to the enemies' artillery; but the aggressors must be exposed to theirs.

5. All the parts of a fortification should be so disposed, as that they may defend each other. In order to this, every part ought to be flanked, i.e. seen sideways, capable of being seen and defended from some other part; so that there be no place where an enemy can lodge himself, either unseen, or under shelter.

6. All the champaign around must lie open to the defendants; so that no hill or eminence be allowed, behind which the enemy might shelter himself from the guns of the fortification; or from which he might annoy them, with his own. Hence, the fortress is to command entirely the place surrounding it; and consequently the outworks must all be lower than the body of the place.

7. No line of defence must exceed the point-blank musket-shot, which is from 120 to 150 fathoms.

8. The more acute the angle at the centre, the stronger is the place; as consisting of the more sides, and consequently more defensible.

9. All the defences should be as nearly direct as possible.

10. The works that are most remote from the centre of the place, ought always to be open to those that are nearer. These are the general laws and views of fortification. As

to the particular ones, or such as respect the several members or parts of the work, they are given under those articles respectively.

Fortification is either theoretical or practical.

Theoretical FORTIFICATION, consists in tracing the plans and profiles of a work on paper, with scales and compasses; and in examining the systems proposed by different authors, to discover their advantages and defects.

Practical FORTIFICATION, consists in forming a project of a work according to the nature of the ground, and other necessary circumstances, tracing it on the ground, and executing the project, with all the military buildings; as magazines, storerooms, bridges, &c.

Again, fortification is either defensive or offensive.

Defensive FORTIFICATION, is the art of defending a town that is besieged, with all the advantages the fortification of it will admit. And

Offensive FORTIFICATION, is the same with the attack of a place, being the art of making and conducting all the different works in a siege, in order to gain possession of the place.

FORTIFICATION is also used for the place fortified; or the several works raised to defend and flank it, and keep off the enemy. All fortifications consist of lines and angles, which have names according to their various offices. The principal lines are those of circumvallation, or contravallation, of the capital, &c. The principal angles are those of the centre, the flanking angle, flanked angle, angle of the epaule, &c.

Fortifications are either durable or temporary.

Durable FORTIFICATION, is that which is built and intended to remain a long time. Such are the usual fortifications of cities, frontier places, &c. And a

Temporary FORTIFICATION, is that which is erected on some emergent occasion, and only for a short time. Such are field-works, thrown up for the seizing and maintaining a post, or passage; those about camps, or in sieges; as circumvallations, contravallations, redoubts, trenches, batteries, &c.

Again, fortifications are either regular or irregular.

Regular FORTIFICATION, is that in which the bastions are all equal; or which is built in a regular polygon, the sides and angles of which are usually about a musket-shot from each other. A regular fortification, having the parts all equal, has the advantage of being equally defensible; so that there are no weak places.

Irregular FORTIFICATION, is that in which the bastions are unequal, and unlike; or the sides and angles not all equal, and equidistant. In an irregular fortification, the defence and strength being unequal, it is necessary to reduce the irregular shape of the ground, as near as may be, to a regular figure: i.e. by inscribing it in an oval, instead of a circle; so that one half may be similar and equal to the other half.

Marine FORTIFICATION, is sometimes used for the art of raising works on the sea-coast, &c, to defend harbours against the attacks of shipping.—See a neat treatise on Marine Fortification, at the end of Robertson's Elements of Navigation.

There are many modes of fortification, &c, that have been much esteemed and used; a small specimen of a comparative view of the principal of these, is represented in plate xii, viz, those of Count Pagan, and Mess. Vauban, Cochorn, Belidor, and Blondel; the explanation of which is as follows:

1. *Pagan's System.*

- A** Half bastions.
- B** Ravelin and counterguard.
- C** Counterguards before the bastions.
- D** The ditch.
- E** The glacis.
- G** The place of arms.
- H** Retired flanks.
- a** Line of defence.

2. *Vauban's System.*

- b** Angle of the bastion, or flanked angle.
- c** Angle of the shoulder.
- d** Angle of the flank.
- e** Salient angle.
- f** Face of the bastion.
- g** The flank.
- h** The curtain.
- i** Tenailles.
- k** Traverses in the covert way.

3. *Cochorn's System.*

- 1** Concave flanks.
- 2** The curtains.
- 3** Redoubts in the re-entering angles
- 4** Traverses.
- 5** Stone lodgments.
- 6** Round flanks.
- 7** Redoubt.
- 8** Coffers planked on the sides, and above covered overhead with a foot of earth.

4. *Belidor's System.*

- I** Cavaliers.
 - K** Rams-horns, or Tenailles.
 - L** Retrenchments within the detached bastions.
 - M** Circular curtain.
 - N** The ravelin.
 - P** Lunettes with retired batteries.
 - Q** Redoubt.
 - R** Detached redoubt.
 - s** An arrow.
 - T** Small traverses.
5. *Blondel's System.*
- l** Retired battery.
 - m** Lunettes.
 - n** Ravelin, with retired bastion.
 - o** Orillons.

Another, or new method of fortification has lately been proposed by M. Montalambert, called Fortification Perpendiculaire, because the faces of the works are made by a series of lines running zigzag perpendicular to each other.

Profile of a Fortification, is a representation of a vertical section of a work; serving to show those dimensions which cannot be represented in plans, and are necessary in the building of a fortification. The names and dimensions of the principal parts are as follow (see fig. 8, p. ix), where the numbers or dimensions are all expressed in feet.

- AB** The level of the ground plane;
- AC = 27**;
- CD = 18**, and **cw = 16½**; also **DN** is parallel to **AB**;
- DE = 30**;
- EF = 2**, **FG = 3**, **GH = 3**, **HI = 4½**, **IL = 1½**;
- LK = 18**, **KM = 2½**, **NP = 36**, **NO = 5**, **PR = 7**;
- RS = 1**, **ST = 12** or **18**, **OV = 9**, **vn = 120**;
- mz = 3**, **nu = 3**, **mc = 30**, **cd = 2**;
- de = 3**, **cf = 3**, **fl = 4½**, **rg = 120**, **lh = 1**;
- aw** The interior talus or slope of the rampart;

- WE, or DE**, The terre-plein of ditto;
- FG** The talus, **gn** the upper part, of the banquette;
- HL** The interior side of the parapet;
- LM** The upper part of ditto;
- N** The cordon of 1 foot radius;
- NP** The depth, and **rn** the breadth of the ditch;
- OQ** Interior side of revetement;
- NR** The scarp or exterior side of ditto;
- ST** The depth of the foundation;
- YZ** Revetement of the parapet;
- nu** The counterscarp;
- mc** The covert-way;
- ce** Talus of the banquette;
- ef** The upper part of ditto;
- fh** Parapet of the covert-way;
- hg** The glacis.

Other sections are at fig. 2, pl. 14.

FORTIFIED Place, a fortress, or fortification, i. e. a place well flanked, and sheltered with works.

FORTIN, or *Forlet*, a diminutive of the word *Fort*, meaning a small fort, or sconce, called also *Field Fort*.

Star FORTIN, is that whose sides flank each other, &c.

FORTRESS, the same as *Fort*, or a *Fortification*.

FOSTER (*SAMUEL*), an English mathematician, was born in Northamptonshire, and admitted a sizer at *Emmanuel-college Cambridge* in 1616. He took the degree of bachelor of arts in 1619, and of master in 1623. He applied early to the mathematics, and attained a great proficiency in them, of which he gave the first specimen in 1624, in a treatise on the use of the quadrant.

On the death of Mr. Gellibrand, our author was chosen to succeed him, in 1636, as astronomy-professor in *Gresham-college, London*. He quitted it again however the same year, though for what reason does not appear, and was succeeded by Mr. Mungo Murray, professor of philosophy at *St. Andrews in Scotland*. But this gentleman marrying, the professorship again became vacant, and Mr. Foster was re-elected in 1641.

Mr. Foster was one of those gentlemen who held private meetings for cultivating philosophy and useful knowledge, which afterwards gave rise to the Royal Society. In 1646, Dr. Wallis, who was one of those associating gentlemen, received from Mr. Foster a theorem *De triangulo sphærico*, which he published in his *Mechanics*. Neither was it only in this branch of science that he excelled, but he was also well versed in the ancient languages; as appears from his revising and correcting the Lemmata of Archimedes, which had been translated into Latin from an Arabic manuscript by Mr. John Greaves. He made also several curious observations on eclipses of the sun and moon, in various places; and was particularly noted for inventing, as well as improving, astronomical and other mathematical instruments. After a long declining state of health, he died at *Gresham-college* in 1652.

His printed works are as follow; of which the first two articles were published before his death, and the rest of them after it.

1. *The Description and Use of a small Portable Quadrant, for the easy finding the Hour of Azimuth*; 4to, 1624. Originally published at the end of *Gunter's Description of the Cross-Staffe*, as an appendix to it.

2. *The Art of Dialling*; 4to, 1638. Reprinted, with additions, in 1675.

3. *Posthumus Fosteri*; by Wingate; 4to, 1652.

4. *Four Treatises of Dialling*; 4to, 1654.

5. *Miscellanies, or Mathematical Lucubrations*. Pub-

lished by John Twysden, with additions of his own; and an appendix by Leybourne; folio, 1659.

6. The Sector altered, and other Scales added, &c. Published by Leybourne in 1661, in 4to.

There have been two other persons of the same name, who have published some mathematical pieces. The first was,

FOSTER (WILLIAM), a disciple of Mr. Oughtred, and afterwards a teacher of the mathematics in London. He distinguished himself by a book, which he dedicated to Sir Kenelm Digby, entitled, *The Circles of Proportion, and the Horizontal Instrument, &c;* 4to, 1633.—The other was,

FOSTER (MARK), who lived later in point of time than either of the other two, and published a treatise entitled, *Arithmetical Trigonometry: being the Solution of all the usual Cases in Plain Trigonometry by Common Arithmetic*, without any tables whatsoever. 12mo, 1690.

FOUNDATION, that part of a building which is underground: or the mass which supports a building, and on which it stands: or it is the coffer or bed dug below the level of the ground, to raise a building on.

FOUNTAIN, in Philosophy, a spring or source of water rising out of the ground. See SPRING.

FOUNTAIN, or Artificial Fountain, in Hydraulics, a machine or contrivance by which water is violently spouted or thrown up; called also *jet d'eau*.

There are various kinds of artificial fountains, but all formed by a pressure of one kind or other, on the water &c, viz, either the pressure or weight of a head of water, or the pressure arising from the spring and elasticity of the air, &c. When these are formed by the pressure of a head of water, or any other fluid of the same kind with the fountain, or jet, &c, then will this spout up nearly to the same height as that head, abating only a little for the resistance of the air, with that of the adutage &c, in the fluid's rushing through; but, when the fountain is produced by any other force than the pressure of a column of the same fluid with itself, it will rise to such a height as may be nearly equal to the altitude of a column of the same fluid whose pressure is equal to the given force that produces the fountain.

To Construct an Artificial Fountain, playing by the pressure of the water. This is to be effected by making a close connexion between a head or elevated piece of water, and the lower place, where the fountain is to play; which may be done in this manner: Having a head of water, naturally, or, for want of such, make an artificial one, raising the water by pumps, or other machinery: from this head convey the water in close pipes, in any direction, down to the place where the fountain is to play; and there let it issue through an adutage or small hole, turned upwards, by which means it will spout up nearly as high as the head of the water it comes from, as above mentioned.

To Construct an Artificial Fountain, playing by the spring or elasticity of the air. A vessel proper for a reservoir, as AB, fig. 4, plate x, is provided either of metal, or glass, or the like, ending in a small neck c, at the top: through this neck is put a tube cd, till the lower end come near the bottom of the vessel, this being about half full of water. The neck is so contrived, that a syringe, or condensing pipe, may be screwed on the tube; by means of which a large quantity of air may be intruded through the tube into the water, out of which it will disengage itself, and emerge into the vacant part of the vessel, and lie over the surface of the water cd.

Now, the water in the vessel being thus pressed by the air, which is, for ex. double the density of the external air; and the elastic force of air being proportional to its density, or to its gravitating force, the effect will be the same, as if the weight of the column of air, over the surface of the water, were double that of the column pressing in the tube; so that the water must be forced upwards through the tube, when the syringe is removed, with a force equal to the excess of pressure of the included air, above that of the external, that is, in this case, with a force equal to the pressure of an entire column of the atmosphere; which being equal to the pressure of a column of 33 or 34 feet of water, it follows that the fountain will play to nearly 33 or 34 feet high.

These aerial or aquatic fountains may be applied in different ways, so as to exhibit various appearances; and from these alone arises the greatest part of artificial water-works: even the engine for extinguishing fire, is a fountain playing by the force of confined air.

A Fountain spouting the water in various directions. Suppose AB the vertical tube, or spout, in which the water rises, (fig. 5, pl. x): into this let several other tubes be fitted; some horizontal, others oblique, or inclining, or reclining, &c, as at E, B, L, N, P, &c. Then, as all water retains the direction of the aperture through which it comes, that issuing through A will rise perpendicularly; and the rest will tend different ways, describing arches of different magnitudes.

Or thus: Suppose the vertical tube AB (fig. 6) through which the water rises, to be stopped at the top, as in A; and, instead of pipes or cocks, let it be only perforated with small holes all around, or only half round its surface: then will the water spout out, in all directions, through the little holes, to different distances.

And hence, if the tube AB be about the height of a man, and having a turn-cock at C; on opening this cock, the spectators will be sprinkled unexpectedly with a shower.

FOUNTAIN playing by drawing the breath. Suppose AB (fig. 8, plate viii), a globe of glass, or metal, in which is fitted a tube CD, having a small orifice in C, and reaching almost to D, the bottom of the globe. Then if the air be sucked, or drawn with the mouth, out of the tube CD, and the orifice C be immediately immersed under cold water, the water will ascend through the tube into the sphere. Thus proceeding, by repeated exsuctions, till the vessel be above half full of water; then applying the mouth to C, and blowing air into the tube, on removing the mouth, the water will spout forth.—Or, if the globe be put into hot water, the air being thus rarefied, will make the water spout before.

And this kind of fountain is called Pila Heronis, or Hero's Ball, from the name of its inventor.

FOUNTAIN, whose stream raises and plays a brass ball. Provide a hollow brass ball A (fig. 9, pl. viii), made very thin, that its weight may not be too great for the force of the water; and let the tube BC, through which the water rises, be exactly perpendicular to the horizon. Then the ball, being laid in the bottom of the cup or basin B, will be carried up by the stream, and sustained at a considerable height, playing a little up and down.

FOUNTAIN which spouts water in form of a shower. To the tube in which the water is to rise, fit a spherical or lenticular head AB (fig. 1, pl. xiii) made of a plate of metal, and perforated at the top with a great number of small holes. The water rising violently towards AB, will be

there divided into innumerable little threads, and afterwards broken, and dispersed into the finest drops.

FOUNTAIN which spreads the water in form of a table-cloth. To the tube *AB* (fig. 2, pl. xiii) solder two spherical segments, *c* and *d*, almost touching each other, with a screw *e*, to contract or amplify the interstice or chink, at pleasure. Some choose to make a smooth and even cleft, in a spherical or lenticular head, fitted upon the tube. The water spouting through this chink or cleft will expand itself like a cloth.—And thus, the fountain may be made to spout out in the figure of men, or other animals.

FOUNTAIN, which, when it has done spouting, may be turned like an hour-glass. Provide two glasses, *A* and *B*, (fig. 3, pl. xiii) to be so much the larger as the fountain is to play the longer, and placed at so much the greater distance from each other as the water is desired to spout the higher. Let *CDE* be a crooked tube, furnished in *E* with a jet; and *GHI* another bent tube, furnished with a jet in *I*: *GF* and *KL* are to be other lesser tubes, open at both ends, and reaching near the bottom of the vessels *A* and *B*, to which the tubes *CD* and *GH* are likewise to reach.

Now if the vessel *A* be filled with water, it will descend through the tube *CD*; and it will spout up through the jet *E*, by the pressure of the column of water *CD*. But unless the pipe *GF* were open at *G*, to let the air run up to *R*, and press at the top of the surface of the water in the cavity *A*, the water could not run down and spout at *E*. After its fall again, it will sink through the little tube *KL*, into the vessel *B*, and expel the air through the tube *GI*. At length, when all the water is emptied out of the vessel *A*, by turning the machine upside-down, the vessel *B* will be the reservoir, and make the water spout up through the jet *I*, the pipe *KL* supplying *B* with air to let the water descend in the direction *GHI*.

Hence, if the vessels *A* and *B* contain just as much water as will be spouted up in an hour's time, we shall have a spouting clepsydra, or water-clock; which may be graduated or divided into quarters, minutes, &c.

FOUNTAIN of Command. This depends on the same principles with those of the former: *CAE* (fig. 4, pl. xiii) is a vessel of water secured against the entrance of the air, except through the pipe *GF*, when the cock *C*, by which it is filled, is shut. There is another pipe *EDHB*, going from the bottom of the water to the jet *B* in the bason *DB*; but this is stopped by the cock *H*. At the lowest part of the bason *DB*, there is a small hole at *I*, to let the water of the bason *DB* run into the bason *GN* under it; there also is a small triangular hole or notch, in the bottom of the pipe *FG*, at *G*. Turn the cock *H*, and the fountain will play for some time, then stop, then play again alternately for several times together. When those times of playing and stopping are known before-hand, you may command the fountain to play or stop; whence its name. The cause of this phenomenon is as follows: the water coming down the pipe *EDHB*, would not come out at *B*, if the air *ss*, above the water, were not supplied as it dilated: now it is supplied by the pipe *GR*, which takes it in at the notch *G*, and delivers it out at *F*; but after some time the water, which was spouted out at *B*, falling down into the bason *DB*, rises high enough to come above the notch *G*, which stops the passage of the air; so that the air *ss*, above the water in the vessel *CAE*, wanting a supply, cannot sufficiently press, and the fountain ceases playing.—But when the water of *DB* has run down into the lower bason *GN*, through the hole *I*, till it falls below

the top of the notch *G*, the air runs up into the upper receptacle, and supplies that at *ss*, and the fountain plays again. This is seen a little before-hand, by a skin of water on the notch *G*, before the air finds a passage, and then you may command the fountain to play. It is evident that the hole *I* must be less than the hole of the jet, or else all the water would run out into the lower bason, without rising high enough to stop the notch *G*.

FOUNTAIN that begins to play upon the lighting of candles, and ceases as they go out. Provide two cylindrical vessels, *AB* and *CD*, (fig. 7, pl. xiii) connect them by tubes, open at both ends, *KL*, *BE*, &c, so that the air may descend out of the higher into the lower: to the tubes solder candlesticks, *H*, &c, and to the hollow cover of the lower vessel *CS*, fit a little tube or jet, *FG*, furnished with a cock *C*, and reaching almost to the bottom of the vessel. In *C* let there be an aperture, furnished with a screw, by which water may be poured into *CD*. Then, on lighting the candle *H*, &c, the air in the contiguous tubes becoming rarefied by the heat, the water begins to spout through *GF*.

By the same contrivance may a statue be made to shed tears on the shining of the sun, or on lighting a candle, &c: all that is here required, being only to lay tubes from the cavity where the air is rarefied, to some other cavities placed near the eyes, full of water.

A FOUNTAIN by the Rarefaction of the Air, may be made in the following manner: Let *AB* and *CD*, fig. 5, pl. xiii, be two pipes fixed to a brass head *C*, made to screw into a glass vessel *E*, which having a little water in it, is inverted till the pipes are screwed on; then reverting it suddenly, so as to put *A*, the lower end of the spouting pipe *AB*, into a jar of water *A*, and the lower end of the descending pipe *CD*, into a receiving vessel *D*, the water will spout up from the jar *A* into the tall glass vessel *E*, from which it will go down at the mouth *C*, through *CD*, into the vessel *D*, till the water is wholly emptied out of *A*, making a fountain in *E*, into *D*. The reason of the play of the fountain is this: the pipe *CD*, being 2 feet 9 inches long, lets down a column of water, which rarefies the air 1-12th part in the vessel *E*, where it presses against the water spouting at *B* with 1-12th of the force by which the water is pushed up at the hole *A*, by the pressure of the common air on the water in the vessel *A*; so that the water spouts up into *E*, when the air is rarefied 1-12th, with the difference of the pressure of the atmosphere, and the aforementioned rarefied air; i.e. of 33 to $2\frac{1}{2}$, or of 12 to 1. This would raise the water 2 feet 9 inches; but the length of the pipe *AB*, of 9 inches, being deducted, the jet will only rise 2 feet. This, says Desaguliers, may be called a syphon fountain, where *AB* is the driving leg, and *CD* the issuing leg.

FOUNTAIN of Hero of Alexandria, so called; because it was contrived by him. In the second fountain above described, the air is compressed by a syringe; in this, (see fig. 6, pl. xiii) the air, being only compressed by the concealed fall of water, makes a jet, which, after some continuance, is considered by the ignorant as a perpetual motion; because they imagine that the same water which fell from the jet rises again. The boxes *CE* and *DYX*, being close, we see only the bason *ABW*, with a hole at *w*, into which the water spouting at *B* falls; but that water does not come up again; for it runs down through the pipe *WX* into the box *DYX*, whence it drives out the air, through the ascending pipe *YZ*, into the cavity of the box *CE*, where, pressing upon the water that is in it, it forces it out through the spouting-pipe *OB*, as long as there is any water in *CE*; so that this

whole play is only while the water contained in $C E$, having spouted out, falls down through the pipe $W X$, or of the boxes $C E$ and $D Y$ above one another; the height of the water, measured from the basin $A B W$ to the surface of the water in the lower box $D Y X$, is always equal to the height measured from the top of the jet to the surface of the water in the middle cavity at $C E$. Now, since the surface $C E$ is always falling, and the water in $D Y$ always rising, the height of the jet must continually decrease, till it is shorter by the depth of the cavity $C E$, which is emptying, added to the depth of the cavity $D Y$, which is always filling; and when the jet is fallen so low, it immediately ceases. The air is represented by the points in this figure.

To prepare this fountain for playing, which should be done unobserved, pour in water at W , till the cavity $D Y X$ is filled; then invert the fountain, and the water will run from the cavity $D Y X$ into the cavity $C E$, which may be known to be full, when the water runs out at B held down. Set the fountain up again, and, to make it play, pour in about a pint of water into the basin $A B W$; and as soon as it has filled the pipe $W X$ it will begin to play, and continue as long as there is any water in $C E$. You may then pour back the water left in the basin $A B W$, into any vessel, and invert the fountain, which being set upright again, will be made to play, by putting back the water poured out into $A B W$; and so on as often as you please.

Spouting Fountain, or Jet d'Eau, is any fountain whose water is darted forth impetuously through jets, or ajutages, and returns in form of rains, nets, folds, or the like.

Fountain-Pen, is a pen contrived to contain a quantity of ink, and let it flow very gently, so as to supply the writer a long time without the necessity of taking fresh ink.

The fountain-pen, represented fig. 8, pl. xiii., consists of divers pieces of metal, r , e , n , the middle piece r carrying the pen, which is screwed into the inside of a small pipe; and this again is soldered into another pipe of the same size as the lid e ; in which lid is soldered a male screw, for screwing on the cover; as also for stopping a little hole at the place, and hindering the ink from passing through it: at the other end of the piece r is a small pipe, on the outside of which may be screwed the top cover n . A porteraion goes in the cover, to be screwed into the last-mentioned pipe, to stop the end of the pipe into which the ink is to be poured by a funnel.

To use the pen, the cover e must be taken off, and the pen a little shaken, to make the ink run more freely.

FOURTH, in Music, one of the harmonic intervals, or concords. It consists in the mixture of two sounds, which are in the ratio of 4 to 3; i.e. of two sounds produced by chords, whose lengths are to each other as 4 to 3.

FRACTION, or *Broken Number*, in Arithmetic and Algebra, is a part, or some parts, of another number or quantity considered as a whole, but divided into a certain number of parts; as 3-4ths, which denotes 3 parts out of 4, of any quantity. Fractions are usually divided into vulgar, decimal, duodecimal, and sexagesimal. For the last three sorts, see the respective words.

Vulgar Fractions, called also simple *Fractions*, are usually denoted by two numbers, the one set under the other, with a small line between them: thus $\frac{3}{4}$ denotes the fraction three-fourths, or 3 parts out of 4, of some whole considered as divided into 4 equal parts.

The lower number 4, is called the Denominator of the fraction, showing into how many parts the whole or inte-

ger is divided; and the upper number 3, is called the Numerator, and shows how many of those equal parts are contained in the fraction. Hence it follows that as the numerator is to the denominator, so is the fraction itself, to the whole of which it is a fraction; or as the denominator is to the numerator, so is the whole or integer, to the fraction: thus, the integer being denoted by 1, as $4:3::1:\frac{3}{4}$ the fraction.—And hence there may be innumerable fractions all of the same value, as there may be innumerable quantities all in the same ratio, viz, of 4 to 3; such as 8 to 6, or 12 to 9, &c. So that if the two terms of any fraction, i.e. the numerator and denominator, be either both multiplied or both divided by any number, the resulting fraction will still be of the same value: thus, $\frac{2}{3}$ or $\frac{6}{9}$ or $\frac{12}{18}$ &c, are all of the same value with each other.

Fractional expressions are usually distinguished into proper and improper, simple and compound, and mixt numbers.

Proper Fraction, is that whose numerator is less than the denominator; and consequently the fraction is less than the whole or integer; as $\frac{3}{4}$.

Improper Fraction, is when the numerator is either equal to, or greater than, the denominator; and consequently the fraction either equal to, or greater than, the whole integer, as $\frac{4}{3}$, which is equal to the whole; or $\frac{5}{2}$, which is greater than the whole.

Simple Fractions, or *Single Fractions*, are such as consist of only one numerator, and one denominator; as $\frac{2}{3}$ or $\frac{4}{5}$, or $\frac{22}{7}$.

Compound Fractions are fractions of fractions, and consist of several fractions, connected together by the word of: as $\frac{3}{4}$ of $\frac{2}{3}$, or $\frac{1}{2}$ of $\frac{3}{4}$, of $\frac{2}{3}$.

A Mixt Number consists of an integer and a fraction together: as $1\frac{1}{2}$, or $12\frac{2}{3}$.

The arithmetic of fractions consists in the reduction, addition, subtraction, multiplication, and division of them.

Reduction of Fractions is of several sorts; as 1. To reduce a given whole number into a fraction of any given denominator. Multiply the given integer by the proposed denominator, and the product will be the numerator. Thus, it is found that $3 = \frac{6}{2}$, and $5 = \frac{25}{5}$.

If no denominator be given, or it be only proposed to express the integer fraction-wise, or like a fraction; set 1 beneath it, for its denominator. So $3 = \frac{3}{1}$, and $5 = \frac{5}{1}$, and $7 = \frac{7}{1}$.

2. To reduce a given fraction to another fraction equal to it, that shall have a given denominator. Multiply the numerator by the proposed denominator, and divide the product by the former denominator, then the quotient set over the proposed denominator will form the fraction required. Thus, if it be proposed to reduce $\frac{3}{4}$ to an equal fraction whose denominator shall be 8; then $3 \times 8 = 24$, and $24 \div 4 = 6$ the numerator, so that $\frac{6}{8}$ is the fraction sought, being $= \frac{3}{4}$, and having 8 for its denominator.

3. To abbreviate, or reduce fractions to lower terms. Divide their terms, i.e. the numerator and denominator, by any number that will divide them without a remainder, so shall the quotients be the corresponding terms of a new fraction, equal to the former, but in smaller numbers. In like manner abbreviate these new terms again, and so on till there be no number greater than 1 that will divide them without a remainder, and then the fraction is said to be in its least terms. Thus, to abbreviate $\frac{15}{20}$; first divide both terms by 5, and the fraction becomes $\frac{3}{4}$; next divide these by 3, and it becomes $\frac{1}{4}$: so that $\frac{15}{20} = \frac{3}{4} = \frac{1}{4}$, in its least terms.

To reduce a fraction at once to its lowest terms; divide both numerator and denominator by their greatest common measure: to find which, see the article **COMMON MEASURE**.

It may further be observed, that a proper fraction is in its lowest terms, when the numerator and denominator are not both divisible by their difference, or by some submultiple of their difference, without a remainder.

4. To reduce fractions to other equivalent ones of the same denominator. Multiply each numerator, separately taken, by all the denominators except its own, and the products will be the new numerators; then multiply all the denominators continually together, for the common denominator, to these numerators. Thus, $\frac{2}{3}$ and $\frac{3}{4}$ reduce to $\frac{12}{15}$ and $\frac{15}{20}$; and $\frac{2}{3}$, $\frac{3}{4}$, and $\frac{4}{5}$ reduce to $\frac{40}{60}$, $\frac{45}{60}$, and $\frac{48}{60}$.

5. To find the value of a fraction, in the known parts of its integer. Multiply always the numerator by the number of parts of the next inferior denomination, and divide the : 6) 180 (11s products by the denominator. Do the same with the remainders through all the denominations. So to find the value of $\frac{9}{16}$ of a pound sterling; multiply 9 by 20 for shillings, and dividing by 16, gives 11 for the shillings; then multiply the remainder 4 by 12 pence, and dividing by 16 gives 3 for pence: so that 11s. 3d. is the value of $\frac{9}{16}$ l.

6. To reduce a mixt number to an equivalent improper fraction. Multiply the integer by the denominator, and to the product add the numerator, for the new numerator, to be set over the same denominator as before. Thus $3\frac{5}{8}$ becomes $\frac{29}{8}$.

7. To reduce an improper fraction to its equivalent whole or mixed number. Divide the numerator by the denominator; so shall the quotient be the integral part, and the remainder set over the denominator will form the fractional part of the equivalent mixed number. Thus $\frac{29}{8}$ reduces to $3\frac{5}{8}$, and $\frac{29}{4}$ = 8.

8. To reduce a compound fraction to a simple one. Multiply all the numerators together for the numerator, and all the denominators together for the denominator, of the simple fraction sought. Thus, $\frac{1}{2}$ of $\frac{2}{3}$ = $\frac{1}{3}$, and $\frac{2}{3}$ of $\frac{4}{5}$ of $\frac{5}{6}$ = $\frac{5}{9}$.

To reduce a vulgar fraction to a decimal. See DECIMALS. And for several other particulars concerning Reduction, as well as the other operations in fractions; see my Arithmetic.

Addition of FRACTIONS. First reduce the fractions to their simplest form, and reduce them also to a common denominator, if their denominators are different; then add all the numerators together, and set the sum over the common denominator, for the sum of all the fractions required.

$$\text{Thus, } \frac{2}{3} + \frac{3}{5} = \frac{5}{3} = 1;$$

$$\text{And } \frac{2}{7} + \frac{3}{4} = \frac{8}{28} + \frac{21}{28} = \frac{29}{28} = 1\frac{1}{28}.$$

Subtraction of FRACTIONS. Reduce the fractions the same as for addition; then subtract the one numerator from the other, and set the difference over the common denominator.

$$\text{So } \frac{2}{3} - \frac{3}{5} = \frac{4}{15};$$

$$\text{And } \frac{2}{7} - \frac{3}{4} = \frac{8}{28} - \frac{21}{28} = \frac{15}{28}.$$

To Multiply FRACTIONS together. Reduce them all to the form of simple fractions, if they be not so; then multiply all the numerators together for the numerator, and all the denominators together for the denominator of the product sought.

VOL. I.

$$\text{Thus } \frac{2}{3} \times \frac{4}{5} = \frac{8}{15};$$

$$\text{And } \frac{2}{3} \times \frac{3}{4} \times \frac{15}{16} = \frac{15}{48} = \frac{5}{16} = \frac{1}{2}.$$

To Divide FRACTIONS. Divide the numerator by the numerator, and the denominator by the denominator, if they will exactly divide. Thus, $\frac{8}{15} \div \frac{3}{4} = \frac{8}{15} \times \frac{4}{3} = \frac{32}{45}$.

But if they will not divide without a remainder, then multiply the dividend by the reciprocal, or the divisor, that is, by the fraction obtained by inverting or changing its terms. Thus, $\frac{8}{15} \div \frac{3}{4} = \frac{8}{15} \times \frac{4}{3} = \frac{32}{45}$.

Algebraic FRACTIONS, or FRACTIONS in Species, are exactly similar to vulgar fractions, in numbers, and all the operations are performed exactly in the same way; therefore the rules need not be repeated, and it may be sufficient here to set down a few examples to the foregoing rules. Thus,

$$1. \text{ The fraction } \frac{ab}{bc} \text{ abbreviates to } \frac{a}{c}.$$

$$2. \frac{6a^2 - 9ax^2}{6a^2 + 3ax} = \frac{2a^2 - 3x^2}{2a + x}, \text{ by dividing by } 3a.$$

$$3. \frac{a^2 - ax^2 + ax^2 - x^2}{a^2 - ax^2} = \frac{a^2 + x^2}{a}, \text{ by dividing by } a - x.$$

See COMMON MEASURE.

4. $\frac{a}{b}$ and $\frac{c}{d}$ become $\frac{ad}{bd}$ and $\frac{bc}{bd}$, when reduced to a common denominator.

$$5. \frac{a}{b} + \frac{c}{d} = \frac{ad + bc}{bd}.$$

$$6. \frac{a}{x} - \frac{b}{z} = \frac{az - bx}{xz}.$$

$$7. \frac{a}{b} \times \frac{c}{d} = \frac{ac}{bd}.$$

$$8. \frac{a}{z} \div \frac{b}{x} = \frac{a}{x} \times \frac{z}{b} = \frac{az}{bx}.$$

Continued FRACTION, is used for a fraction whose denominator is an integer with a fraction, which latter fraction has for its denominator an integer and a fraction, and the same for this last fraction again, and so on, to any extent, whether supposed to be infinitely continued, or broken off after any number of terms. Euler, Analys. Inf. vol. 1, p. 295.

$$\text{or } \frac{2}{3} + \frac{1}{2} + \frac{1}{4},$$

$$\text{or } \frac{2}{3} + \frac{1}{3} + \frac{3}{4} + \frac{3}{4} + \frac{4}{5} + \&c.$$

Or, using letters instead of numbers,

$$\frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \frac{1}{d} + \frac{1}{e} + \&c. \quad \text{or } \frac{a}{a} + \frac{b}{a} + \frac{c}{a} + \frac{d}{a} + \frac{e}{a} + \&c.$$

When these series are not far extended, it is not difficult to collect them by common arithmetic.

Lord Brouncker, it appears, was the first who considered continued fractions, or at least, who applied them to the quadrature of curves, in Wallis's Arith. Infim. prop. 191, vol. 1, pa. 469 &c, where this author explains the manner of forming them, giving several numeral examples, in approximating ratios, as well as the general series

$$\frac{a}{\alpha} - \frac{b}{\beta} - \frac{c}{\gamma} - \frac{d}{\delta} - \&c., \text{ as he denotes it.}$$

Huygens also used it for the like purpose, viz, to approximate the ratios of large numbers, in his Descrip. Autom.

Planet. in Oper. Reliq. pa. 173 &c, edit. Amst. 1728. And a special treatise on Continued Fractions was given by Euler, in his Analys. Infin. vol. 1, pa. 295 &c.

This subject is perhaps capable of much improvement, though it has been rather neglected, as very little use has been made of it, except, by those authors, in approximating to the value of fractions, and ratios, that are expressed in large numbers; besides a method of Goniometry by De Lagny, explained in the Introduction to my Logarithms, pa. 78; as also some use I have made of it in summing very slowly converging series, in my Tracts, vol. 1, pa. 203.

As to the reducing of common fractions, and ratios, that are expressed in large numbers, to continued fractions, it is no more than the common method of finding the greatest common measure of those two numbers, by dividing the greater by the less, and the last divisor always by the last remainder; for then the several quotients are the denominators of the fractions, the numerators being always 1 or unity. Thus, to find approximating values

of the fraction $\frac{31415926535}{10000000000}$, or to the ratio of 31415926535 to 10000000000, being the ratio of the circumference of a circle to its diameter, by means of a continued fraction; or, to change the said common fraction to a continued fraction: Dividing the greater term always by the less, the same as to find the greatest common measure of the said numbers or terms, the several quotients will be 3, 7, 15, 1, 292, 1, 1, &c, which, after the first, will be the denominators, to the common numerator 1; and therefore the said fraction will be changed into this continued fraction,

$$3 + \frac{1}{7} + \frac{1}{7^3} + T = \frac{1}{2^2 9^2} + \frac{1}{T} + \frac{1}{T^3} + \&c.$$

Hence, stopping at any part of these single fractions, one after another, will give several values of the proposed ratio, all successively nearer and nearer the truth, but alternately too great and too little. So, stopping at $\frac{7}{5}$, it is $\frac{3^2}{2^2} = 3\frac{1428571}{10000000}$, too great, or 22 to 7 , the ratio of the circumference to the diameter as given by Archimedes. Again, leaving off at $\frac{13}{8}$, it is

$$3\frac{1}{7\frac{1}{15}} = 3\frac{15}{106} = \frac{333}{106} = 3.141509 \text{ &c, too little.}$$

But stopping at $\frac{1}{7^{15}}$, it is $3 \cdot \frac{1}{7^{15} + 1} = 3 \cdot \frac{1}{7^{15}} = 3 \cdot \frac{1}{7^{15} \cdot 3} = \frac{3^{15}}{7^{15} \cdot 3}$ (the ratio of Mc-tius) = $3 \cdot 1415929 \&c.$, which is rather too great. And so on, always nearer and nearer, but alternately too great and too little.

And, in like manner is any algebraic fraction thrown into a continued fraction. As the fraction

$\frac{ab\gamma\delta + a\beta\delta + a\beta\delta}{a\beta\gamma\delta + ab\delta + a\gamma\delta + b\gamma\delta + bd^2}$ which being in like manner divided, the quotients are $\frac{a}{a}, \frac{\beta}{b}, \frac{\gamma}{c}, \frac{\delta}{d}$; which single fractions being considered as denominators to other fractions whose common numerator is 1, these will be the reciprocals of the former, and so will become $\frac{a}{a}, \frac{b}{\beta}, \frac{c}{\gamma}, \frac{d}{\delta}$; and hence the proposed common fraction is equal to this terminate continued,

$$\frac{a}{x} + \frac{b}{y} + \frac{c}{z} + \frac{d}{w}$$

On the other hand, any continued fraction being given, its equivalent common fraction will be found, by beginning at the last denominator, or lowest end of the given continued fraction, and gradually collecting the fractions backwards, till we arrive at the first, when the whole will thus be brought to one common fraction; as was done above in collecting the fractions

$$\frac{1}{7} + \frac{1}{75} + \frac{1}{1} + \frac{1}{225} + \&c.$$

And in like manner the continued fraction

$$\frac{a}{\alpha} + \frac{b}{\beta} + \frac{c}{\gamma} + \frac{d}{\delta} \text{ collects into the fraction}$$

When the given continued fraction is an infinite one, collect it successively, first one term, then two together, three together, &c, till the sum is sufficiently exact. Or, if these collected sums be found to converge too slowly to the true value, having collected a few of the terms into successive sums, these being alternately too great and too little, the true value will be found as near as you please by the method of arithmetical means, explained in my Tracts, vol. 1, Tract 8, pa. 176.

When the denominators of a continued fraction recur in any certain order, as in the following:

$$q + \frac{1}{r + \frac{1}{q + \frac{1}{r + \ddots}}} \text{, or } \sqrt{a + \frac{b}{a + \frac{b}{\sqrt{a + \ddots}}}}$$

its value may be computed by making it first equal to x , and then solving the equation: thus, suppose the value of the first was required; then put the whole $= x$, and

we get $\frac{1}{q + \frac{r}{r+x}} = x$, or $\frac{r+x}{qr+qx+1} = x$: hence $r+x = qr+qx+1$
 $= qr x + qx^2 + x$, and $x^2 + rx - \frac{1}{q} = 0$, from which x ,
and consequently the value of the fraction, may be determined, by solving the quadratic.

In the same manner may the values of other quantities, which run on in infinitum, be found if the factors recur.

Example. Required the value of

$\sqrt{a + \sqrt{b + \sqrt{a + \sqrt{b + \text{&c.}}}}}$ in infinitum.

Let $\sqrt{a + \sqrt{b + \sqrt{a + \sqrt{b + \text{etc}}}}} = x$; then

by squaring both sides $a + \sqrt{b + \sqrt{a + \sqrt{b + \text{etc}}}} = x^2$; and

fore $b + \sqrt{a + \sqrt{b + \text{ &c}}} = x^4 - 2ax^2 + a^2$, or
 $b + x = x^4 - 2ax^2 + a^2$; hence $x^4 - 2ax^2 - x + a^2 - b = 0$, whence the value of x may be found.

If the letters be all equal, as

$\sqrt{a + \sqrt{a + \sqrt{a + \sqrt{a + \text{etc.}}}}}$. Put it $= x$, then square
the equation, so shall $x^2 = a +$

$\sqrt{a + \sqrt{a + \sqrt{a + \sqrt{a + \sqrt{a + \text{ &c}}}}}}$; hence $x^2 - a =$
 $\sqrt{a + \sqrt{a + \sqrt{a + \sqrt{a + \sqrt{a + \text{ &c}}}}}} = x$ the first value, because
it reverts to the same quantity; and from this quadratic
equation we find $x = \frac{1}{2} + \sqrt{\left(a + \frac{1}{2}\right)}$.
Again, let $a = 6$, then $x = \frac{1}{2} + \sqrt{\left(6 + \frac{1}{2}\right)} = \frac{1}{2} + \sqrt{\frac{13}{2}} = \frac{1}{2} + \sqrt{6.5} = \frac{1}{2} + 2.56 = 3.06$.

Again, to find the value of

$\sqrt{a \times \sqrt{b \times \sqrt{a \times \sqrt{b+c}}}}$: putting it $= x$, and squaring, we have $x^2 = a \sqrt{b \sqrt{a \sqrt{b+c}}}$, or $\frac{x^2}{a} = \sqrt{b \sqrt{a \sqrt{b+c}}}$; then this squared, and divided by b ,

gives $\frac{x^4}{a^2b} = (\sqrt{a}\sqrt{b}\sqrt{\sqrt{a}\sqrt{b} \cdot c}) = x$; or $x^4 = a^2bx$,
 or $x^3 = a^2b$, and $x = \sqrt[3]{a^2b}$. If $b = a$, or the radicals
 be always the same letter a , then $x = \sqrt[3]{a^3} = a$.

In like manner, $\sqrt{\frac{a}{b} \cdot \frac{c}{d} \cdot \frac{e}{f} \cdot \frac{g}{h} \cdot \frac{i}{j}}$ is =

$\sqrt[7]{a^4b^2c}$, or $= \sqrt[7]{a^7} = a$, when b and c are taken $= 1$.

Vanishing FRACTIONS. Such fractions as have both their numerator and denominator vanish, or equal to 0, at the same time, may be called Vanishing Fractions. We are not to conclude that such fractions are equal to nothing, or have no value; for that they have a certain determinate value, has been shown by the best mathematicians. The idea of such fractions as these, first originated in a very severe contest among some French mathematicians, in which Varignon and Rolle were the two chief opposite combatants, concerning the then new or differential calculus, of which the latter gentleman was a strenuous opponent. Among other arguments against it, he proposed an example of drawing a tangent to certain curves at the point where the two parts cross each other; and as the fractional expression for the subtangent, by that method, had both its numerator and denominator equal to 0 at the point proposed, Rolle considered it as an absurd expression, and as an argument against the method of solution itself. The seeming mystery however was soon explained, and first of all by John Bernoulli. See an account of this controversy in Montucla, Hist. Math. vol. 2, pa. 366, 1st ed.

Since that time, such kind of fractions have often been contemplated by mathematicians. As, by Maclaurin, in his fluxions, vol. 2, pa. 698 : Saunderson, in his Algebra, vol. 2, art. 469 ; De Moivre, in Miscel. Anal. pa. 165 : Emerson, in his Algebra, pa. 212 : and by many others. The same fractions have also proved a stumbling-block to more mathematicians than one, and the cause of more violent controversies : witness that between Powell and Waring, at the time when Mr. Maseres was a competitor of the latter for the professorship at Cambridge. In the specimen of a work published on occasion of that competition, by Waring, was the fraction $\frac{p - p^2}{1 - p}$, which he said became 4 when p was 1. This was struck at by Powell, as absurd, because he said when $p = 1$, then the fraction $\frac{p - p^2}{1 - p} = \frac{1 - 1}{1 - 1} = \frac{0}{0}$. Waring replied that $\frac{p - p^2}{1 - p} = p + p^2 + p^3 + p^4$ (by common division)

$\frac{p - p^4}{1 - p}$ is $= p + p^2 + p^3 + p^4$ (by common division)
 $= 1 + 1 + 1 + 1 = 4$, when p is $= 1$. See the contro-

versial pamphlets that passed between those two gentlemen at that time.

There are several methods of finding the value of such fractions, that have been given by the gentlemen above quoted. The one is by considering the terms of the fraction as two variable quantities, continually decreasing, till they both vanish together; or finding the ultimate value of the ratio denoted by the fraction. In this way of considering the matter, it appears that, as the terms of the fraction are supposed to decrease till they vanish, or become only equal to their fluxions or their increments, the value of the fraction at that state, will be equal to the fluxion or increment of the numerator divided by that of the denominator. Hence then, taking the example $\frac{x-x^5}{1-x}$, when $x=1$, the fluxion of the numerator is $\dot{x}-5x^4\dot{x}$, and of the denominator $-\dot{x}$; therefore

$$\frac{\dot{x}-5x^4\dot{x}}{-x} = \frac{1-5x^3}{-1} = \frac{5x^3-1}{1} = 5x^4 - 1 = 5 - 1 = 4,$$
the value of the fraction $\frac{x-x^5}{1-x}$ when $x=1$.—Or, thus,
because $x=1$, therefore $\frac{x-x^5}{1-x} = \frac{1-x^5}{1-x}$; then the fluxion of the numerator, $-4x^4\dot{x}$, divided by the fluxion of the denominator, or $-\dot{x}$, gives $4x^3$ or 4, the same as before.

Another method is by reducing the given expression to another, or simpler form, and then substituting the values of the letters. So in the above example $\frac{x-x^3}{1-x}$, or $\frac{1-x^3}{x-1}$, when $x = 1$; divide the numerator by the denominator, and it becomes $1 + x + x^2 + x^3$, which when $x = 1$, becomes 4, for the given fraction, the same as before.— Again, to find the value of $\frac{\sqrt[3]{ax}-\sqrt{ax}}{a-\sqrt{ax}}$ when $x = a$, in which case both the numerator and denominator become = 0. Divide the numerator by the denominator, and the quotient is $\sqrt{ax} + x + \sqrt{x}\frac{x}{a}$; which when $x = a$, becomes $a + a + a = 3a$, for the value of the fraction in that state of it.

Mr. Woodhouse, in his *Principles of Analytical Calculation*, has endeavoured to prove, that the method of expanding these fractions for estimating their values, is an arbitrary operation; that there is nothing contained in the significance of such expressions which renders any such step necessary. He admits, that in the investigations of extension and of motion, we are necessitated, from the nature of the case, to compute a vanishing fraction by a process exactly similar to that just adverted to; but contends the necessity of such operation when it is abstractedly proposed to find its value. For, says he; 'Propose the question separately, what does $\frac{x^m - a^m}{x^n - a^n}$ become, when $x = a$? and the obvious answer to any mind undebauched with mathematical sophistry is $\frac{x^m - a^m}{x^n - a^n} = \frac{0}{0}$. A different result can be obtained by a different process, but why ought that process to be followed? No satisfactory answer can be given to this question, when it is abstractedly proposed to find its value.'

In order to show somewhat the importance of this question, let us suppose that in the investigation of a problem, we obtained for the fluent corrected

$z = x^{\frac{s}{2}} - (x^2 + b^2)^{\frac{t}{2}} \times \frac{x^2 - a^2}{x - a}$, what would be the value

of z when $x = a$? It is evident that a case is here presented, in which the computation of a vanishing fraction becomes an abstract proposition: but does it hence follow, that to expand the expression for effecting such computation is an arbitrary process? Surely not. The bare assertion that there is nothing contained in the significance of the fraction which renders the expansion of the same necessary for the estimation of its value, is no proof whatever against the truth of the method; or that it is not a necessary step; since if it were true, that the fraction did not contain a value in this case, such truth would evidently appear in the result of that operation; that is neither more nor less than nothing would be expressed by the quotient. Now it is obvious that if $\frac{a^2 - a^2}{a - a}$ has a value, we have no other means of determining it than by expanding the expression: for in the form $\frac{a^2 - a^2}{a - a}$, we can derive nothing as a true and precise value of it. Let $\frac{a^2 - a^2}{a - a}$ be put $= \frac{0}{0}$; it may be so, and we see even in this case that the fraction *may be equal to some finite quantity*; that is to say, this expression does not preclude the possibility of its having some definite value, though it affords no clue for computation in this particular state. Hence, since it must be granted, that a fraction and its equivalent whole number are in all cases equal to each other; it follows that if in any case a value be exhibited in one form, it is likewise contained in the other, and consequently must be given to that other; therefore, the equivalent whole number of $\frac{a^2 - a^2}{a - a} = \frac{0}{0}$, having some definite value, $\frac{a^2 - a^2}{a - a}$ itself, has also the same value. And hence the true value of z , in the case where $x = a$ is $a^{\frac{1}{2}} - (a^2 + b^2)^{\frac{1}{2}} \times 2a$, or $a \times [a\sqrt{a} - 2\sqrt{(a^2 + b^2)}]$.

It is not therefore true that to expand the fractions to obtain its true value, is an arbitrary operation, but a process of necessity, rendered unavoidable by something contained in the significance of the expression. To admit the necessity of expanding the fraction when its quantity is to be computed, in any investigation of extension or of motion; and to deny that necessity when it is abstractedly proposed to find its value, is confessing, that a fraction and its equivalent whole number are to be considered equal only in particular cases, which is absurd.

FRAISE, in Fortification, a kind of defence, consisting of pointed stakes, driven almost parallel to the horizon into the retracements of a camp, &c, to ward off and prevent any approach or scalade.

FRANKLIN (DR. BENJAMIN), one of the most celebrated philosophers and politicians of the 18th century, was born at Boston in North America in the year 1706, being the youngest of 13 children. His father was a tallow-chandler in Boston, and young Franklin was taken from school at 10 years of age, to assist him in his business. In this situation he continued two years; but disliking that occupation, he was bound apprentice to an elder brother, who was then a printer in Boston, but had learned that business in London, and who in the year 1721 began to print a newspaper, being the second ever published in America; the copies of which our author was sent to distribute, after having assisted in composing and printing it. On this occasion, our young philosopher enjoyed the secret and singular pleasure of being the much-admired author of many essays in this paper; a circum-

stance which he had the address to keep a secret even from his brother himself; and this when he was only 15 years of age. The frequent ill usage from his brother, induced our author to quit his service, which he did, at the age of 17, and went to New York. But not meeting employment here, he went forward to Philadelphia, where he worked with a printer a short time; after which, at the instance of Sir William Keith, governor of the province, he returned to Boston to solicit pecuniary assistance from his father, to set up a printing-house for himself at Philadelphia, on the promise of great encouragement from Sir William, &c. His father, however, thought fit to refuse such aid, alleging that he was yet too young (18 years old) to be intrusted with such a concern; so our author again returned to Philadelphia without it. Upon this, Sir William said he would advance the sum that might be necessary, and our young philosopher should go to England, and purchase all the types and materials, for which purpose he would give him letters of credit. He could never however get these letters; yet by dint of fair promises of their being sent on board the ship after him, he sailed for England, expecting these letters of credit were in the governor's packet, which he was to receive on its being opened. In this however he was cruelly deceived, and thus he was sent to London without either money, friends, or credit, at 18 years of age.

Under these circumstances his only resource was that of employment, which he shortly obtained, as a journeyman printer, first at a Mr. Palmer's, and afterwards with Mr. Watts, with whom he worked a considerable time, and by whom he was greatly esteemed, being also treated with such kindness, that it was ever after most gratefully remembered by our philosopher.

After a stay of 18 months in London, he returned to Philadelphia, in 1726, with a merchant of that town, as his clerk, on a salary of 50 pounds a year. But his master dying the year after, he again engaged to direct the printing business of the same person with whom he had worked before. After continuing with him the best part of a year, Franklin, in partnership with another young man, at length set up a printing-house himself.

A short time previous to this, our author had gradually associated a number of persons, like himself, of a rational and philosophic turn of mind, and formed them into a club or society, to hold meetings, to converse together for their mutual improvement in all kinds of useful knowledge, which was in high repute for many years after. Among many other useful regulations, they agreed to bring such books as they had into one place, to form a common library. This resource being found defective, at Franklin's persuasion they resolved to contribute a small sum monthly towards the purchase of books for their use from London. Thus their stock began to increase rapidly; and the inhabitants of Philadelphia, being desirous of having a share in their literary knowledge, proposed that the books should be lent out on paying a small sum for the indulgence. Thus in a few years the society became rich, and possessed more books than were perhaps to be found in all the other colonies: the collection was advanced into a public library; and the other colonies, sensible of its advantages, began to form similar plans; whence originated the libraries at Boston, New York, Charlestown, &c; that of Philadelphia being now not inferior to any in Europe.

About 1728 or 1729, our author set up a newspaper, the second in Philadelphia, which proved very profitable,

and otherwise useful, as affording an opportunity of making himself known as a political writer, by inserting several of his writings of that kind in it. In addition to his printing-house, he set up a shop to sell books and stationery; and in 1730, entering into a matrimonial engagement, his wife proved very useful in assisting to manage the shop, &c. He afterwards began to have some leisure, both for reading books, and writing them, of which he gave many specimens from time to time. In 1732 he began to publish Poor Richard's Almanac, which was continued for many years. It was always remarkable for the numerous and valuable concise maxims which it contained, for the economy of human life, all tending to exhort to industry and frugality: and in the almanac for the last year, all the maxims were collected in an address to the reader, entitled, *The Way to Wealth*. This has been translated into various languages, and inserted in different publications. It has also been printed on a large sheet, proper to be framed, and hung up in conspicuous places in all houses, as it justly deserves to be. Mr. Franklin became gradually more known for his political talents, and in the year 1736, he was appointed clerk to the General Assembly of Pennsylvania; and was re-elected by succeeding assemblies for several years, till he was chosen a representative for the city of Philadelphia; and in 1737 he was appointed post-master of that city. In 1738, he formed the first fire-company there, to extinguish and prevent fires and the burning of houses: an example which was soon followed by other persons, and in other places. And soon after, he suggested the plan of an association for insuring houses and ships from losses by fire, which was adopted; and the association continues to this day. In the year 1744, during a war between France and Great Britain, some French and Indians made inroads on the frontier inhabitants of the province, who were unprovided for such an attack: the situation of the province, was at this time truly alarming, being destitute of every means of defence. At this crisis Franklin stepped forth, and proposed to a meeting of the citizens of Philadelphia, a plan of a voluntary association for the defence of the province. This was approved of, and signed by 1200 persons immediately. Copies of the same were circulated through the province; and in a short time the number of signers amounted to 10,000. Franklin was chosen colonel of the Philadelphia regiment; but he did not think proper to accept of the honour.

Pursuits of a different nature now occupied the greatest part of his attention for some years. Being always much addicted to the study of natural philosophy; and the discovery of the Leyden experiment in electricity having rendered that science an object of general curiosity; Mr. Franklin applied himself to it with great diligence, and soon began to distinguish himself very eminently in that way. He engaged in a course of electrical experiments with all the ardour and thirst for discovery which characterized the philosophers of that day. By these, he was enabled to make a number of important discoveries, and to propose theories to account for various phenomena; which have been generally adopted, and which will probably endure for ages. His observations he communicated, in a series of letters, to his friend Mr. Collinson; the first of which is dated March 28, 1747. In these he makes known the power of points in drawing and throwing off the electric matter, which had hitherto escaped the notice of electricians. He also made the discovery of a plus and minus, or of a positive and negative state of electricity;

from which he explained in a satisfactory manner the phenomena of the Leyden phial, first observed by Cuneus or Muschenbroeck, which had much perplexed philosophers. He showed that the bottle, when charged, contained no more electricity than before, but that as much was taken from one side as was thrown upon the other; and that, to discharge the same, it was only necessary to make a communication between the two sides, by which the equilibrium might be restored, and that no signs of electricity would remain. He afterwards demonstrated by experiments, that the electricity did not reside in the coating, as had been supposed, but in the pores of the glass itself. After a phial was charged, he removed the coating, and found that upon applying a new coating the shock might still be received. In the year 1749, he first suggested his idea of explaining the phenomena of thunder-gusts, and of the aurora borealis, upon electrical principles. He points out many particulars in which lightning and electricity agree; and likewise adduces many facts, and reasoning from facts, in support of his positions. In the same year he conceived the bold and grand idea of ascertaining the truth of his doctrine, by actually drawing down the forked lightning, by means of sharp-pointed iron rods, raised into the region of the clouds; whence he derived his method of securing buildings and ships from being damaged by lightning. It was not until the summer of 1752 that he was enabled to complete his grand discovery—the experiment of the electrical kite, which being raised up into the clouds, brought thence the electricity or lightning down to the earth; and M. D'Alibard made a like experiment about the same time in France, by following the track which Franklin had before pointed out. The letters which he sent to Mr. Collinson, it is said, were refused a place among the papers of the Royal Society of London; and Mr. Collinson published them in a separate volume, under the title of *New Experiments and Observations on Electricity, made at Philadelphia, in America*; which were read with avidity, and soon translated into different languages. His theories were at first opposed by several philosophers, and by the members of the Royal Society of London; but in 1755, when he returned to that city, they voted him the gold medal which is annually given to the person who presents the best paper on some interesting subject. He was also admitted a member of the society, and had the degree of doctor of laws conferred on him by different universities: but at this time, by reason of the war which broke out between Britain and France, he returned to America, and interested himself in the public affairs of that country. Indeed he had done this long before; for although philosophy was a principal object of Franklin's pursuit for several years, he did not confine himself to it alone. In the year 1747 he became a member of the General Assembly of Pennsylvania, as a burgess for the city of Philadelphia. Being a friend to the rights of man from his infancy, he soon distinguished himself as a steady opponent of the unjust schemes of the proprietaries. He was looked up to as the head of the opposition; and to him have been attributed many of the spirited replies of the assembly, to the messages of the governors. His influence in the body was very great. This arose not from any superior powers of eloquence; he spoke but seldom, and he never was known to make any thing like an elaborate harangue. His speeches often consisted of a single sentence, or of a well-told story, the moral of which was always obviously to the point. He never attempted the flowery fields of

oratory. His manner was plain and mild. His style in speaking was, like that of his writings, simple, unadorned, and remarkably concise. With this plain manner, and his penetrating and solid judgment, he was able to confound the most eloquent and subtle of his adversaries, to confirm the opinions of his friends, and to make converts of the unprejudiced who had opposed him. With a single observation, he has rendered of no avail a long and elegant discourse, and determined the fate of a question of importance.

In the year 1749 he proposed the plan of an academy, to be erected in the city of Philadelphia, as a foundation for posterity to erect a seminary of learning, more extensive and suitable to future circumstances; and in the beginning of 1750, three of the schools were opened, namely, the Latin and Greek school, the Mathematical, and the English schools. This foundation soon after gave rise to another more extensive college, incorporated by charter May 27, 1755, which still subsists, and in a very flourishing condition. In 1752, he was instrumental in the establishment of the Pennsylvania Hospital, for the cure and relief of indigent invalids, which has proved of the greatest use to that class of persons. Having conducted himself so well as postmaster of Philadelphia, he was, in 1753, appointed deputy postmaster-general for the whole British colonies.

These being much exposed to depredations on their frontier by the Indians and the French, at a meeting of commissioners from several of the provinces, Mr. Franklin proposed a plan for the general defence, to establish in the colonies a general government, to be administered by a president-general, appointed by the crown, and by a grand council, consisting of members chosen by the representatives of the different colonies; a plan which was unanimously agreed to by the commissioners present. The plan however had a singular fate: it was disapproved of by the ministry of Great Britain, because it gave too much power to the representatives of the people; and it was rejected by every assembly, as giving to the president-general, who was to be the representative of the crown, an influence greater than appeared to them proper, in a plan of government intended for freemen. Perhaps this rejection, on both sides, is the strongest proof that could be adduced of the excellence of the system, as suited to the situation of Great Britain and America at that time. It appears to have steered exactly in the middle, between the opposite interests of both. Whether the adoption of this plan would have prevented the separation of America from Great Britain, is a question which might afford much room for speculation.

In the year 1755, General Braddock, with some regiments of regular troops, and provincial levies, was sent to dispossess the French of the posts on which they had seized in the back settlements. After the men were all ready, a difficulty occurred, which had nearly prevented the expedition. This was the want of wagons. Franklin now stepped forward, and with the assistance of his son, in a very short time procured 150. After the defeat of Braddock, our author introduced into the assembly a bill for organizing a militia, and had the dexterity to get it passed. In consequence of this act a very respectable militia was formed; and Franklin was appointed colonel of a regiment in Philadelphia, which consisted of 1200 men; in which capacity he acquitted himself with much propriety, and was of singular service; though this militia was soon after disbanded by order of the English ministry.

In 1757, he was sent to England, with a petition to the king and council, against the proprietaries, who refused to bear any share in the public expenses and assessments; which he got settled to the satisfaction of the state. After the completion of this business, Franklin remained at the court of Great Britain for some time, as agent for the province of Pennsylvania; and also for those of Massachusetts, Maryland, and Georgia. Soon after this, he published his Canada pamphlet, in which he pointed out, in a very forcible manner, the advantages that would result from the conquest of this province from the French. An expedition was accordingly planned and fitted out, and the command given to General Wolfe; the success of which is well known. He now divided his time indeed between philosophy and politics, rendering many services to both. While here, he invented the elegant musical instrument called the Harmonica, formed of glasses played on by the fingers. In the summer of 1762 he returned to America; on his passage to which he observed the singular effect produced by the agitation of a vessel, containing oil floating on water: the upper surface of the oil remaining smooth and undisturbed, while the water was agitated with the utmost commotion. On his return he received the thanks of the Assembly of Pennsylvania, which having annually elected him a member in his absence, he again took his seat in this body, and continued a steady defender of the liberties of the people.

In 1764, by the intrigues of the proprietaries, Franklin lost his seat in the assembly, which he had possessed for 14 years; but was immediately appointed provincial agent to England, for which country he presently set out. In 1766 he was examined before the parliament relative to the stamp-act; which was soon after repealed. The same year he made a journey into Holland and Germany; and another into France; being everywhere received with the greatest respect by the literati of all nations. In 1773 he attracted the public attention by a letter on the duel between Mr. Whately and Mr. Temple, concerning the publication of Governor Hutchinson's letters, declaring that he was the person who had discovered those letters. On the 29th of January next year, he was examined before the privy-council, on a petition he had presented long before, as agent for Massachusetts Bay, against Mr. Hutchinson; but this petition being disagreeable to ministry, it was precipitately rejected, and Dr. Franklin was soon after removed from his office of postmaster-general for America. Finding now all efforts to restore harmony between Great Britain and her colonies useless, he returned to America in 1775; just after the commencement of hostilities. Being named one of the delegates to the Continental Congress, he had a principal share in bringing about the revolution and declaration of independency on the part of the colonies. In 1776 he was deputed by Congress to Canada, to negotiate with the people of that country, and to persuade them to throw off the British yoke; but the Canadians had been so much disgusted with the hot-headed zeal of the New Englanders, who had burnt some of their chapels, that they refused to listen to the proposals, though enforced by all the arguments Dr. Franklin could make use of. On his return to Philadelphia, Congress, sensible how much he was esteemed in France, sent him thither to put a finishing hand to the private negotiations of Mr. Silas Deane; and this important commission was readily accepted by the doctor, though then in the 71st year of his age. The event is well known; a treaty of alliance and commerce was signed between France and America; and

M. Le Roi asserts, that the doctor had a great share in the transaction, by strongly advising M. Maurepas not to lose a single moment, if he wished to secure the friendship of America, and to detach it from the mother-country. In 1777 he was regularly appointed plenipotentiary from Congress to the French court; but obtained leave of dismission in 1780. Having at length seen the full accomplishment of his wishes by the conclusion of the peace in 1783, which gave independency to America, he became desirous of revisiting his native country. He therefore requested to be recalled; and, after repeated solicitations, Mr. Jefferson was appointed in his stead. On the arrival of his successor, he repaired to Havre de Grace, and crossing the channel, landed at Newport in the Isle of Wight; whence, after a favourable passage, he arrived safely at Philadelphia in September 1785. He was received amidst the acclamations of a vast multitude, who flocked from all parts to see him, and who conducted him in triumph to his own house; where in a few days he was visited by the members of the Congress and the principal inhabitants of Philadelphia. He was afterward twice chosen president of the Assembly of Philadelphia; but his increasing infirmities obliged him to ask permission to retire, and to spend the remainder of his life in tranquillity; which was granted, in 1788. After this, the infirmities of age increased fast upon him; he became more and more afflicted with the gout and the stone, till the time of his death, which happened the 17th of April 1790, about 11 at night, at 84 years of age; leaving one son, governor William Franklin, a zealous loyalist, who resided in London, on a pension from the English government, till his death in the year 1813; and a daughter, married to Mr. William Bache, merchant in Philadelphia.

Doctor Franklin was author of many tracts on electricity, and other branches of natural philosophy, as well as on politics, and miscellaneous subjects. He had also many papers inserted in the Philosophical Transactions, from vol. 47 to vol. 64.

FREEZE, or **FRIZE**, in Architecture, a large flat member, being that part of the entablature of columns that separates the architrave from the cornice.

FREEZING, or **Congelation**, the fixing of a fluid body into a firm or solid mass by the abstraction of its caloric: in which sense the term is applied to water when it freezes into ice; to metals when they resume their solid state, after being melted by heat; or to glass, wax, pitch, tallow, &c, when they harden again after having been rendered fluid by heat. But it differs from crystallization, which is rather a separation of the particles of a solid from a fluid, in which it had been dissolved more by the moisture than the action of heat.

The process of congelation is always attended with the emission of heat or caloric, as is found by experiments on the freezing of water, wax, spermacci, &c; for in such cases it is always found, that a thermometer dipt into the fluid mass, keeps continually descending as this cools, till it arrive at a certain point, being the point of freezing, which is peculiar to each fluid, where it is rather stationary, and then rises for a little, while the congelation proceeds. But by what means it is that fluid bodies should thus be rendered solid by cold, or loss of caloric; or fluid by the absorption of this substance; or what is introduced into the bodies by either of these principles, are matters which philosophers have never yet been able to discover, or to satisfy themselves upon. The following phenomena however are usually observed. Water, and some other

fluids, suddenly dilate and expand in the act of freezing, so as to occupy a greater space in the form of ice than before, in consequence of which it is that ice is specifically lighter than the same fluid, and floats in it. And the degree of expansion of water, in the state of ice, is by some authors computed at about $\frac{1}{10}$ of its volume. Oil however is an exception to this property, and quicksilver too, which shrinks and contracts still more after freezing. Boyle relates several experiments of vessels made of metal, very thick and strong; in which, when filled with water, close stopped, and exposed to the cold, the water being expanded in freezing, and not finding either room or vent, burst the vessels. A strong barrel of a gun, filled with water, and close stopped and frozen, was rent the whole length. Huygens, to try the force with which water expands when freezing, filled a cannon with it, whose sides were an inch thick, and then closed up the mouth and vent, so that none could escape; the whole being exposed to a strong freezing air, the water froze in about 12 hours, and burst the piece in two places. Mathematicians have computed the force of the ice upon this occasion; and they say, that such a force would raise a weight of 27720 pounds. Lastly, Major Edward Williams, of the Royal Artillery, made many experiments on the force of freezing water at Quebec, in the years 1784 and 1785. He filled all sizes of iron bomb-shells with this fluid, then plugged the fuze hole close up, and exposed them to the strong freezing air of the winter in that climate; sometimes driving in the iron plugs as hard as possible with a sledge hammer; and yet they were always thrown out by the sudden expansion of the water in the act of freezing, like a ball shot by gunpowder, sometimes to the distance of 4 or 500 feet, though they weighed nearly 3 pounds; and when the plugs were screwed in, or furnished with hooks or bars, to lay hold of the inside of the shell by, so that they could not possibly be forced out, in this case the shell was always split in two, though the thickness of the metal of the shell was an inch and three quarters. It is further remarkable, that through the circular crack, round about the shells, where they burst, there stood out a thin film or sheet of ice, like a fin; and in the cases when the plugs were projected by freezing water, there suddenly issued out from the fuze-hole, a bolt of ice, of the same diameter, and stood over it to the height sometimes of 8 inches and a half. And hence we need not be surprised at the effects of ice in destroying the substance of vegetables and trees, and even splitting rocks, when the frost is carried to excess. See other similar instances in the article **COLD**.

It is also observed that water loses its weight by freezing, being found lighter after thawing again, than before it was frozen. And indeed it evaporates almost as fast when frozen, as when it is fluid.

We likewise find it asserted, that water does not freeze in vacuo; requiring for that purpose the presence and contiguity of the air. But this circumstance is liable to some doubt, and it may be suspected that the degree of cold has not been carried far enough in these particular instances; as it is found that mercury in thermometers has even been frozen, though it requires a vastly greater degree of cold to freeze this fluid than water. Besides, the assertion has been lately disproved by the experiments of Professor Leslie and Dr. Marct, &c, who have frozen not water only, but even mercury, in the exhausted receiver, and that only by simple evaporation.

That water which has been boiled freezes more readily than that which has not been boiled; and that a slight

commotion of the fluid disposes it to freeze more speedily; having sometimes been cooled several degrees below the freezing point, without congealing when kept quite still, but suddenly freezing into ice on the slightest agitation.

That the water, being covered over with a surface of oil of olives, does not freeze so readily as without it; and that nut oil absolutely preserves it under a strong frost, when olive oil would not.

That rectified spirit of wine, nut oil, and oil of turpentine, seldom freeze.

That the surface of the water, in freezing, appears all wrinkled; the wrinkles being sometimes in parallel lines, and sometimes like rays, proceeding from a centre to the circumference. See the articles CONGELATION, COLD, and ICE.

FREEZING Mixture, a preparation for the artificial congelation of water, and other fluids. According to Mr. Boyle, all kinds of salts, whether alkaline or acid; and even all spirits, as spirit of wine, &c.; as also sugar, and saccharum saturni, mixed with snow, are capable of freezing most fluids; and the same effect is produced, in a very high degree, by a mixture of oil of vitriol, or spirit of nitre, with snow.

The same is also remarked by M. Homberg of equal quantities of corrosive sublimate, and sal ammoniac, with four times the quantity of distilled vinegar.

Boerhaave gives a method of producing artificial frost without either snow or ice: we must have for this purpose, at any season of the year, the coldest water that can be procured; this is to be mixed with a proper quantity of any salt (sal ammoniac will answer the intention best), at the rate of about 3 ounces to a quart of water. Another quart of water must be prepared in the same manner with the first; the salt, by being dissolved in each, will make the water much colder than it was before. The two quarts are then to be mixed together, and this will make them colder still. Two quarts more of water prepared and mixed in the same manner are to be mixed with these, which will increase the cold to a much higher degree in all. The whole of this operation is to be carried on in a cold cellar; and a glass of common water is then to be placed in the vessel of the fluid thus artificially cooled, and it will be turned into ice in the space of 12 hours.

There is also a method of making artificial ice by means of snow, without any kind of salt. For this purpose fill a small pewter dish with water, and upon that set a common pewter plate filled, but not heaped, with snow. Bring this simple apparatus near the fire, and stir the snow in the plate: the snow will dissolve, and the ice will be formed on the back of the plate, which was set in the dish of water.

M. Reaumur tried the effect of several salts, and examined the various degrees of cold by an ice thermometer, which being placed in the fluid to be frozen, showed very exactly the degree of cold by the descent of the spirit.

Nitre, or saltpetre, usually passes for a salt that may be very serviceable in these artificial congelations; but the experiments of this gentleman prove that this opinion is erroneous. The most perfectly refined saltpetre employed in the operation sunk the spirit in the thermometer only $3\frac{1}{2}$ degrees below the fixed point. Less refined nitre depressed the thermometer lower, and gave a greater degree of cold; owing to the common or sea-salt that it contains when less pure, which has a greater effect than the pure saltpetre itself.

Two parts of common salt being mixed with three parts of powdered ice in very hot weather, the spirit in the ther-

mometer immediately descended 15 degrees, which is half a degree lower than it would have descended in the severest cold of our winters. M. Reaumur then tried the salts all round, determining with great regularity and exactness, what was the degree of cold occasioned by each in a given dose. Among the neutral salts, none produced a greater degree of cold than the common sea salt. Among the alkalies, sal ammoniac sunk the thermometer only to 13 degrees. Pot-ashes sunk it just as low as well-refined saltpetre.

For the common uses of the table, the ice is not required to be very hard, or such as is produced by long continuance of violent cold: it is rather desired to be like snow. Saltpetre, which is no very powerful agent in freezing, is therefore more fit for the purpose than a more potent salt. It is not necessary that the congelation should be very suddenly made; but that it may retain its form as long as may be, when made, is of great importance. If it be desired to have ices very hard and firm, and very suddenly prepared, then sea salt is of all others most to be chosen for the operation. The ices thus made will be very hard, but they will soon run. Pot-ashes afford an ice of about the hardness that is usually required. This forms indeed very slowly, but then it will preserve a long time. And common wood-ashes will perform the business very nearly in the same manner as the pot-ashes; but for this purpose, the wood which is burnt, ought to be fresh.

The strong acid spirits of the neutral salts act much more powerfully in these congelations than the salts themselves, or indeed than any simple salt can do. Thus, spirit of nitre mixed with twice its quantity of powdered ice, immediately sinks the spirit in the thermometer to 19 degrees, or 4 degrees more than that obtained by means of sea salt, the most powerful of all the salts in making artificial cold. A much greater degree of cold may be given to this mixture, by piling it round with more ice mixed with sea salt. This gives a redoubled cold, and sinks the thermometer to 24 degrees. If this whole matter be covered with a fresh mixture of spirit of nitre and ice, a still greater degree of cold is produced, and so on; the cold being by this method of fresh additions to be increased almost without bounds: but it is to be observed, that every addition gives a smaller increase than the former.

It is very remarkable in the acid spirits, that though sea salt is so much more powerful than nitre in substance in producing cold, yet the spirit of nitre is much stronger than that of sea salt; and another not less wonderful phenomenon is, that spirit of wine, which is little else than liquid fire, has as powerful an effect in congelations, or very nearly so, as the spirit of nitre itself.

The several liquid substances which produce cold, in the same manner as the dry salts on being mixed with ice, are much more speedy in their action than the salts: because they immediately and much more intimately come into contact with the particles of the ice, than the salts can. Of this nature are spirit of nitre, spirit of wine, &c. To produce the expected degree of cold, it is always necessary that the ice and the additive matter, whatever it may be, should both rush together, and intimately uniting, form one clear fluid. It is hence that no new cold is produced with oil, which, though it melts the ice, yet cannot mix itself into a homogeneous liquid with it, but must always remain floating on the surface of the water that is produced by the melting of the ice. Mem. Acad. Scienc. Par. 1734.

It has been discovered, that fluids standing in a current of air, grow by this means much colder than before. Fah-

renheit had long since observed, that a pond, which stands quite calm, often acquires a degree of cold much beyond what is sufficient for freezing, and yet no congelation ensued: but if a slight breath of air happens in such a case to glide over the surface of the water, it stiffens the whole in an instant. It has also been discovered, that all substances become colder by the evaporation of the fluids they contain, or with which they are mixed. If both these methods therefore be practised on the same body at the same time, they will increase the cold to almost any degree of intensest we please.

Most extraordinary instances of artificial freezing have since been made in Russia and at Hudson's Bay, and other parts, by which quicksilver was frozen into a solid mass of metal. This indeed had before been effected by the natural cold of the atmosphere alone, in Siberia. In the winter of 1733, Professor Gmelin, with two other gentlemen of the Russian academy, were sent by Anne Ivanoua, the new empress, to explore and describe the different parts of her Asiatic dominions, with the communication of Asia and America. In the same season of the year 1734-5, M. Gmelin being at Yenesieisk in $55^{\circ} 30'$ north lat. and 92° long. east from Greenwich, first observed such a descent of the mercury, as must have been attended with congelation, being far below its freezing point, now fixed at -40 of Fahrenheit's thermometer. "Here," says he, "we first experienced the truth of what various travellers have related, with respect to the extreme cold of Siberia; for, about the middle of December, such severe weather set in, as we were sure had never been known in our time at Petersburg. The air seemed as if it were frozen, with the appearance of a fog, which did not suffer the smoke to ascend as it issued from the chimneys." Birds fell from the air as dead, and froze immediately, unless they were brought into a warm room. Whenever the door was opened, a fog suddenly formed round it. During the day, short as it was, parhelion and haloes about the sun were frequently seen; and in the night mock moons, and haloes about the moon. Finally, our thermometer, not subject to the same deception as the senses, left us no doubt of the excessive cold; for the quicksilver in it was reduced, on the 5th of January, old style, to -120° of Fahrenheit's scale, lower than it had ever been observed in nature."

The next instance of congelation occurred at Yakutsk, in 62° north lat. and 150° east longitude. The weather here was unusually mild for the climate, yet the thermometer fell to -72° ; and one person informed the professor by a note, that the mercury in his barometer was frozen. He hastened immediately to his house to behold such a surprising phenomenon; but though he was witness to the fact, observing that the mercury did not continue in one column, but was divided in different places as into little cylinders, which appeared frozen, yet the prejudice he had entertained against the possibility of the congelation, would not allow him to believe it.

Another set of observations, in the course of which the mercury must frequently have been congealed, were made by Professor Gmelin at Kirenga-fort, in $57\frac{1}{2}$ north lat., and 108 east long.; his thermometer, at different times, standing at -108 , -86 , -100 , -113 , and many other intermediate degrees; in the course of the winter of 1737-8. On the 27th of November, after the thermometer had been standing for two days at -46° , he observed it sunk at noon to -108 . Suspecting some mistake, after he had noted down the observation, he instantly ran back, and

found it at -102 ; but ascending with such rapidity, that in the space of half an hour it had risen to -19° . This phenomenon, which appeared so surprising, doubtless depended on the expansion of the mercury frozen in the bulb of the thermometer, and which, now melting, forced upwards the small thread in the stem. Similar appearances were observed afterwards, when the thread of quicksilver in the thermometer was separated about 6 degrees.

A second instance, where a natural congelation of mercury has certainly been observed, is recorded in the Transactions of the Royal Academy of Sciences at Stockholm, as made by Mr. Andrew Heilan. The weather, in January 1760, was remarkably cold in Lapland; so that on the 5th of that month, the thermometers fell to -76 , -128 , or lower; on the 23d and following days they fell to -58 , -79 , -92 , and below -238 entirely into the ball. This was observed at four different places in Lapland, situated between the 65° and 78° degrees of north lat. and the 21° and 28° degrees of east longitude.

But the congelation of quicksilver, by an artificial freezing mixture, was first observed, and put beyond doubt, by Mr. Joseph Adam Braun, professor of philosophy at Petersburg. This gentleman, wishing to try how many degrees of cold he could produce, availed himself of a good opportunity, which offered for that purpose, on the 14th of December 1759, when the mercury in the thermometer stood in the natural cold at -34 , which it is now known is only 5 or 6 degrees above its point of congelation. Assisting this natural cold therefore, with a mixture prepared of aquafortis and pounded ice, his thermometer was sunk to -69 . Part of the quicksilver must now have been really congealed, but unexpected by him, and he only thought of pursuing his object of producing still greater degrees of cold; and having expended all his pounded ice, he was obliged to use snow instead of it. With this fresh mixture the mercury sunk to -100 , -240 , and -350° . Taking the thermometer out, he found it whole, but the quicksilver fixed, and it continued so for 12 minutes. On repeating the experiment, with another thermometer which had been graduated no lower than -220 , all the mercury sunk into the ball, and became solid as before, and did not re-ascend till after a still longer interval of time. Mr. Braun now suspected that the quicksilver was really frozen, and prepared for making a decisive experiment. This was accomplished on the 25th of the same month, and the bulb of the thermometer broken as soon as the metal was congealed; when it appeared that the mercury was changed into a solid and shining metallic mass, which flattened and extended under the strokes of a pestle, being rather less hard than lead, and yielding a dull sound like that metal. Mr. Æpinus made similar experiments at the same time, employing as well thermometers as tubes of a larger bore; in which last he remarked, that the quicksilver fell sensibly on being frozen, assuming a concave surface, and also, that the congealed pieces sunk in fluid mercury: also, in their further experiments, they invariably found that the mercury sunk lower when the whole of it was congealed, than if any part of it remained fluid: all showing that, contrary to water, mercury contracted in freezing. It was further observed, that the mercury when congealed looked like the most polished silver, and when beaten flat, it was easily cut with a penknife, like soft thin sheet lead.

The fact being thus established, and fluidity no longer to be considered as an essential property of quicksilver, Mr. Braun communicated an account of his experiments

to the Petersburg academy, on the 6th of September 1760; of which a large extract was inserted in the Philos. Trans. vol. 52, pa. 156. He afterwards declared that he never suffered a winter to pass without repeating the experiment of freezing quicksilver, and never failed of success when the natural cold was of a sufficient strength for the purpose; and this degree of natural cold he supposes at -10 ° Fahrenheit; though some commencement of the congelation might be perceived when the temperature of the air was as high as $+2$.

The results of all his experiments were, that with the abovementioned frigorific mixtures, and once with rectified spirits and snow, when the natural cold was at -28° , he congealed the quicksilver, and discovered that it is a real metal, that melts with a very small degree of heat. However, not perceiving the necessary consequence of its great contraction in freezing, he always confounded its point of congelation, with that of its greatest contraction in freezing, and thus marked the former a great deal too low.

In the process of his observations, Mr. Braun found that double aquafortis was more effectual than spirit of nitre; but with this simple spirit, which seldom brings the mercury lower than -148 , this metal may be frozen in the following manner: Six glasses being filled with snow as usual, and the thermometer placed in one of them, the spirit of nitre was poured upon it; when the mercury would fall no lower in this, the thermometer was removed to the second, and so on to the third and fourth, in which fourth immersion the mercury was congealed.

Mr. Æpinus gives the following direction for using the fuming spirit of nitre: Take some of this spirit, cooled as much as possible, and put it into a wine-glass till it be about half full, filling it up with snow, and stirring them till the mixture become of the consistence of pap; by which means you obtain, almost in an instant, the necessary degree of cold for the freezing of quicksilver.

It is remarked by Mr. Braun, that by the mixture of snow and spirit of nitre, which congealed the mercury, he never was able to bring thermometers, filled with the most highly rectified spirit of wine, lower than -148 : so that the cold which will freeze mercury, will not freeze spirit of wine; and therefore spirit thermometers are the most fit to determine the degree of coldness in frigorific mixtures, till we can construct solid metallic thermometers with sufficient accuracy. This author tried the effects of different fluids in his frigorific compositions: he always found that Glauber's spirit of nitre and double aquafortis were the most powerful; and from a number of experiments made when the temperature of the air was between 21 and 28 of Fahrenheit, he concludes, that spirit of salt poured upon snow increased the natural cold 36° ; spirit of sal ammoniac, 12; oil of vitriol, 42; Glauber's spirit of nitre, 70; aquafortis, 48; simple spirit of nitre, 36; dulcified spirit of vitriol, 24; Hoffman's anodyne liquor, 38; spirit of hartshorn, 12; spirit of sulphur, 12; spirit of wine rectified, 24; camphorated spirit, 18; French brandy, 14; and several kinds of wine increased the natural cold to 7, 8, or 9 degrees.

The most remarkable congelation of mercury, by natural cold, that has ever been observed, was that related by Dr. Peter Simon Pallas, who had been sent by the empress of Russia, with some other gentlemen, on an expedition similar to that of M. Gmelin. Being at Krasnoyarsk in the year 1772, in north lat. $56^{\circ} 30'$, and east long. 93° , he had an opportunity of observing the pheno-

nomen we speak of. On the 6th and 7th of December that year, says he, there happened the greatest cold I have ever experienced in Siberia: the air was calm at the time, and seemingly thickened; so that, though the sky was in other respects clear, the sun appeared as through a fog. I had only one small thermometer left, in which the scale went no lower than -7° ; and on the 6th in the morning, I remarked that the quicksilver in the tube sunk into the ball, except some short columns which stuck fast to its surface. When the ball of the thermometer, as it hung in the open air, was touched with the finger, the quicksilver rose; and it could plainly be seen that the solid columns stuck and resisted a good while, and were at length pushed upward with a seeming violence. He also placed upon the gallery, on the north side of his house, some quicksilver in an open bowl. Within an hour he observed the edges and surface of it frozen solid; and some minutes afterward the whole was condensed by the natural cold into a soft mass very much like tin. While the inner part was still fluid, the frozen surface exhibited a great variety of branched wrinkles; but in general it remained pretty smooth in freezing. The congealed mercury was more flexible than lead; but on being bent short, it was found more brittle than tin; and when hammered over thin, it appeared somewhat granulated. When the hammer was not perfectly cooled, the quicksilver melted away under it in drops; and the same thing happened when the metal was touched with the finger, by which also the finger was immediately benumbed. When the frozen mass was broken to pieces in the cold, the fragments adhered to each other and to the bowl in which they were placed. In the warm room it thawed on its surface gradually, by drops, like wax on the fire. Though the frost seemed to abate a little towards night, yet the congealed quicksilver remained unaltered, and the experiment with the thermometer could still be repeated. On the 7th of December he had an opportunity of making the same observations all day; but some hours after sunset, a north-west wind sprung up, which raised the thermometer to -46° , when the mass of quicksilver began to melt.

The experiments of Mr. Braun were successfully repeated at Gottingen, in 1774, by Mr. John Frederick Blumenbach; being encouraged to this attempt by the excessive cold of the winter that year, especially the night of January the 11th, when he made the experiment, the thermometer standing at -10 in the open air. Mr. Blumenbach at 5 in the evening, put 3 drachms of quicksilver into a small sugarglass, and covered it with a mixture of snow and Egyptian sal ammoniac, setting the glass out in the air upon a mixture also of sal ammoniac. At one the next morning, the mercury was found frozen quite solid, and hard to the glass; and did not melt again till 7 or 8 the next morning. The colour of the frozen mercury was a dull pale white with a blueish cast, like zinc, very different from the natural appearance of quicksilver.

By similar means, quicksilver was twice frozen by Mr. Hutchins, governor of Albany-fort, in Hudson's-bay, in the months of January and February of 1775. And the same was done on the 28th of January 1776, by Dr. Lambert Bicker, secretary of Rotterdam. The temperature of the atmosphere was then at $+2^{\circ}$; and the lowest it could reduce the thermometer by artificial cold, was -94 ; when, on breaking the glass, the mercury was found congealed.

In the beginning of the year 1780, M. Von Elterlein of

Vytegra, a town of Russia, in lat. 61° north, and long. 36° east, froze quicksilver by natural cold. On the 4th of January 1780, the cold being increased to -34 that evening at Vytegra, he exposed to the open air 3 ounces of very pure quicksilver in a china teacup, covered with paper pierced full of holes. Next day, at 8 in the morning, he found it solid, and looking like a piece of cast lead, with a considerable depression in the middle. On attempting to loosen it in the cup, his knife raised shavings from it as if it had been lead, which remained sticking up; and at length the metal separated from the bottom of the cup in one mass. He then took it in his hand to try if it would bend: it was stiff like glue, and broke into two pieces; but his fingers immediately lost all feeling, and could scarcely be restored in an hour and a half by rubbing them with snow. At 8 o'clock the thermometer stood at -57 ; but half after 9 it was risen to -40 ; and then the two pieces of mercury which lay in the cup had lost so much of their hardness, that they could no longer be broken, or cut into shavings, but resembled a thick amalgam, which, though it became fluid when pressed by the fingers, immediately afterwards resumed the consistence of pap. With the thermometer at -39 , the quicksilver became fluid. The cold was never less on the 5th than -28 , and by 9 in the evening it had increased again to -33 . This experiment seems to fix the freezing point of mercury at -40 of Fahrenheit's thermometer, or 40 below 0 ; which is 72° below the freezing point of water.

During the winter of 1781 and -82 , Mr. Hutchins resumed the subject of freezing quicksilver by artificial cold, with such success, that from his experiments and those of M. Von Elterlein, last mentioned, the freezing point of mercury is now almost as well settled, viz, at -40 , as that of water is at $+32$.

An instance of the natural congelation of quicksilver also occurred in Jemtland, one of the provinces of Sweden, on the 1st of January 1782; and lastly, on the 26th of the same month, Mr. Hutchins observed the same effect of the cold at Hudson's-bay; when he found that at the point of its freezing a mercurial thermometer stood at -40 , and a spirit thermometer at -30 .

On this subject, see the article COLD; see also the Philos. Trans. vol. 51, pa. 672; vol. 52, pa. 156; vol. 66, pa. 174; vol. 73, pa. 303 and 325; vol. 76, pa. 241; vol. 77, pa. 285; vol. 78, pa. 43; and several others, particularly vol. 79, pa. 199, &c, being experiments on the congelation of quicksilver in England, by Mr. Richard Walker, where he proves that mercury may be frozen not only in England in summer, but even in the hottest climate, at any season of the year, and without the application of ice or snow.

About the year 1810, Professor Leslie, of Edinburgh, simply by evaporation, succeeded in freezing water inclosed in an exhausted receiver, to promote a quick evaporation. The water is placed over an open vessel, containing sulphuric acid, which absorbs the vapour as it exhales from the water; the whole being inclosed within the receiver of an air-pump, the water cools as the exhaustion proceeds; and is ultimately changed into ice. Mr. Leslie afterwards succeeded in freezing mercury by a similar process; viz, by investing the bulb of a mercurial thermometer with a thin coat of ice, and exposing this to the joint effect of exhaustion and of sulphuric acid.

Dr. Marcet too has since effected the congelation of mercury with great facility and quickness, simply by sub-

stituting the evaporation of ether, instead of that of water, in the process. See the particulars in Nicholson's Journal, vol. 34, p. 119.

Dr. W. H. Wollaston has even succeeded in freezing water at a distance from the mixture. His method consists of a tube, with a ball at each end, bent at right angles: one of the balls contains a little water; and the remainder of the space is to be as perfect a vacuum as can be obtained. When this instrument has been successfully exhausted, if the empty ball be immersed in a freezing mixture of salt and snow, the water in the other ball, though at the distance of 2 or 3 feet, will be frozen solid in the course of a very few minutes. The vapour contained in the empty ball is condensed by the common operation of cold, and the vacuum produced by this condensation gives opportunity for a fresh quantity to arise from the opposite ball, with proportional reduction of its temperature. See Philos. Trans. 1813, pt. 1.

FREEZING Point, denotes the point or degree of cold, shown by a mercurial thermometer, at which certain fluids begin to freeze, or, when frozen, at which they begin to thaw again. On Fahrenheit's thermometer, this point is at $+32$ for water, and at -40 for quicksilver; these fluids congealing at those two points respectively. It would also be well if the freezing points for other fluids were ascertained, and the whole arranged in a table.

It may here be proper to remark, that though the freezing point of water be 32° , yet it may be cooled down in favourable circumstances considerably below that temperature, before it begins to shoot into crystals. Experiments were made on this subject by Mairan and Fahrenheit; but it is to Sir Charles Blagden that we are indebted for the fullest investigation of it. He succeeded in cooling water down to 21° before it froze, by exposing it slowly to the action of freezing mixtures. The experiment succeeds best when the water tried is well purged of its air. It ought also to be transparent; for opaque bodies floating therein cause it to shoot into crystals when only a few degrees below the freezing point. When a piece of ice is thrown into water thus cooled, it causes it instantly to shoot out into crystals. The same effect is produced by throwing the liquid into a tremulous motion; but not by stirring it. It freezes also when cooled down too suddenly.

FREEZING Rain, or Raining Ice, a very uncommon sort of shower which sometimes falls during winter. A remarkable shower of this kind happened in December 1672, in the west of England: of which some accounts are given in the Philos. Transact. No. 90. This rain, as soon as it touched any thing above ground, as a bough, or the like, immediately settled into ice; and by enlarging and multiplying the icicles, it broke all down with its weight. The rain that fell on the snow, immediately congealed, without sinking in the snow at all. It made also an amazing destruction of trees, beyond any thing in all history. "Had it concluded with some gust of wind," said a gentleman on the spot, "it might have been of terrible consequence. Having weighed the sprig of an ash-tree, the wood of which was just three quarters of a pound, the ice upon it amounted to 16 pounds. Some were frightened with the noise in the air; till they discerned it was the clatter of icy boughs dashing against each other." Dr. Beale observes, that there was no considerable frost perceived on the ground during the whole of the shower; from which he concludes, that a frost may be very fierce and dangerous on the tops of some hills, while

in other places it keeps at some feet above the ground; and may wander about very furiously in some places, and be remiss in others not far off. This rain was followed by glowing heats, and a great forwardness of vegetation.

FRENICLE (BERNARD), a celebrated French mathematician of the 17th century. He was the contemporary and companion of Descartes, Fermat, and the other learned mathematicians of their time. He was admitted Geometrician of the French Academy in 1666; and died in 1675. Frenicle had many papers inserted in the Ancient Memoirs of the Academy, of 1666, particularly in vol. 5 of that collection, viz. 1. A method of resolving problems by Exclusions.—2. Treatise of right-angled Triangles in Numbers.—3. Short tract on Combinations.—4. Tables of Magic Squares.—5. General method of making Tables of Magic Squares.

FRESCO, is a sort of painting which is made upon the plastering of walls before it is dry.

FRIABILITY, the quality of a body that is friable.

FRIABLE, a quality of bodies by which they are rendered tender and brittle, easily crumpled or reduced to powder between the fingers; their force of cohesion being such as easily exposes them to such solution. Such are pumice, and all calcined stones, burn alum, &c.

It is supposed that friability arises from hence, that the body consists wholly of dry parts irregularly combined, and which are readily separated, as having nothing uncouth or glutinous to bind them together.

FRICITION, the act of rubbing or grating the surfaces of bodies against or over each other, called also attrition.—The phenomena arising from the friction of divers bodies, under different circumstances, are very numerous and considerable. Mr. Hawksbee gives a number of experiments of this kind; particularly of the attrition or friction of glass, under various circumstances; the result of which was, that it yielded light, and became electrical. Indeed all bodies by friction are brought to conceive heat; many of them to emit light; particularly a cat's back, sugar, beaten sulphur, mercury, sea-water, gold, copper, &c, but above all diamonds, which when briskly rubbed against glass, gold, or the like, yield a light equal to that of a live coal when blown by the bellows.

FRICITION, in Mechanics, denotes the resistance a moving body meets with from the surface on which it moves.

Friction arises from the roughness or asperity of the surface of the body moved on, and that of the body moving: for such surfaces consisting alternately of eminences and cavities, either the eminences of the one must be raised over those of the other, or they must be both broken and worn off: but neither can happen without motion, nor can motion be produced without a force impressed. Hence the force applied to move the body is either wholly or partly spent on this effect; and consequently there arises a resistance, or friction, which will be greater as the eminences are greater, and the substance the harder; and as the body, by continual rubbing, becomes more and more polished, the friction in consequence diminishes.

As the friction is less in a body that rolls, than when it slides, hence in machines, less the friction should employ a great part of the power, care is to be taken that no part of the machine slide along another, if it can be avoided; but rather that they roll, or turn upon each other, or at least slide as little as possible. With this view it may be proper to lay the axes of cylinders, not in a groove or concave matrix, as usual, but between two checks forming an

angle, or on an horizontal support and between two upright pins; or best of all between little wheels, called friction wheels, moveable on their respective axes: for by this contrivance, the friction is transferred from the circumference of those wheels to their pivots, and is so much less as these are smaller. In like manner the attrition or resistance may be still farther diminished, by making the axis of those wheels rest upon other friction wheels that turn round with them. This was long since recommended by P. Casabas; and experience confirms the truth of it. Hence also it is, that a pulley moveable on its axis resists less than if it were fixed, and the cord sliding over the circumference. And the same may be observed of the wheels of coaches, and other carriages. Indeed about 40 years ago friction balls or rollers were placed within the naves of carriage-wheels by some persons, particularly a Mr. Varlo; and lately Mr. Garnett had a patent for an improved manner of applying friction wheels to any axis, as of carriage-blocks or pulleys, scale beams, &c, in which the inclosed wheels or rollers are kept always at the same distance by connecting rods or bars.

From these principles, with the assistance of the higher geometry, Olaus Roemer determined the figure of the teeth of wheels, that should make the least resistance possible, which he found should be epicycloids. And the same was afterwards demonstrated by Lahire, and Camus.

M. Amontons by experiment attempted to settle a foundation for the precise calculation of the quantity of friction; which M. Parent endeavoured to confirm from reasoning and geometry. Amontons' principle is, that the friction of two bodies depends only on the weight or force with which they press each other, being always more or less in proportion to that pressure; esteeming it a vulgar error, that the quantity of friction has any dependence on the extent of the surface that is rubbed, or that the friction increases with the surface; arguing that it will require the same weight to draw along upon a plane, a piece of wood on its narrow edge, as on its broad and flat side; because, though on the broad side there be 4 times the number of touching particles, yet each particle is pressed with but $\frac{1}{4}$ of the weight bearing on those of the narrow side; and since 4 times the number multiplied by $\frac{1}{4}$ of the weight is equal to $\frac{1}{4}$ of the number multiplied by 4 times the weight, it is plain that the effect, that is, the resistance, is equal in both cases, and therefore requires the same force to overcome it.

On the first proposal of this paradox, M. Lahire very properly had recourse to experiments, as the best test, had they been judiciously performed: such as they were, however, they succeeded in favour of this system. He laid several pieces of unpolished wood on a rough table, whose sizes were unequal; and afterwards placed weights on them, so as to render them all equally heavy: and he found that the same precise force, or weight, applied to them by a small pulley, was required to put each in motion, notwithstanding the inequality of the surfaces. The experiment succeeded in the same manner with pieces of marble, on a marble table. After this, by reasoning, M. Lahire gave a physical solution of the effect. And M. Amontons settled a calculus of the value of friction, with the loss sustained by it in machines, on the foundation of this new principle. In wood, iron, lead, and brass, which are the chief materials used in machines, he makes the resistance caused by friction to be nearly the same in all, when those materials are anointed with oil or fat; and the quantity of

this resistance; independent of the magnitude of the surface, he finds nearly equal to a third part of the weight of the body moved, or of the force with which the two bodies are pressed together. Others have asserted that if the surfaces be hard and well polished, the friction will be less than a third part of the weight; but if the parts be soft or rugged, it will be much greater. It was farther observed, that in the cylinder moved on two small gudgeons, or on a small axis, the friction would be diminished in the same proportion as the diameter of these gudgeons is less than the diameter of the cylinder; because in this case, the parts on which the cylinder moves and rubs, will have less velocity than the power which moves it in the same proportion, which is in effect making the friction to be proportional to the velocity. So that, from the whole of their observations, this general proposition is deduced, viz., That the resistances arising from friction, are to each other in a ratio compounded of the pressures of the rubbing parts, and the velocities of their motions. Principles which, it is now known from better experiments, are both erroneous; notwithstanding the hypothesis of M. Amontons has been adopted, and attempted to be confirmed by Camus, Desaguliers, and others.

M. Muschenbroek and the abbé Nollet, however, on the other hand, have concluded from experiments, that the friction of bodies depends on the magnitude of their surface, as well as on their weight. Though the former observes, that in small velocities the friction varies very nearly as the velocity, but that in great velocities the proportion increases faster: he has also attempted to prove, that by augmenting the weight of a body, the friction does not always increase exactly in the same ratio. *Introd. ad Phil. Nat. vol. 1, c. 9;* and *Lect. Phys. Exp. tom. 1, p. 241.* Heslham and Ferguson, from the same kind of experiments, have endeavoured to prove, that the friction does not vary by changing the quantity of surface on which the body moves; and the latter of these asserts, that the friction increases very nearly as the velocity; and that by increasing the weight, the friction is also increased in the same ratio. Indeed there is scarce any subject of experiment, with regard to which, different persons have formed such various conclusions. Of those who have written on the theory, no one has established it altogether on true principles, till the experiments lately made by Mr. Professor Vince of Cambridge: Euler, whose theory is extremely elegant, and would have been quite satisfactory had his principles been founded on good experiments, supposes the friction to vary in proportion to the velocity of the body, and its pressure upon the plane; neither of which is true: and others, though they have justly imagined that friction is uniformly retarding force, have yet retained the other supposition, and so rendered their solutions not at all applicable to the cases for which they were intended.

For these reasons a new and ingenious set of experiments was successfully instituted by the Rev. Mr. Vince, Plumian Professor of Astronomy and Experimental Philosophy in the university of Cambridge, which are published in the 75th vol. of the *Philos. Trans.* p. 165. The object of these experiments was to determine, 1st, Whether friction be a uniformly retarding force.—2d, The quantity of friction.—3d, Whether friction varies in proportion to the pressure or weight.—4th, Whether the friction be the same, on whichever of its surfaces a body moves.

The professor says, "The experiments were made with the utmost care and attention, and the several results

agreed so very exactly with each other, that I do not scruple to pronounce them to be conclusive."—"A plane was adjusted parallel to the horizon, at the extremity of which was placed a pulley, which could be elevated or depressed in order to render the string which connected the body and the moving force parallel to the plane or horizon. A scale accurately divided was placed by the side of the pulley perpendicular to the horizon, by the side of which the moving force descended; on the scale also was placed a moveable stage, which could be adjusted to the space through which the moving force descended in any given time, which time was measured by a well regulated pendulum clock vibrating seconds. Every thing being thus prepared, the following experiments were made to ascertain the law of friction. But let me first observe, that if friction be a uniform force, the difference between it and the given force of the moving power must be also uniform, and therefore the moving body must descend with a uniformly accelerated velocity, and consequently the spaces described from the beginning of the motion must be as the squares of the times, just as when there was no friction, only they will be diminished on account of the friction." Accordingly the experiments are then related, which are performed agreeably to these ideas, and from them are deduced these general conclusions, which may be considered as established and certain facts or maxims, viz.,

1st, That friction is a uniformly retarding force in hard bodies; and is not subject to alteration by the velocity; except when the body is covered with cloth, woollen, &c, in which case the friction increases a little with the velocity.

2dly, Friction increases in a less ratio than the quantity of matter, or weight of the body. This increase however is different for the different bodies, more or less; nor is it yet sufficiently known, for any one body, what proportion the increase of friction bears to the increase of weight.

3dly, The smallest surface has the least friction; the weight being the same. But the ratio of the friction to the surface is not yet accurately known.

It is observed, that the professor's experiments consisted in determining how far the sliding bodies would be drawn, in given times, by a weight hanging freely over a pulley. This method would both show him if the friction were a constant retarding force, and the other conclusions above stated. For, as the spaces described by any constant force, in given times, are as the squares of the times; and as the weight drawing the body is a constant force, if the friction, which acts in opposition to the weight, should also be a constant force, then their difference, or the force by which the body is urged, will also be constant, in which case the spaces described ought to be as the squares of the times; which happened accordingly in the experiments.

Mr. Vince adds some remarks likewise on the nature of the experiments which have been made by others. These, he observes, the authors "have instituted, to find what moving force would just put a body at rest, in motion: and they concluded from thence, that the accelerative force was then equal to the friction; but it is manifest, that any force which will put a body in motion must be greater than the force which opposes its motion, otherwise it could not overcome it; and hence, if there were no other objection than this, it is evident that the friction could not be very accurately obtained; but there is another objection, which totally destroys the experiment, so far as it tends to show the quantity of friction, which is, the strong cohesion of the body to the plane when it lies

at rest." This he confirms by several experiments, and then adds, " From these experiments therefore it appears, how very considerable the cohesion was, in proportion to the friction when the body was in motion : it being, in one case almost $\frac{1}{2}$, and in another it was found to be very nearly equal to the whole friction. All the conclusions therefore deduced from the experiments, which have been instituted to determine the friction from the force necessary to put a body in motion (and I have never seen any described but upon such a principle) have manifestly been totally false ; as such experiments only show the resistance which arises from the cohesion and friction conjointly." *Philos. Trans.* vol. 75, pa. 165.

Emerson, in his Principles of Mechanics, deduces from experiments the following remarks relating to the quantity of friction : When a cubic piece of soft wood, of 8 pounds weight, moves upon a smooth plane of soft wood, at the rate of 3 feet per second, its friction is about $\frac{1}{2}$ of the weight ; but if the plane be rough, the friction is little less than half the weight : on the same supposition, when both the pieces of wood are very smooth, the friction is about $\frac{1}{8}$ of the weight : the friction of soft wood on hard, or of hard wood upon soft, is $\frac{1}{2}$ or $\frac{1}{3}$ of the weight ; of hard wood upon hard wood, $\frac{1}{3}$ or $\frac{1}{4}$; of polished steel moving on steel or pewter, $\frac{1}{2}$; moving on copper or lead, $\frac{1}{5}$ of the weight. He observes in general, that metals of the same kind have more friction than those of different kinds ; that lead makes much resistance ; that iron or steel running in brass makes the least friction of any ; and that metals oiled make the friction less than when polished, and twice as little as when unpolished. Desaguliers also observes that, in M. Camus's experiments on small models of sledges in actual motion, there are more cases in which the friction is less than where it is more than $\frac{1}{2}$ of the weight. See a table, exhibiting the friction between various substances, formed from his experiments in *Desag. Exp. Philos.* vol. 1, pa. 193 &c; also pa. 133 to 138, and pa. 182 to 254, and pa. 458 to 460. On the subject of friction, see several vols. of the *Philos. Trans.* as vol. 1, pa. 206 ; vol. 34, pa. 77 ; vol. 37, pa. 394 ; vol. 53, pa. 139, &c.

FRIDAY, the 6th day of the week, so called from Friga, or Friya, a goddess worshipped by the Saxons on this day. It is a fast-day in the church of England, in memory of our Saviour's crucifixion, unless Christmas-day happen to fall on Friday, which is always a festival.

Good FRIDAY, the Friday next before Easter, representing the day of our Saviour's crucifixion.

FRIGID Zone, the space about either pole of the earth to which the sun never rises for one whole day at least in their winter. These two zones extend to about $23\frac{1}{2}$ degrees every way from the pole considered as their centre.

FRIGORIFIC, in Physics, something belonging to, or that occasions cold.—Some philosophers, as Gassendus, and other corpuscularians, denying cold to be a mere privation, or absence of heat, contend that there are actual frigorific corpuscles or particles, as well as fiery ones : whence proceed cold and heat. But later philosophers allow of no other frigorific particles beside those nitrous salts, &c, which float in the air in cold weather, and occasion freezing.

FRISI, or **FRISIUS** (**GEMMA**), appears to have been a native of the Flemish Netherlands, and flourished the beginning of the 16th century. As Werner had proposed to find the longitude by observations on the moon ; so

Gemma Frisi, in a tract entitled, *De Principiis Astronomiae et Cosmographiae*, printed at Antwerp 1530, advised keeping the time by means of small clocks or watches, for the purpose, then, as he says, lately invented. He also contrived a new kind of cross-staff, described in his treatise *De Radio Astronomico et Geometrico*, printed at the same place 1545, and in his additions to Peter Apian's *Cosmography*, gives the figure of an instrument, he calls a nautical quadrant, as very useful in navigation, promising to write largely on the subject : accordingly, in an edition he made in the year 1553, of his above mentioned book, *De Principiis Astronomiae, &c*, he delivers several nautical axioms, as he calls them, which with some alterations were repeated by his son Cornelius Gemma, in the father's posthumous piece on the *Universal Astrolabe*, published in 1556.—Gemma Frisi died in 1555, at 45 years of age.

FRIZE, **FRIEZE**, or **FREEZE**, in Architecture, a part of the entablature of columns, between the architrave and cornice.

FRONT, in Architecture, denotes the principal face or side of a building ; or that presented to their chief aspect or view.

FRONT, in Perspective, a projection or representation of the face, or forepart of an object, or of that part directly opposite to the eye, called also more usually *Orthography*.

FRONTISPICE, in Architecture, the portale, or principal face of a fine building.

FRONTON, in Architecture, an ornament among us more usually called *Pediment*.

FROST, such a state of the atmosphere as causes the congelation or freezing of water, or other fluids into ice.

The nature and effects of frost in different countries, are mentioned under the articles *CONGELATION*, and *FREEZING*. In the more northern parts of the world, even solid bodies are affected by frost, though this is only or chiefly in consequence of the moisture they contain, which being frozen into ice, and so expanding as water is known to do when congealed, it bursts and lacerates any thing in which it is contained, as plants, trees, stones, and large rocks. Some fluids expand by frost, as water, which expands about $\frac{1}{10}$ th part of its natural bulk, for which reason ice floats in water ; but others again contract, as quicksilver, and hence frozen quicksilver sinks in the fluid metal.

Frost, being derived from the atmosphere, naturally proceeds from the upper parts of bodies downwards, as the water and the earth : so, the longer a frost is continued, the thicker the ice becomes upon the water in ponds, and the deeper into the earth the ground is frozen. In about 16 or 17 days frost, Mr. Boyle found it had penetrated 14 inches into the ground. At Moscow, in a hard season, the frost will penetrate 2 feet deep in the ground ; and Capt. James found it penetrated 10 feet deep in Charlton-island, and the water in the same island was frozen to the depth of 6 feet. Scheffler assures us, that in Sweden the frost pierces 2 cubits, or Swedish ells, into the earth, and turns what moisture is found there into a whitish substance, like ice ; and standing waters to 3 ells, or more. The same author also mentions sudden cracks or rifts in the ice of the lakes of Sweden, 9 or 10 feet deep, and many leagues long ; the rupture being accompanied with a noise not less loud than if many guns were discharged together. By such means, however, the fishes are furnished with air ; so that they are rarely found dead.

The several natural histories of frosts furnish very ex-

traordinary effects of them. The trees are often scorched, and burnt up, as with the most excessive heat; and split or shattered. In the great frost in 1683, the trunks of oak, ash, walnut, &c, were miserably split and cleft, so that they might be seen through, and the cracks often attended with dreadful noises like the explosion of fire-arms. Philos. Trans. No. 105.

The close of the year 1708, and the beginning of 1709, were remarkable, through the greatest part of Europe, for a severe frost. Dr. Durham says, it was the greatest in degree, if not the most universal, in the memory of man; extending through most parts of Europe, though scarcely felt in Scotland or Ireland.

In very cold countries, meat may be preserved by the frost 6 or 7 months, and prove tolerably good eating. See Capt. Middleton's observations made in Hudson's-bay, in the Philos. Trans. No. 465, sect. 2. In that climate the frost seems never out of the ground, it having been found hard frozen in the two summer months. Brandy and spirit of wine, placed in the open air, congeal to solid ice in 3 or 4 hours. Lakes and standing waters, not above 10 or 12 feet deep, are frozen to the ground in winter, and all their fish perish. But in rivers, where the current of the tide is strong, the ice does not reach so deep, and the fish are preserved. Id. ib. Some remarkable instances of frost in Europe, and chiefly in England, are recorded as below; In the year

- 220, Frost in Britain that lasted 5 months.
- 250, The Thames frozen 9 weeks.
- 291, Most rivers in Britain frozen 6 weeks.
- 359, Severe frost in Scotland for 14 weeks.
- 508, The rivers in Britain frozen for 2 months.
- 558, The Danube quite frozen over.
- 695, Thames frozen 6 weeks; booths built on it.
- 759, Frost from Oct. 1 till Feb. 26, 760.
- 827, Frost in England for 9 weeks.
- 859, Carriages used on the Adriatic sea.
- 908, Most rivers in England frozen 2 months.
- 923, The Thames frozen 13 weeks.
- 987, Frost lasted 120 days: began Dec. 22.
- 998, The Thames frozen 5 weeks.
- 1035, Severe frost on June 24: the corn and fruits destroyed.
- 1063, The Thames frozen 14 weeks.
- 1076, Frost in England from Nov. till April.
- 1114, Several wooden bridges carried away by ice.
- 1205, Frost from Jan. 14 till March 22.
- 1407, Frost that lasted 15 weeks.
- 1434, From Nov. 24 till Feb. 10. Thames frozen down to Gravesend.
- 1683, Frost for 13 weeks.
- 170⁸, Severe frost for many weeks.
- 1715, The same for many weeks.
- 1739, One for 9 weeks. Began Dec. 24.
- 1742, Severe frost for many weeks.
- 1747, Severe frost in Russia.
- 1754, Severe one in England.
- 1760, The same in Germany.
- 1776, The same in England.
- 1788, Thames frozen below bridge; booths on it.
- 1794, Hard frost of many weeks.
- 1813, Severe frost from the middle of December to the middle of March 1814. The Thames from Blackfriars to London bridge, completely frozen over, booths and thousands of people upon it.

Hoar Frost, is the dew frozen or congealed, early in cold mornings; chiefly in autumn: though many Cartesians will have it formed of a cloud; and either congealed in the cloud, and so let fall; or ready to be congealed as soon as it arrives at the earth.

This kind of frost, M. Regis observes, consists of an assemblage of small parcels of ice crystals; which are of various figures, according to the different disposition of the vapours, when met and condensed by the cold.

FRUSTUM, in Geometry, is the part of a solid next the base, left by cutting off the top, or segment, by a plane parallel to the base: as the frustum of a pyramid, of a cone, of a conoid, of a spheroid, or of a sphere, which is any part comprised between two parallel circular sections; and the middle frustum of a sphere, is that whose ends are equal circles, having the centre of the sphere in the middle of it, and equally distant from both ends.

For the Solid Content of the Frustum of a cone, or of any pyramid, whatever figure the base may have. Add into one sum, the areas of the two ends and the mean proportional between them; then $\frac{1}{3}$ of that sum will be a mean area, or the area of an equal prism, of the same altitude with the frustum; and consequently that mean area being multiplied by the height of the frustum, the product will be the solid content of it.

That is, if a denote the area of the greater end, a' that of the less, and h the height;

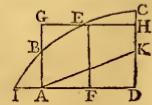

$$\text{then } (a + a' + \sqrt{aa'}) \times \frac{1}{3}h \text{ is the solidity.}$$

Other rules for pyramidal or conic frustums may be seen in my Mensuration, part 3.

The curve Surface of the Zone or Frustum of a sphere, is had by multiplying the circumference of the sphere by the height of the frustum. Mensur. pa. 146.

And the Solidity of the same Frustum is found, by adding together the squares of the radii of the two ends, and $\frac{1}{3}$ of the square of the height of the frustum, then multiplying the sum by the said height and by the number 1·5708. That is $(r^2 + r'^2 + \frac{1}{3}h^2) \times \frac{4}{3}\pi ph$ is the solid content of the spheric frustum, whose height is h , and the radii of its ends r and r' , p being = 3·1416. Mensur. pa. 152.

For the frustums of spheroids, and conoids, either parabolic or hyperbolic, see Mensur. part 3. sect. 5, 6, 7. And in pa. 352, &c, are general theorems concerning the frustum of a sphere, cone, spheroid, or conoid, terminated by parallel planes, when compared with a cylinder of the same altitude, on a base equal to the middle section of the frustum made by a parallel plane. The difference between the frustum and the cylinder is always the same quantity, in different parts of the same, or of similar solids, or whatever the magnitude of the two parallel ends may be; the inclination of those ends to the axis, and the altitude of the frustum being given; and the said constant difference is $\frac{1}{4}$ part of a cone of the same altitude with the frustum, and the radius of its base is to that altitude, as the fixed axis is to the revolving axis of the frustum. Thus, if BEC be any conic section, or a right line, or a circle, whose axis, or a part of it, is AD ; AB and CD the extreme ordinates, FE the middle ordinate, AF being = FD ; then taking as AD to DK , so is the whole fixed axis, of which AD is a part, to its conjugate axis; and completing the parallelogram $AGHD$: then if the whole figure revolve about the axis AD , the line BEC will generate the frustum of the cone or conoid, according as it

is a right line or a conic section, or it will generate the whole solid when AB vanishes, or A and B meet in the same point; likewise $AGHD$ will generate a cylinder, and ADK a cone: then is the 4th part of this cone always equal to the difference between the said cylinder generated by $AGHD$, and the solid or frustum generated by $ABCD$; having all the same altitude or axis AD .

In the parabolic conoid, this difference and the cone vanish, and the frustum, or whole conoid $ABCD$, is always equal to the cylinder $AGHD$, of the same altitude.—In the sphere, or spheroid, the frustum $ABCD$ is less than the cylinder $AGHD$, by $\frac{1}{3}$ of the cone AKD .—And, in the cone or hyperboloid, that frustum is greater than the cylinder, by $\frac{1}{3}$ of the said cone AKD , which is similar to the other cone BCD .

These relations are likewise true, whether the ends of the frustum are perpendicular or oblique to the axis. And the same will obtain for the frustum of any pyramid, whether right or oblique; and such a frustum of a pyramid will exceed the prism, of the same altitude, and on the middle section of the frustum, by $\frac{1}{3}$ of the same cone.

It has been observed, that the difference, or $\frac{1}{3}$ of the cone AKD , is the same, or constant, when the altitude and inclination of the ends of the frustum remain the same. But when the inclination of the ends varies, the altitude being constant; then the said difference varies so as to be always reciprocally as the cube of the conjugate to the diameter AD . And when both the altitude and inclination of the ends vary, the differential cone is as the cube of the altitude directly, and the cube of the said conjugate diameter reciprocally: but if they vary so, as that the altitude is always reciprocally as that diameter, then the difference is a constant quantity.

Another general theorem for Frustums, is this. In the frustum of any solid, generated by the revolution of any conic section about its axis, if to the sum of the two ends be added 4 times the middle section, $\frac{1}{6}$ of the last sum will be a mean area, which being drawn into the altitude of the solid, will produce the content. That is $(AB + DC + 4FE) \times \frac{1}{6} AD$ is the content of $ABCD$.—And this theorem is general for all frustums, as well as the complete solids, whether right or oblique to the axis, and not only of the solids generated from the circle or conic sections, but also of all pyramids, cones, and in short of any solid whose parallel sections are similar figures.—The same theorem also obtains for any parabolic area $ABCD$, and is very nearly true for the area of any other curve whatever, or for the content of any other solid than those above mentioned.

FUGUE, in music, is when the different parts of a musical composition follow each other, each repeating in order what the first had performed.

FULCRUM, or *Prop*, in Mechanics, is the fixed point about which a lever &c moves.

FULGURATING *Phosphorus*, a term used by some English writers, to express a substance of the phosphorus kind. It was prepared both in a dry and liquid state, but the preparation it appears was not well known to any but the inventor of it. This matter not only shone in the dark in both states, but communicated its light to any thing it was rubbed on. When inclosed in a glass vessel well stopped, it would frequently fulgurate, or throw out little flashes of light, and sometimes fill the whole phial with waves of flame. It does not require having its light recruited at the fire, or in the sunshine, like the phosphorus of the Bolognian stone, but of itself continues in a state of

shining for several years together, and is seen as soon as exposed in the dark; the solid or dry matter always resembling a burning coal of fire, though not consuming itself. Philos. Trans. No. 184.

FULGINOUS, an epithet applied to thick smoke or vapour replete with soot or other crass matter.—In the first fusion of lead, there exhales a great deal of fuliginous vapour, which being retained and collected, makes what is called Litharge. And lampblack is what is gathered from the fuliginous vapours of pines, and other resinous wood, when burnt.

FULMINANT, FULMINANS, or FULMINATING, a term applied to any thing thundering, or that makes a noise like thunder.

Aurum Fulminans. See AURUM.

Pulvis FULMINANS, is a composition of 3 parts of nitre, 2 parts of salt of tartar, and 1 of sulphur.—Both the aurum and pulvis fulminans produce their effect chiefly downwards; in which they differ from gun-powder, which acts in orbem, or all around, but principally upwards. When the composition is laid in brass ladles, and so set on fire, after fulmination, the ladles are often found perforated. It differs also from gunpowder in this, that it does not require to be confined, in order to fulminate, and it must be slowly and gradually heated. Some instants before explosion, a light blue flame appears on its surface, proceeding from the vapours beginning to kindle. No more fire or flame is perceived during the fulmination, being suffocated and extinguished by the quickness and violence of the combustion. Nor does the fulminating powder generally kindle the combustible bodies in contact with it, because the time of its inflammation is too short.

FULMINATING Damp. See DAMP.

FULMINATION, or FULGURATION, a vehement noise or shock resembling thunder, caused by the sudden explosion and inflammation of divers preparations; as aurum fulminans, &c, when set on fire.

FUNCTION, a term used in analytics, for an algebraical expression any how compounded of a certain letter or quantity with other quantities or numbers: and the expression is said to be a function of that letter or quantity. Thus $a - 4x$, or $ax + 3x^2$, or $2x - a\sqrt{(a^2 - x^2)}$, or x^c , or c^x , is each of them a function of the quantity x .

FUNCTIONS of *Calculus*, is that branch of analysis which treats of the doctrine of functions.

Landen, we believe, was the first who proposed to treat the method of fluxions as a branch of pure algebra, independently of any metaphysical considerations, or of such as are drawn from the principles of motion. Soon after him, M. Lagrange endeavoured to establish the analytical principles in a memoir published in the Berlin Acts for the year 1772: and a farther developement of his ideas was presented in 1796, under the title of *Theorie des Fonctions Analytiques*, a work in which it is the object of the author to fix the principles of the differential calculus, independently of the consideration of infinitely small, or vanishing quantities, of limits, or of flowing quantities. Another work also by M. Lagrange, entitled *Leçons sur le Calcul des Fonctions*, has since been published, which is meant to serve as a commentary and supplement to the first part of the *Theorie des Fonctions Analytiques*, and offers a course of analysis on that branch of modern calculus which is commonly called Infinitesimal or Transcendental, and which, in the estimation of this very distinguished mathematician, is alone properly the calculus of functions.

The following extract will suffice to convey an idea, both of the nature of analytic functions, and of part of the notation employed by this author.

"The earlier analysts (says Lagrange) have only employed the word functions to design the different powers of the same quantity; it was afterwards extended in signification to every quantity formed in any manner whatever from another quantity; and it is now generally adopted to denote that the value of a quantity depends, according to a given law, on one or many other given quantities.

"Under this point of view, algebra must be regarded as the science of functions; and it is easy to perceive that the resolution of equations consists, generally, in finding the values of the unknown quantities in determinate functions of known quantities. These functions represent, then, the different operations which must be performed on known quantities, to obtain the values of those which are sought, and they are, properly, only the ultimate result of the calculation.

"But, in algebra, we only consider the functions in as much as they result from arithmetical operations, generalized and transferred to the letters; while in the calculus of functions, properly speaking, we consider the functions which result from the algebraic operation of the development in series, when we attribute to one or to several quantities of the function indeterminate augmentations.

"The development of functions, viewed in a general manner, gives rise to derivative functions of different orders; and the algorithm of these functions once discovered, they may be considered in themselves and independent of the series whence they result. Thus, a given function being regarded as primitive, we may deduce, by simple and uniform rules, other functions which I call derivative; and when we have an equation between several variables, we may pass successively to the derivative equations, and return again from these to the primitive equations. These transformations correspond to differentiations and integrations; but in the theory of functions they depend alone on operations purely algebraical, founded on the simple principles of the calculus.

"The derivative functions present themselves naturally in geometry, when we consider areas, tangents, radii of curvature, &c.; and in mechanics, when we consider velocities and forces. If we regard, for example, the area of a curve as a function of the abscissa, the ordinate is then the first derivative function, or prime function; the relation of the ordinate to the subtangent is expressed by the prime function of the ordinate, and of consequence by the second derivative function or second function of the area; the radius of the osculatory circle depends on two prime derivative functions of the ordinate, and so of others. In like manner, regarding the space run over as a function of the time, the velocity is then the prime function, and the accelerating force is the second function. It is not perhaps one of the least advantages of the calculus of functions, that it furnishes for these elements of the geometry of curves, and of mechanics, expressions as simple and intelligible as are the algebraic expressions of powers and roots.

"When we consider a function with respect to one of the quantities which compose it, we make our abstraction of the value of that quantity, and consider it only as to the manner in which it enters the function; that is to say, in which it is combined with itself, and with the other quantities. Thus, the function is considered as remaining the same, while this quantity varies in any manner whatever,

provided that the other quantities with which it is blended remain constant: hence is introduced naturally, with respect to functions, the distinction of quantities into variable and constant quantities.

"In ordinary algebra, quantities are simply distinguished into known and unknown, and it is customary to denote the former by the first letters of the alphabet, and the other by the latter. The application of algebra to the theory of curves first caused the distinction of the quantities which enter the equation of a curve into given ones, such as the axes, the parameters, &c., and indeterminates, such as the co-ordinates. Afterwards these quantities became viewed under the more natural aspect of constant and variable quantities; and the consideration of functions leads us naturally to regard the quantities which compose them under the same point of view.

"We call therefore, simply, a function of one or of several quantities, every expression in which these quantities enter in any manner whatever, connected or not with other quantities considered as having given and invariable values, while the quantities of the functions are deemed capable of receiving all possible values.

"We ordinarily design the variable parts of functions by the final letters of the alphabet $x, y, \&c.$; and the constant parts by the initial letters $a, b, c, \&c.$. And to denote a function of a single variable x , we merely place before that quantity the characteristic letter f or φ ; but when we would design the function of a quantity already composed of that variable, as x^2 , or $a + bx$, &c., we include this quantity in a parenthesis. Thus $f(x)$ indicates a function of x , $f(x^2)$, $f(a + bx)$, &c., denote functions of x^2 and of $a + bx$.

"To express a function of two independent variables as x, y , we write $f(x, y)$, and so of others.

"If two functions of two different variables, x, y , that is to say, the one of x , the other of y , are composed in the same manner, and with the same constant quantities; these functions will be similar, and may be designed in the same investigation by the same characteristic, thus fx , and fy , will be two similar functions which become identical when $x = y$. But if, while the two functions are composed in the same manner, the constant quantities which they contain are different, then we can no longer, generally speaking, represent them by the same characteristic in the course of the same calculation. Still, however, if the two functions differ only, for example, by the value of a constant quantity, which will be a in the one, and b in the other, we may yet design them by the same characteristic, representing them by $f(x, a)$, and $f(y, b)$, as similar functions of x, a , and of y, b . Thus, in this case, the quantities a and b enter likewise into the expression of the function; since, though they are constant quantities in each function, they may be regarded as variables from one function to the other."

For other particulars of the notation of the Calculus of Functions, and the doctrine itself, we must refer the reader to the works of Lagrange already named, where he will find his curiosity for such researches amply satisfied. On the subject of functions, their divisions, transformations, explication by infinites, &c., see also Euler's "Analys. Infinitorum," c. 1, where this branch of analysis is likewise fully treated. See also preface to Woodhouse's Principles of Analytical Calculation, for many very proper remarks on the Theorie des Fonctions Analytiques of M. Lagrange.

FUNDAMENTAL, something that serves as a base or foundation for another.

FUNDAMENTAL, in *Music*. A fundamental sound is that which forms the lowest note of the chord, and from which are deduced the harmonical relations of the rest ; or it is that which serves for a key to the tone.

FUNDAMENTAL CHORD, is that which consists of the three fundamental consonances, the 3d, the 5th, and the 8th, or their inversions.

FUNDAMENTAL BASS, is that formed by the fundamental notes of every perfect chord that constitutes the harmony of the piece; so that under each chord it causes to be heard, or understood, the fundamental sound of that particular chord ; that is to say, the sound from which it is derived by the rules of harmony. Whence we may see, that the fundamental bass can have no other contexture than that of a regular and fundamental succession, without which the procedure of the upper parts would be illegitimate.

FUNICULAR CURVE, the same as the Catenary; which see.

FUNICULAR POLYGON, is that formed by a chain hanging freely by its extremities.

FURLONG, an English long-measure, containing 660 feet, or 220 yards, or 40 poles or perches, or the 8th part of a mile.

FURNITURE, in Dialling, certain additional points and lines drawn on a dial, by way of ornament : such as the signs of the zodiac, length of days, parallels of declination, azimuths, points of the compass, meridians of chief cities, Babylonian, Jewish, or Italian hours, &c.

FUSAROLE, in Architecture, a small round member cut in form of a collar, with oval beads, under the echinus, or quarter round, in the Doric, Ionic, and Composite capitals.

FUSEE, or **FUSY**, in Watch-work, is that part resembling a low cone with its sides a little sunk or concave, which is drawn by the spring, and about which the chain or string is wound.

The spring of a watch is the first mover. It is rolled up in a cylindrical box, against which it acts, and causes to turn round in unbending itself. The chain, which at one end is wound about the fusee, and at the other fastened to the spring-box, disengages itself from the fusee in proportion as the box is turned. And hence the motion of all the other parts of the spring-watch. The effort or action of the spring is continually diminishing from first to last ; and unless that inequality were rectified, it would draw the chain with more force, and wind a greater quantity of it on the box, at one time than another ; so that the movement would never keep equal time. To correct this irregularity of the spring, it was very happily contrived to have the spring applied to the arms of levers, which are continually longer as the force of the spring is weaker : this foreign assistance, always increasing as it is most needed, maintains the action and effect of the spring in an equality. It is for this reason then that the fusee

is made tapering somewhat conically, its radius at every point of the axis answering to the corresponding strength of the spring.

Now if the action of the spring diminished equally, as the parallels to the base of a triangle do ; the cone, which is generated of a triangle, would be the precise figure required for the fusee ; but it is certain that the weakening of the spring is not in that proportion ; and therefore the fusee should not be exactly conical ; and in fact experience shows that it should be a little hollowed about the middle, because the action of the spring is not there sufficiently diminished of itself.

M. Varignon has investigated the figure of the fusee, or the nature of the curve by whose revolution about its axis, shall be produced the solid whose figure the fusee is to have. This curve, it may easily be shown, is an hyperbola, whose asymptote is the axis of the fusee. Thus,

let $D E F$ be the curve of the fusee, its axis being

$A B C$: let $A D$ express the greatest strength of

the spring when the watch is quite wound up, or when the spring

acts at D , and $B G$ the least strength when the watch is

down, or when the spring acts at E ; so that as $B E : A D ::$

$A D : B G$, or $B E \times B G = A D^2$; join $D G$, producing it to

meet the axis produced in C ; then shall $H I$ denote the

strength of the spring acting at the corresponding point F of the fusee ; and the nature of it must be such that the

rectangle $H I \times H F$ be equal to a constant quantity, or

$H F$ must be reciprocally as $H I$, or $H I : B G :: B E : H F$;

but because $A D : B G :: H I : C A$, $H I$, $B G$,

are directly proportional to $C A$, $C H$, $C B$, therefore these are reciprocally propor. to $A D$, $H F$, $B E$;

and consequently the curve $D E F$ is an hyperbola, whose

centre is C , and asymptotes $A C$ and $K L$: so that the figure

of the fusee is the solid generated by an equilateral hyper-

bola about its asymptotic. See also Martin's Mathem.

Instit. vol. 2, pa. 364.

FUSE, **FUSE**, or **FUZE**, in Artillery, is a wooden tap or tube used to set fire to the powder in a bomb-shell.

The bore of this tube is filled with a composition, of sul-

phur one part, saltpetre 3 parts, and mealed powder 3, 4,

or 5 parts. The tube is driven hard into the hole in the

shell, having first cut it to the exact length, answering to

the time of the intended flight of the shell, so that, the

composition in the fuse catching fire by the discharge of

the shell from the mortar, it just burns down to its lower

end, and so sets fire to the powder in the shell, thereby

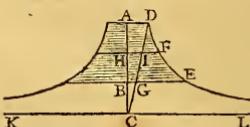

bursting it at the moment when it arrives at the end of its

range or flight.

FUST, in Architecture, the shaft of a column, or that

part comprehended between the base and the capital, called also the *Naked*.

FUZE, or **FUZEE**. See **FUSEE**.

G.

G A G

GABIONS, in Fortification, are large cylindrical baskets, open at both ends, made of osier twigs, of 3 or 4 feet in diameter, and from 3 to 6 feet high. These, being filled with earth, are sometimes used as merlons for the batteries, and sometimes as a parapet for the lines of approach; when the attacks are carried on through a stony or rocky ground, and to advance them with extraordinary vigour. They serve also to make lodgments in some posts, and to secure other places from the shot of the enemy; who, on their part, endeavour to burn and destroy the gabions, by throwing lighted pitch-faggots among them.

GABLE, or **GABLE-end**, of a house, is the upright triangular end, from the cornice or eaves to the top of its roof.

GAGE, in Hydrostatics, Pneumatics, &c, is an instrument for ascertaining measures of various kinds.

GAGE of the Air-pump, is adapted for showing the degree to which the air is rarefied, or the receiver is exhausted, at any time by the air-pump. This is either the common barometer-gage, both long and short, or the pear-gage, which at first was thought a great improvement, but afterwards it was discovered that its seeming accuracy was founded on a fallacy, which gave an erroneous indication of exhaustion. See *Air-pump*.

GAGE of the Barometer, is a contrivance for estimating the exact degree of the rise and fall of the mercury in the tube of that instrument. It is well known that while the mercury rises in the tube, it sinks in the cistern, and vice versa; and consequently, the divisions on the scale, fixed near the top of the tube, had their distance from the surface of the mercury in the cistern always various; from which there must often happen errors in determining the height of the mercury in the tube. To remedy this inconvenience, a line is cut upon a round piece of ivory, which is fixed near the cistern: this line is accurately placed at a given distance from the scale; for example, at 27 inches; and a small float of cork, with a cylindrical piece of ivory fixed to its upper surface, on which a line is cut at the exact distance of 2 inches from the under side of the cork, is left to play freely on the quicksilver, and the cylinder works in a groove made in the other piece. From this construction it appears, that if these marks are made to coincide, by raising or lowering the screw which acts on the quicksilver, then the divisions on the scale will express the true measure of the distance from the surface.

GAGE of the Condenser, is a glass tube of a particular construction, adapted to the condensing engine, and designed to show the exact density and quantity of the air contained at any time in the condenser. See Desaguliers's *Exper. Philos. vol. 2, pa. 394.*

Sea GAGE, an instrument for sounding the depth of the sea. Several kinds of these have been invented, by Dr. Hales, Dr. Desaguliers, and others. Formerly, the machines for this purpose consisted of two bodies, the one specifically lighter, and the other specifically heavier, than the water, so joined together, that as soon as the heavy one came to the bottom, the lighter should get loose from it, and emerge; and the depth was to be estimated by the time the compound was in falling from the top to

the bottom of the water, together with the time the lighter body was in rising, reckoned from the disappearing of the machine, till the emergent body was seen again. But no certain conclusion could be drawn from so precarious and incomplete an experiment.

But that invented by Drs. Hales and Desaguliers was of a more exact nature, depending on the pressure of the fluid only. For as the pressure of fluids, in all directions, is the same at the same depth, a gage which discovers what the pressure is at the bottom of the sea, will show what the true depth of the sea is in that place, whether the time of the machine's descent be longer or shorter.

Dr. Hales, in his *Vegetable Statics*, describes his gage for estimating the pressures made in opaque vessels; where honey being poured over the surface of mercury in an open vessel, rises upon the surface of the mercury as it is pressed up into a tube whose lower orifice is immersed into the honey and mercury, and whose top is hermetically sealed. Now, as by the pressure, the air in the tube is condensed, and the mercury rises, so the mercury comes down again when the pressure is taken off, and would leave no mark of the height to which it had risen; but the honey (or treacle, which does better) which is upon the mercury, sticking to the inside of the tube, leaves a mark, which shows the height to which it had risen, and consequently gives the quantity of pressure, and the height of the surface of the fluid.

Desaguliers's addition to this machine, consisted in a contrivance to carry it down to the bottom of the sea by means of a heavy weight, which was immediately disengaged by striking the bottom, and the gage, made very light for the purpose, re-ascented to the top.

Dr. Hales afterwards made more experiments of this kind, and proposed another sea gage for vast depths, which is described in the *Philos. Trans. No. 405*, and is to this effect. Suppose a pretty long tube of copper or iron, close at the upper end, to be let down into the sea, to any depth, the water will rise in the tube to a height bearing a certain proportion to the depth of the sea, to which the machine is sunk. And this proportion is as follows: 33 feet of sea water being nearly equal to the mean pressure of the atmosphere, therefore at 33 feet deep, the air in the tube will be compressed into half the length of the tube, or the water will rise and fill one half of the tube; in like manner, at 66 feet deep, the water will occupy $\frac{2}{3}$ of the tube; at 99 feet deep it will fill $\frac{3}{4}$ of the tube; and so on. Hence therefore, by knowing the height to which the water rises in the tube, there will be known the consequent depth of the sea.

But, in very great depths, the scale near the top of the tube would be so small, and the divisions so close, that there would be no accuracy in the experiment, unless the tube were of a very great length, and this again would render it both liable to be broken, and quite impracticable. To remedy this inconvenience, the Doctor made the following contrivance: To the bottom of the tube he screwed a large hollow globe of copper, with a small orifice, or a short pipe at bottom of the globe, to let in the

water; by which means he had a very great quantity of air, and the scale enlarged. See also Desagul. Exp. Phil. vol.2, pa. 224 and 241.

Bucket Sea GAGE, is an instrument contrived also by Dr. Hales, to find the different degrees of coolness and saltiness of the sea, at different depths. This gage consists of a common pail or bucket, with two heads; each of which has a round hole in the middle, about 4 inches in diameter, covered with square valves opening upward. That these heads may both open and shut together, there is a small iron rod, having one end fixed to the upper side of the lower valve, and the other end to the lower side of the upper valve: so that as the bucket descends with its sinking weight into the sea, both the valves may open by the force of the water, which by that means has a free passage through the bucket. But when the bucket is drawn up, then both the valves shut by the force of the water at the upper end of the bucket; and consequently the bucket will be filled with the lowest sea water to which it has descended, and immediately the mercurial thermometer, fixed within it, is examined, to see the degree of temperature; and the degree of saltiness is afterwards ascertained at leisure. Philos. Trans. No. 9, pa. 149, and No. 24, pa. 447.

Lord Charles Cavendish adapted a thermometer for the temperature of the sea water, at different depths. See Philos. Trans. vol. 50, pa. 300, and Phipps's Voyage towards the North Pole, pa. 142, &c.

Aquæ-mercurial GAGE, is the name of an apparatus contrived by Dr. Hales, and applied, in various forms, to the branches of trees, to determine the force with which they imbibe moisture. Vegetable Statics, vol. 1, ch. 2, pa. 84.

Sliding GAGE, a tool used by mathematical-instrument-makers, for measuring and setting off distances; consisting of a beam, tooth, sliding socket, and the shoulder of the socket.

Tide GAGE, an instrument used for determining the height of the tides, by Mr. Bayly, in the course of a voyage towards the south pole, &c., in the Resolution and Adventure, in the years 1772, 1773, 1774, and 1775. This instrument consisted of a glass tube, whose internal diameter was 7-10ths of an inch, lashed fast to a 10-foot fir rod, divided into feet, inches, and parts; the rod being fastened to a strong post fixed firm and upright in the water. At the lower end of the tube was an exceeding small aperture, through which the water was admitted. In consequence of this construction, the surface of the water in the tube was so little affected by the agitation of the sea, that its height was not altered the 10th part of an inch, when the swell of the sea was 2 feet; and Mr. Bayly was certain, that with this instrument he could discern a difference of the 10th of an inch in the height of the tide.

Water GAGE. See ALTITUDE, and HYDROMETER.

Wind GAGE, an instrument for measuring the force of the wind upon any given surface. Several of these gages are of former invention; but there is one lately invented by Dr. Lind, which is described in the Philos. Trans. vol. 65. See several also under the article ANEMOMETER.

GAGER. See GAUGER.

GAGING. See GAUGING.

GAJAXY, or Milky-Way, or Via Lactea, in Astronomy, that long, whitish, luminous track, which appears to encompass the heavens like a swath, scarf, or girdle; and which is easily seen in a clear night, especially when the

moon is not up. It is of a considerable, though unequal breadth; being also in some parts double, but in others single. The galaxy passes through many of the constellations in its circuit round the heavens, and keeps its exact place or position with respect to them.

There have been various strange and fabulous stories and opinions concerning the galaxy. The ancient poets, and even some of the philosophers, speak of it as the road or way by which the heroes went to heaven. But the Egyptians called it the Way of Straw, from the story of its rising from burning straw, thrown behind the goddess Isis in her flight from the giant Typhon. While the Greeks, who affect to derive every thing in the heavens from some of their own fables, have two origins for it; the one, that Juno, without perceiving it, accidentally gave suck to Mercury when an infant, but that as soon as she turned her eyes upon him, she forced him from her, and as the nipple was drawn from his mouth, the milk streamed about for a moment and formed the galaxy. The other relates, that the infant Hercules being laid by the side of Juno when asleep, on wakening she gave him the breast; but soon perceiving who it was, she threw him from her, and the heavens were marked by the wasted milk.

Other philosophers however gave it a different turn, and different origin: these esteemed it to be a tract of liquid fire, spread in this manner along the skies: and others again, supposing a celestial region beyond all that was visible, and imagining that fire, at some time let loose from thence, was to consume the world, made this a part of that celestial fire, and appealed to it as a presage of what would surely happen. This diffused brightness they considered as a crack in the vault or wall of heaven, and fancied this a glimmering of the celestial fire through it, and that there required nothing more than the undoing of this crack by some accident in nature, or by the will of the gods, to make the whole frame start, and let out the fire of destruction.

Aristotle makes the galaxy a kind of meteor, formed from a collection of vapours, drawn into that part by certain large stars disposed in the region of the heavens answering to it. Others, finding that the galaxy was perceived in most parts of the globe, that it always corresponded to the same fixed stars, and that it was situated far above the highest planets, set Aristotle's opinion aside, and placed the galaxy in the firmament or region of the fixed stars; thence concluding that it was nothing else but an assemblage of an infinite number of minute stars. And since the invention of telescopes, this opinion has been abundantly confirmed. For, by directing a good telescope to any part of the milky way, we perceive an innumerable multitude of very small stars, where before was only observed a confused whiteness, arising from the assemblage and union of their joint light; like as any thing powdered with fine white powder, at a distance we only observe the confused whiteness, but on examining it very near we perceive all the small particles of the powder separately; as Milton finely expresses it,

"A broad and ample road, whose dust is gold,
And pavement stars, as stars to thee appear,
Seen in the galaxy, that milky way,
Which mighty, as a circling zone thou seest
Powder'd with stars."

There are other similar appearances in the heavens; as the nebulae, or nebulous stars, and certain whitish parts about the south pole, called Magellanian clouds, which are

all of the same nature, appearing to be vast clusters of small stars when viewed through a telescope, which are too faint to affect the eye singly.

M. le Monnier however, not being able to discover more stars in this space, than in other parts of the heavens, disputes the opinion above recited, as to the reason of the whiteness, and supposes that this and the nebulous stars are occasioned by some other kind of matter. Inst. Ast. pa. 60. And Dr. Herschel has lately announced something of a similar opinion. See Philos. Trans. vol. 81, or my Abridg. vol. 17, pa. 18.

GALILEI (GALILEO), a most excellent philosopher, mathematician and astronomer, was born at Pisa in Italy, in 1564. From his infancy he had a strong propensity to philosophy and mathematics, which he indulged with such success that in 1592 he was chosen professor of mathematics at Padua. While he was professor there, visiting Venice, then famous for the art of glass-making, he heard that in Holland a glass had been invented, through which very distant objects were seen distinctly as if near at hand. This was sufficient for Galileo; his curiosity was raised, and his attention immediately engaged in considering what must be the form of such a glass, and the manner of making it. The result of his inquiry was the invention of the telescope, produced merely from this hint, without having seen the Dutch glass. All the discoveries he made in astronomy were easy and natural consequences of this invention, which opening a way, till then unknown, into the heavens, thence brought to light the finest discoveries. One of the first of these, was that of 4 of Jupiter's satellites, which he called the Medicean stars or planets, in honour of Cosmo the 2d, grand-duke of Tuscany, who was of that family. Cosmo sent for our astronomer from Padua, and made him professor of mathematics at Pisa in 1611; and soon after inviting him to Florence, gave him the office and title of principal philosopher and mathematician to his highness.

Our author had been but a few years at Florence, before the Inquisition began to be very troublesome concerning his opinions. Having observed some solar spots in 1612, he printed that discovery the following year at Rome; in which, and in some other pieces, he ventured to assert the truth of the Copernican system, and brought several new arguments to confirm it. For these he was cited before the Inquisition at Rome, in 1615: after some months imprisonment, he was released, and sentence pronounced against him, that he should renounce his heretical opinions, and not defend them by word or writing, or insinuate them into the minds of any persons. But having afterwards, in 1632, published at Florence his Dialogues of the two Great Systems of the World, the Ptolemaic and Copernican, he was again summoned before the holy-office, and committed to the prison of that ecclesiastical court at Rome. The inquisitors convened in June that year; and in his presence pronounced sentence against him and his books, obliging him to abjure his errors in the most solemn manner; committed him to the prison of their office during pleasure; and enjoined him, as a saving penance, for three years to come, to repeat once a week the seven penitential psalms; reserving to themselves, however, the power of moderating, changing, or taking away, altogether or in part, the said punishment and penance. On this sentence he was detained in prison till 1634; and his Dialogues of the System of the World were burnt at Rome.

Galileo lived ten years after this period; 7 of which were

employed in making still further discoveries with his telescope. But by the continual application to that instrument, added to an injury of sight from the nocturnal air, his eyes grew gradually weaker, till he became totally blind in 1639. He bore this calamity with patience and resignation, worthy of a great philosopher. The loss neither broke his spirit, nor stopped the course of his studies. He supplied the defect by constant meditation; by which means he prepared a large quantity of materials, and began to arrange them by dictating his ideas; when, by a distemper of three months continuance, wasting away by degrees, he expired at Arcetri near Florence, in January 1642, being the 78th year of his age.

Galileo was in his person of small stature, though of a venerable aspect, and vigorous constitution. His conversation was affable and free, and full of pleasantry. He took great delight in architecture and painting, and designed extremely well. He played exquisitely on the lute; and whenever he spent any time in the country, he took great pleasure in husbandry. His learning was very extensive; and he possessed in a high degree a clearness and acuteness of wit. From the time of Archimedes, nothing had been done in mechanical geometry, till Galileo, who being possessed of an excellent judgment, and great skill in the most abstruse points of geometry, first extended the boundaries of that science, and began to reduce the resistance of solid bodies to its laws. Besides applying geometry to the doctrine of motion, by which philosophy became established on a sure foundation, he made surprising discoveries in the heavens, by means of his telescope. He made the evidence of the Copernican system more sensible, when he showed, from the phases of Venus, like to those of the moon, that Venus actually revolves about the sun. He proved the rotation of the sun on his axis, from many observations on the spots contained on its surface; and thence the diurnal rotation of the earth became more credible. The satellites that attend Jupiter in his revolution about the sun, represented, in Jupiter's smaller system, a just image of the great solar system; and rendered it more easy to conceive how the moon might attend the earth, as a satellite, in her annual revolution. By discovering hills and cavities in the moon, and spots in the sun constantly varying, he showed that there was not so great a difference between the celestial bodies and the earth, as had been vainly imagined.

Our author likewise rendered no less service to science by treating, in a clear and geometrical manner, the doctrine of motion, which has justly been called the key of nature. The rational part of mechanics had been so much neglected, that hardly any improvement was made in it for almost 2000 years. But Galileo has given us fully the theory of equable motions, and of such as are uniformly accelerated or retarded, and of these two compounded together. He, first of any, demonstrated that the spaces described by heavy bodies, from the beginning of their descent, are as the squares of the times; and that a body, projected in any direction not perpendicular to the horizon, describes a parabola. These were the beginnings of the doctrine of the motion of heavy bodies, which has been since carried to so great a height by Newton. In geometry, he invented the cycloid, or irochoid; though the properties of this curve were afterwards chiefly demonstrated by his pupil Torricelli. He invented the simple pendulum, and made use of it in his astronomical experiments: he had also thoughts of applying it to clocks;

but did not execute that design : the glory of that invention was reserved for his son Vincenzo, who made the experiment at Venice in 1649; and Huygens afterwards carried the same to perfection. Our author was likewise projector of the machine, with which the Venetians render their Laguna fluid and navigable. He also discovered the gravity of the air, and endeavoured to compare it with that of water ; besides laying the foundation for several other inquiries in natural philosophy. In short, such was the character of this memorable genius, that he was not only esteemed and followed by philosophers, but was honoured by persons of the greatest distinction of all nations.

Galileo had scholars that were worthy of so great a master, by whom the gravitation of the atmosphere was fully established, and its varying pressure accurately and conveniently measured, by the column of quicksilver of equal weight sustained thereby in the barometrical tube. The elasticity of the air, by which it perpetually endeavours to expand itself, and, while it admits of condensation, resists in proportion to its density, was a phenomenon of a new kind (the common fluids having no such property), and was of the utmost importance to philosophy. These principles opened a vast field of new and useful knowledge, and explained a great variety of phenomena, which had been accounted for before that time in a very absurd manner. It seemed as if the air, the fluid in which men lived from the beginning, had been then but first discovered. Philosophers were every where busy inquiring into its various properties and their effects ; and valuable discoveries rewarded their industry. Of the great number who distinguished themselves on this occasion, may be mentioned Torricelli and Viviani in Italy, Pascal in France, Otto Guerick in Germany, and Boyle in England.

Our author wrote a number of treatises, many of which were published in his life-time. Most of them were also collected after his death, and published by Mendessi in 2 vols. 4to, under the title of *L'Opere di Galileo Galilei Lynceo*, in 1656. Some of these, with others of his pieces, were translated into English and published by Thomas Salisbury, in his Mathematical Collections, in 2 vols folio. A volume also of his letters to several learned men, and solutions of several problems, were printed at Bologna in 4to. His last disciple, Vincenzo Viviani, who proved a very eminent mathematician, methodized a work of his master's, and published it under this title, *Quinto libro de gli Elementi d'Eulidi, &c.* at Florence in 1674, 4to. Viviani published also other writings of Galileo, being extracts from his letters to a learned Frenchman, where he gives an account of the works which he intended to have published, and a passage from a letter of Galileo dated at Arcetri, Oct. 30, 1635, to John Camillo, a mathematician of Naples, concerning the angle of contact. Besides all these, he wrote many other pieces, which were unfortunately lost through his wife's devotion ; who, solicited by her confessor, gave him leave to peruse her husband's manuscripts ; of which he destroyed and took away as many as he said were unfit for publication.

GALLERY, in Architecture, a covered place in a building, much longer than broad; which is usually placed in the wings of the building, and serving to walk in as well as to place pictures. It denotes a small aisle, or walk, serving as a common passage to several rooms placed in a line, or row.

GALLERY, in Fortification, a covered walk, or passage,

made across the ditch of a besieged town, with timbers fastened in the ground and covered over.

GALLON, an English measure of capacity, for things both liquid and dry, containing 2 pottles, or 4 quarts, or 8 pints. But those pints and quarts, and consequently the gallon itself, are different, according to the quality of the things measured : the wine gallon, for instance, contains 231 cubic inches, and holds 8lb, $5\frac{1}{2}$ oz, avoirdupois, of pure water; the beer and ale gallon contains 282 cubic inches, and holds 10lb, $3\frac{1}{2}$ oz of water; and the gallon dry measure, for grain, meal, &c, contains $268\frac{1}{2}$ cubic inches, and holds 9lb, $11\frac{1}{2}$ oz of water.

GALLOPER, in Artillery, the name of a carriage serving for the very small guns, and having shafts so as to be drawn without a limber.

GALVANISM, one of the most interesting branches of modern philosophy, which derives its name from its illustrious discoverer, Professor Galvani, late of Bologna : it comprises all those electrical phenomena arising from the chemical agency of certain metals with different fluids.

The following circumstance is said to have given rise to this very curious branch of philosophical inquiry. Professor Galvani had long been considered as one of the most able lecturers in the university to which he belonged ; a character that he owed to his accurate knowledge of anatomy, chemistry, and other philosophical subjects: one day, while engaged in some experiments in his laboratory, a frog, which had been prepared for the purpose of making soup for his wife, who was sick, was laid on the same table where his electrical apparatus were placed ; when one of his assistants in the experiments, by accident or design, brought the point of a scalpel near the crural nerves of the frog, lying not far from the conductor. In an instant the muscles of its limbs were agitated with strong convulsions. The experiment was repeated, the fact ascertained, and a great many ingenious experiments were put in execution, by which he investigated the law of nature, of which accident had thus given him a glimpse ; and the success of his inquiries has immortalized his name.

This publication on the subject was printed for the institute at Bologna in 1791, entitled, *Aloysii Galvani de veribus Electricitatis in motu musculari Commentarius*; which work immediately excited the attention of philosophers both in Italy and in other countries ; and the experiments were repeated and extended. Galvani, soon after he had ascertained the power of electricity on the limbs of dead frogs, and other animals, was led to a further discovery, that a similar effect might be produced without the assistance of any visible electrical agent ; that is, by the mere action of a metallic substance ; and after making a number of experiments on this head, he ascertained, that the convulsions were produced only when dissimilar metals were employed. These experiments, as before observed, were repeated by many philosophers ; none, however, added any thing new to what Galvani had discovered, excepting the celebrated Volta, of whom we shall have frequent occasion to speak in the following pages : this great improvement took place in the year 1800 ; after which time, many other philosophers pursued this subject with very great success and applause ; and none with more than Professor Davy, of the Royal Institution : Dr. Wollaston and Mr. Nicholson likewise have done themselves considerable honour, by the number and accuracy of their experiments, and the consequent development of many new principles connected with this science ; and

Mr. Wm. Cruickshank, a celebrated English chemist, by his invention of the galvanic trough, seems to have furnished the means of increasing the power of the galvanic fluid to its greatest possible extent.

Having thus given a slight view of the discoverer and subsequent improvers of this interesting science, we shall proceed to explain, as much at length as our limits will admit, the nature of its action, and the principal experiments that are necessary, in order to form a connected idea of its several effects.

The discoveries of Galvani, as before observed, were made chiefly with dead frogs; the limbs of which, by means of electricity, acquired a tremulous motion, and generally a certain degree of extension; but this effect is likewise sensible, in a greater or less degree, on any other recently dead and skinned animal; though it is much more perceptible in cold-blooded creatures. The manner in which Dr. Galvani made his first experiments, was as follows: he skinned the legs of a frog recently dead, and left them attached to a small part of the spine, but separated from the rest of the body; and any other limb may be prepared in a similar manner; that is, the limb must be deprived of its integuments, and the nerve which belongs to it must be partly laid bare.

If the limbs thus prepared, for instance, the legs of a frog, be so situated, that a little electricity may pass through them, whether it be by the immediate contact of an electrical body, or by the action of an electric atmosphere; as when the preparation is placed within a certain distance of an electrical machine, and a spark is taken from the prime conductor; the prepared legs will be instantly affected with a kind of spasmodic contraction, and sometimes so strong as to jump a considerable way.

The like movements may be produced in the prepared animal, without the aid of any apparent electrical agent. In an animal recently dead, detach one end of a nerve from the surrounding parts, taking care to cut it not too near its insertion, into the muscle; remove the integuments from over the muscles that depend on that nerve; then take a piece of metal, as a wire, and touch the nerve with one extremity of it, and the muscles with the other extremity; on doing which, the prepared limbs will move in the same manner, as when electricity is made to pass through them. This, however, is not the most effectual way of forming the communication, though it will generally succeed; and the experiment will answer, whether the preparation be laid upon conductors, or on electrics. But if the communication between the nerve and the muscle be formed by nonconducting bodies, such as glass, wax, silk, &c., then no motion will ensue.

The conducting communication between the muscles and the nerve may consist of one or more pieces; and of the same, or, which is much better, of different bodies, connected together, as metals, water, a number of persons, and even of wood: but it must be observed, that the various bodies which form this circuit must be placed with full and perfect contact with each other, which is done by pressure, or by the interposition of water, &c. The less perfect conductors will answer only at first, when the prepared animal retains its vigour; but when the power begins to diminish, as it will after a few hours, then the more perfect conductors only will answer, and even these will produce various effects.

The most effectual way of producing those movements, is by the application of two metals, of which silver and

zinc seem to be rather the best; though silver and tin, or copper and zinc, and some other combinations, are not much inferior. If part of the nerve proceeding from a prepared limb be wrapped up in a piece of tinfoil, or only laid upon zinc; and a piece of silver laid with one end upon the bare muscle, and with the other on the above-mentioned tin or zinc; the motion of the prepared limb will be very vigorous. The two metals may be so placed, as not to be in contact with the preparation; but in any part of the circuit; which may be completed by means of other conductors, as water, &c.

In a similar manner, the action of the galvanic fluid may be made sensible on the human body. Thus, let a man lay a piece of metal, as zinc, upon his tongue; and a piece of some other metal, as silver, under his tongue; then by forming the communication between these two metals, either by bringing their outer edges in contact, or by the interposition of some other piece of metal, he will perceive a peculiar sensation, a kind of irritation, accompanied with a cool and subacid taste, not much unlike that which is produced by artificial electricity. The sensation seems to be more distinct, when the metals are of the usual temperature of the tongue; and on making the communication between the two pieces, the taste will be perceived more sensibly. The effect is rather more remarkable when the zinc touches the tongue in a small part, and the silver in a great portion of its surface, than when the contrary have place; that is, when the zinc touches more than the silver. Instead of the tongue, the two metals also may be placed in contact with the roof of the mouth, as far back as possible, and on completing the communication, a similar effect will be produced.

Different persons are variously affected with this application of metals; with some, the sensation of taste is so slight, as scarcely to be perceptible; while with others it is very strong, and even disagreeable.

The above experiment, which is one of the most simple that can be devised, was accidentally made about 60 years back, by a person of the name of Sultz, who stated the fact in the following terms. If a piece of lead, and a similar piece of silver, be laid together; and the edges of both be brought in contact with the tongue, a taste is perceived similar to that of vitriol of iron, at the same time that the metals applied separately produce no effect. The observer of this experiment does not appear to have been at all surprised with its result: for at that time the doctrine of vibrations was employed to explain all natural phenomena; and he therefore concluded, that some peculiar vibration took place on the application of the metals; and as every body was satisfied with this explanation, nothing further was thought of the experiment; and thus a prominent fact had slept in obscurity, from the time of Sultz to the time of Galvani.

Having seen how the galvanic operation may be made sensible to the taste, by a similar application it may be made visible to the sight; thus, let a person in a dark place, put a piece of tinfoil on the bulb of one of his eyes, and a piece of silver, as a spoon, or the like, in his mouth; then on completing the communication between the spoon, and the tinfoil, a faint flash of white light will appear before his eyes: but this experiment may be performed in a more convenient manner, by placing a piece of zinc between the upper lip and the gums, as high up as possible, and a silver piece of money on the tongue; for when the two metals are made to communicate, either by the imme-

diate contact of their edges, or by the interposition of good conductors, the flash of light will be visible as before; but by continuing the contact of the two metals, the appearance of light is not continued, it being only visible at the moment the contact takes place; and sometimes, though but rarely, at the instant of separation: it may therefore be repeated at pleasure, by disjoining, and again connecting the two metals.

For a considerable time after the first discovery made by Galvani, little more was known of its nature and its effects, than what is above stated; and it was doubtful, whether the convulsions in the animal's limbs, and the sensations produced upon the human body, were owing to an electrical property, peculiar to the animal parts, which it was thought might be conducted through the metals from one part to the other; or to a small quantity of electricity, which might be supplied by the metals themselves: Galvani himself was of the former opinion, and enthusiastic in the application of the electrical theory to animal economy; and particularly when he found the metallic substances were capable of exciting muscular motion, he was confirmed in his opinion, that the inherent electricity of the animal was transmitted from the nerve to the muscles by the metals employed.

About this time, however, Signior Volta took up the subject, adopting a theory of a different nature; which, though not strictly true, has contributed principally to its rapid advancement. Instead of supposing, as Galvani did, that the electricity belonged to the animal, he considered it as inherent in the different metals; which idea was truly fortunate for the cause of philosophy; for the very hypothesis of Galvani prevented him from deriving any farther knowledge of the science; because if the electricity belonged to the animal, no greater power was likely to be produced, than what two pieces of metal could effect; but on Volta's hypothesis, since he conceived the action to be in the metals; it followed, or at least it was highly probable, that by increasing their number, their effect would also be increased in the same proportion.

He therefore repeated the experiments of Galvani, and found that when two pieces of metal of different kinds were placed in different parts of an animal; at the same time that the metals were brought in contact, or were connected by a metallic arc; as often as the contact was made, convulsions were observed: he also found that the greatest effect was produced, when the metals were zinc and silver; and when several pieces of metals were employed, having pieces of wet cloth between them, the effect appeared to be increased as the number of pairs; and hence his idea of the pile.

This important discovery of accumulating the effects of this species of electricity, was made by Volta in 1800, and has hence been denominated the Voltaic pile. The apparatus first made by Volta, consisted of a number of pairs of zinc and silver plates, separated from each other by pieces of wet cloth, the arrangement being as follows; viz, zinc, silver, wet cloth; zinc, silver, wet cloth, and so on: the silver plates were chiefly silver coins, the plates of zinc, and pieces of wet cloth being of the same size; and he found the action of these combined pairs, to be much more powerful when the pieces of cloth were moistened with solution of common salt, instead of pure water: a pile consisting of forty pairs, he found to possess the power of giving a pretty smart shock, similar to that of a small electric jar; and that this effect took place, as

often as a communication was made between each end of the pile; and as long as the pieces of cloth remained moist. An account of this discovery was communicated to the Royal Society, and published in the Philosophical Transactions; but we do not hear of this celebrated philosopher making any farther discovery, after the invention of the pile, and ascertaining the nature and extent of its effects on animals.

A Voltaic pile similar to that we have been describing, is represented, plate vii, fig. 6; it consists of pieces of silver, about the size of half-crowns; pieces of zinc of an equal size; and pieces of cloth, or leather, or other bibulous substance, a little less in diameter than the metallic plates; these last being soaked in water, or any other proper fluid. These pieces are disposed in the order, silver, zinc, wet cloth; as indicated by the letters *s*, *z*, *w*; the pieces of cloth, or leather, must be well soaked in the fluid; but before they are applied, they should be squeezed, in order that the superfluous fluid may not run down the outside of the pile, or insinuate itself between the contiguous pieces of silver and zinc. Those pieces of cloth, particularly if soaked in plain water, lose their moisture very soon, so that they can seldom last longer than for a day or two, after which the pile must be decomposed, the metallic pieces cleaned, those of cloth soaked again; and the whole arranged as before.

The three rods *r*, *n*, *n*, are of glass, or of baked wood, the piece *o*, slides freely up and down the rods, which serves to prevent the falling of the plates: but when such a pile is to be very powerful, viz, to consist of many plates, the best method is to form two, three, or more piles; and to join them by pieces of metal, as *c*, *c*, fig. 5; where two piles are joined together, so that *a* is the negative extremity, and *b* is the other, or positive extremity of the whole arrangement, or of the two piles, considered as one; that is, *a* is a silver plate, and *b* the zinc. It may also be observed, that copper may be substituted for the silver, without much decrease of the effect.

It was with piles similar to what we have been describing, but consisting of a greater or less number of plates that galvanic experiments were first made in this country by Messrs. Nicholson and Carlisle, and many important chemical truths were developed by this means. At length Mr. Cruickshank, after having employed the Voltaic pile for various experiments, fell upon the happy idea of the galvanic trough. This consists of a box of baked wood, of a width and depth agreeable to the size of the plates, and of convenient length for handing about; the inside being furnished with grooves, passing across the side and bottom, for the reception of the metallic plates, and at such a distance, that when these are cemented into the grooves, the trough may be divided into a number of cells, about $\frac{3}{4}$ of an inch wide; each of the plates being compound; viz, consisting of two plates, one of zinc, and the other of silver or copper, soldered together; and the order in which they were placed was such, that all the zinc sides of the plates faced one way, and the copper sides the other: in fact, the trough was the pile placed horizontally, the cells being for the reception of a fluid, to answer the purpose of the pieces of wet cloth. The cementation of the metallic pieces into the sides and bottom of the vessel, must be so accurate, as not to permit the fluid to pass from one cell to another; the proper cement for this purpose being made, by melting together 5 parts of resin, 4 of bees-wax, and 2 parts of powdered red ochre:

two or more such batteries may be joined together, in order to increase the effect, as in the foregoing case of the double pile. See fig. 7, pl. vii, which represents a single battery; with its communicating rods.

The action of all these batteries is the greatest, when they are first completed, or filled with the fluid; and it declines in proportion as the metal is oxidated, or the fluid loses its power: therefore, after a certain time the fluid must be changed, and the metallic pieces cleaned, by removing the oxidated surface; which may be done, either by filing or by rubbing them with sand, or sand paper; or by immersing them for a short time in diluted muriatic acid, and then wiping them with a coarse cloth: the last method is to be preferred for the trough; wiping them by means of a stick, which may be introduced between them, with a piece of cloth upon it.

Having thus described the construction of the best and most simple galvanic arrangements, we shall proceed to state the effects of these combinations, in a popular manner; but omitting as much as possible those experiments that are purely of a chemical nature; as these are not only too numerous to be inserted in the space we have assigned for this article, but they are also incongruous with the plan of the present work; and we must therefore refer the curious reader, who wishes for particular information on this very interesting branch of philosophical inquiry, to the following works, viz. Rees's Cyclopaedia, and the professed chemical treatises, for more ample accounts.

The various powers of different simple galvanic circles may be ascertained, by applying them to such animal preparations as have their irritability more or less exhausted. Thus, M. Volta in his letter to Gren, says, " If you take a frog, the head of which has been cut off, and which has been deprived of all life, by thrusting a needle into the spinal marrow, and immerse it without skinning, or taking out the bowels, or any other preparation, into two glasses of water, the rump into one and the legs into the other, it will be strongly agitated and violently convulsed, when you connect the water in both glasses, by a bow formed of very different metals, such as silver and lead; or, what is better, silver and zinc; but this will not be the case when the two metals are less different in regard to their powers, such as gold and silver, silver and copper, copper and iron, tin and lead; but what is more, the effect will be fully produced on this so little prepared frog, when you immerse in one of the two glasses, the end of a bow merely of tin or zinc; and into the other glass, the other end of this bow, which has been rubbed over with a little alkali: and you may perform the experiment still better with an iron bow, one end of which has been covered with a drop or thin coat of nitrous acid; but it will succeed beyond all expectation, when you take a silver bow, having a little sulphurate of potass adhering to its extremity."

It had long been asserted, that porter, and some other liquors, when drank out of pewter pots, had a different taste, from what they had when drank out of a glass or earthenware; but it was little expected, that this was a truth intimately connected with so interesting a branch of philosophy; though, now, there is no doubt of the fact. A similar, but more evident effect, may be made sensible by the following experiment. If a tin bason be filled with soap-suds, lime water, or a strong ley (which last is the best); and if you then lay hold of the bason with both hands, having first moistened them with pure water, and

apply the tip of your tongue to the fluid in the bason, you will immediately be sensible of an acid taste on your tongue, which is in contact with the alkaline liquor. This taste is very perceptible, and for the moment pretty strong; but it is afterwards changed into a different one, less acid, but more saline and pungent, until at last, it becomes alkaline, and sharp, in proportion as the fluid acts more upon the tongue.

In the foregoing part of this article, other experiments have been noticed, made by single combinations of different metals; we shall therefore now attend to those that are made by means of the more powerful apparatus, such as we have already described; viz, the Voltaic pile; and the trough or battery, invented by Mr. Cruickshank. These powerful combinations not only convulse the prepared limbs of a frog, or produce the appearance of a flash of light before the human eye, but they exhibit all the phenomena of electricity, in a very considerable degree: an arrangement of the kind we have described, will give the shock; it affects the electrometer, shows a luminous spark, accompanied with an audible report; it burns metallic, and other bodies; and continues in action for a very considerable time; viz, until the chemical action between the component parts of the battery be quite exhausted. Some of which effects are enumerated in the following paragraph.

If you take a Voltaic pile, consisting only of 20 repetitions of simple combinations, and touch with one hand one extremity of the pile, as at *b*, fig. 5, and apply the other hand to the other extremity, as at *a*; a very slight shock will be perceived, like that which is communicated by a Leyden phial weakly charged; and it will be scarcely felt beyond the fingers, or at most the wrists; but the shock is felt as often as the contact is renewed; and if you continue the hands in contact with the extremities *b* and *a*, a slight but continued irritation will be perceived: and when the hand, or other part of the body, which touches the extremity of the battery, is excoriated or wounded, this sensation becomes disagreeable, and rather painful; but as the dry skin of the human body is seldom capable of conducting this shock, the touching fingers should be well moistened with water; and it will be still better to immerse a wire, that proceeds from one extremity of the battery, in a bason of water, wherein may be plunged one hand; grasping, at the same time, with the other hand well moistened, a large piece of metal, as a large silver spoon; by which means the shock will be felt more distinctly. Instead of one person, several may join hands, (which must be all well moistened,) and on completing the circuit, they will all feel the shock at the same time, as with an electrical discharge: but the strength of it is thus much diminished by passing through the several persons, as it is in general by passing through bodies that are not perfect conductors.

The shock of a battery, containing 50 or 60 pairs of combinations of silver or copper and zinc will be felt as high as the elbows; and the combined effect of five or six such batteries will of course be much greater, and such as few men would be willing to receive.

From the foregoing experiment it appears, that between the effects resulting from the common electrical machines, and those produced with the pile, there is this difference; that in the former, the effects are annihilated at the instant of contact; while in the other, they remain as long as the

contact is continued. The pile once charged, becomes thus a reservoir of electricity, which, without the aid, and as it were without the knowledge, of the operator, fills itself spontaneously; regains continually what is taken from it; and would be inexhaustible, if the humid bodies, of which the pile is composed, could be prevented from losing their moisture.

If a wire, proceeding from one extremity of a pretty strong galvanic pile, be made to communicate with the inside coating of a common Leyden phial or electrical battery; and a wire which proceeds from the other extremity of the pile, be made to communicate with the outside coating of the same jar or battery; the latter will become weakly, but almost instantaneously charged, in the same manner as would have been done with a few turns of the electrical machine; and with that charge you may either give the shock, or effect an electrometer, &c. In fact, every experiment convinces, more and more, that a galvanic battery produces a vast quantity of electric fluid, which is but little condensed; and indeed it would be impossible to suppose that the electric fluid could proceed in a very condensed state, from an arrangement of bodies, which, whether more or less, are however all good conductors of electricity; for if the fluid was much condensed at one extremity of the battery, and much rarefied at the other extremity, the condensation would soon be made through the pile itself: and indeed it is difficult to comprehend, why this compensation does not take place in all cases.

Having mentioned above, that the charge of a galvanic pile or battery may be communicated to a common electric battery, it is scarcely necessary to observe, that the same may be communicated to a condenser or a multiplier; and from hence to the electrometer; and if the pile consists of 200 repetitions, the electrometer will be affected by simple contact.

The spark or the discharge of an electric battery, when sent through thin inflammable bodies that are in contact with the common or oxygen air, sets them on fire, and consumes them with wonderful activity: it also fires gunpowder, hydrogen gas, phosphorus, and other combustible matter: it also renders red hot, fuses, and consumes, very slender metallic wires, and metallic leaves.

The method of employing the power of the battery for such purposes, is shown at fig. 7, where *AB* represents a powerful galvanic battery; *ACDF* is a wire which communicates with the first plate of the battery *A*; *BHIG* is another wire, which communicates with the last plate at *B*; *DE* and *HJ* are two glass tubes, through which those wires pass, and into which they are fastened sufficiently steady: these tubes serve to move the wires by; or if the operator applies his fingers to the middle part of those tubes, he may move the wires wherever he pleases, without the fear of receiving a shock. If the two extremities *F*, *G*, are brought sufficiently near to each other, the spark will be seen between them; and it is between those extremities, that the combustible substances, or metallic leaf, is to be placed, in order to be fired or consumed; and in the figure is shown the situations of the wires, as they must be poised, in order to accomplish the firing of gunpowder, or the fusion of metals, &c. &c. A battery, consisting of 200 pairs of metallic plates, viz. copper and zinc, each five inches square, will melt 3 inches of very fine iron wire; and a platina wire about $\frac{1}{75}$ of an inch

in diameter, may be melted into a globule by the same apparatus; and more powerful effects will of course be produced from the combination of two or more such batteries.

Under the exhausted receiver of an air-pump, the galvanic battery acts less powerfully than in the open air; but its effect is increased in oxygen air. The flash of light that appears before the eye of the experimenter, when the eye itself, or some other part not very remote from it, is put in the circle of a galvanic combination, does not appear much greater when a battery is employed, than when two plates are applied in the same manner; which experiment has been already mentioned; but when the battery is used, the sensation of a flash may be produced in various ways. If one hand or both be placed in perfect contact with one extremity of the battery, and almost any part of the face be brought into contact with the other extremity of the battery; the flash will appear very distinctly, the operator being in the dark, or keeping his eyes shut. This flash appears very strong, when a wire, that proceeds from one extremity of the battery, is held between the teeth and rests on the tongue, while the other wire is held in the hand; and in this case, the lips and tongue are convulsed, the flash appears before the eyes, and a very pungent taste is perceived in the mouth.

If any part of the human body forming part of the circuit of a galvanic battery be kept some time in that situation, the irritation or numbness is more or less distinct, and more or less painful, according to the sensibility of the parts concerned.

The above are some of the most popular experiments that are made by means of a galvanic battery; but by far the greater number of those that have been made have been directed to chemical purposes, and the results that have thus been obtained are truly curious and interesting: an extensive field has thus been opened for chemical research, too vast for human conception, by the introduction of this powerful agent; and more discoveries have through its means been made in one year than perhaps any one century can boast. But these experiments, as we before observed, do not properly belong to a work of this nature; we have therefore endeavoured, without introducing them, to give a familiar idea of the nature and power of this wonderful agent.

GARDECAUT, or **GUARD DU CORD**, in a watch, is that which stops the fusee, when wound up, and for that end is driven up by the spring. Some call it guard-cock; others guard du Gut.

GARRISON GUNS, such as are mounted and used in a garrison, consisting of the following weights, viz. the 42, 32, 24, 18, 12, 9, and 6 pounds; being made either of brass or iron.

Table of the Weight and Dimensions of Garrison Guns.

Brass Garrison Guns.			Iron Garrison Guns.		
Shot	Length	Weight.	Shot	Length	Weight.
lb.	f. in.	Cw. qr. lb.	lb.	f. in.	Cw. qr. lb.

GAS. The term gas (with the exception of the common air we breathe) is used to signify any permanently elastic exhalation afforded in chemical processes. It was originally given by Van Helmont to the vapour of charcoal,

the same with the fluid called fixed air; and some other factitious airs; and from him has been employed by modern philosophers as a general name for all the fluids about which areology is conversant.

TABLE, showing the absolute weights and specific gravities of gases, and the quantity of each absorbed by water.
Temperature 60° Fahrenheit, Barometer 29·8.

B. denotes Brisson; Cr. Cruickshank; D. Davy; Dal. Dalton; Dei. Deiman; H. Henry; K. Kirwan; S. Shuckburgh; T. Thomson; Th. Thonard; Tr. Tromsdorff.

Kind of Gas.	Weight of 100 cubic inches in grains.	Specific Gravity.			Number of cubic inches absorbed by 100 inches of water.	
		Water, the Standard at 1000.	Air the Standard.	Authority.		
Nitric acid	76	3·	2425	D.	3300	T.
Sulphurous	70·215	2·75	2240	K.

Ditto from water over ignited charcoal	14·5	468	Cr.		
Hydrogen gas	20·13	0·1031	84	K.	1·61	H.
Phosphuretted hydrogen	2·14	H.

The following are the experiments made by professor Jacquin of Vienna on the different gases, as the vehicle of sounds.—A glass-bell being furnished with a metallic stopper cemented to a neck at the top; and in the bore of this cock within the glass, a small flute or pewter (etain) about six inches in length was fixed. The glass being then placed on the shelf of the pneumatic vessel, and filled with any particular kind of gas, a bladder also filled with the same gas, and provided with a cock, was adapted to the external aperture of the cock belonging to the bell-glass. In this disposition of the apparatus the flute was made to sound by gently pressing the bladder. Comparative experiments were also made with atmospheric air, oxygen, hydrogen, carbonic acid, and nitrous gas. The intensity of the sound did not vary; but when compared with that produced by atmospheric air, the oxygen gas afforded a sound half a tone lower; azotic gas, prepared by different methods, constantly gave a sound half a tone lower; hydrogen gas gave nine or eleven tones higher; carbonic acid gas gave one third lower; and nitrous gas

also very nearly a third lower. A mixture of oxygen gas and azote, in the proportion contained in atmospheric air, afforded the tone of this last; that is to say, it was half a tone higher than each of the component parts alone. When the two gases were not uniformly mixed, the sound was abominably harsh. Chladni intends to give a fuller account of these interesting experiments. *Journal de Physique*, vol. 4, N. S. p. 57.

GASCOIGNE, an ingenious young astronomer of Lancashire, who, about the year 1640, made many curious observations on some astronomical objects, and greatly improved that science, by the invention of the micrometer, and by applying telescopic sights to astronomical quadrants. See accounts of his inventions in the article Micrometer. See also my Abridg. of the Philos. Trans. vol. i, p. 169, 195, and vol. x, p. 369.

Mr. Gascoigne was slain in the civil wars in the time of Charles I.

GASSENDI (PETER), one of the most celebrated philosophers France has produced, was born at Chantiers,

about 3 miles from Digne in Provence, in the year 1592. When a child, he took great delight in gazing at the moon and stars whenever they appeared: This pleasure often drew him into bye-places, that he might feast his eyes freely and undisturbed; by which means his parents had him often to seek, with many anxious fears and apprehensions. In consequence of this promising disposition, he was sent to the best schools, to cultivate it with the instructions of the first masters. He profited so well by these aids, that he was invited to be professor of rhetoric at Digne, before he was quite 16 years of age. After filling this office three years, upon the death of his master at Aix, he was appointed to succeed him as professor of philosophy. After a few years residence here, he composed his *Paradoxical Exercitations*; which coming to the hands of Nicholas Peiresc, that great patron of learning joined with Joseph Walter, prior of Valette, in promoting him; and, having entered into holy orders, he was first made canon of the church of Digne and doctor of divinity, and then warden or rector of the same church.

Our author's fondness for astronomy grew up with his years; and his reputation daily increasing, he was appointed the king's professor of mathematics at Paris in 1645. This institution being chiefly intended for astronomy, Gassendi read lectures on that science to a crowded audience. However, he did not long enjoy this situation; for a dangerous cough and inflammation of the lungs obliged him, in 1647, to return to Digne for the benefit of his native air. Having thus, and by the intermission of his studies, recovered his health, he again returned to Paris in 1653; where, after first writing and publishing the lives of Tycho Brahe, Copernicus, Purbach, and Regiomontanus, in 1654 he again renewed his astronomical labours, with the design of completing the system of the heavens. But while he was thus employed, too intensely for the feeble state of his health, he relapsed into his former disorder, under which, with the aid of too copious and numerous bleedings, by order of three physicians, he expired in the year 1655, at 63 years of age.

Gassendi wrote against the metaphysical meditations of Descartes; and divided with that great man the philosophers of his time, almost all of whom were either Cartesians or Gassendists. To his knowledge in philosophy and mathematics, he joined profound erudition and deep skill in the languages. He wrote, 1. Three volumes on Epicurus's philosophy; and six others, which contain his own philosophy.—2. Astronomical Works.—3. The lives of Nicholas de Peiresc, Epicurus, Copernicus, Tycho Brahe, Purbach, and Regiomontanus.—4. Epistles, and other treatises. All his works were collected together, and printed at Lyons in 1658, in 6 volumes folio.

Gassendi was the first person who saw the transit of Mercury over the sun, viz. Nov. 7, 1631; as Horrocks first predicted and showed the transit of Venus.—His library was large and valuable: to which he added an astronomical and philosophical apparatus, which, for their accuracy and magnitude, were purchased by the emperor Ferdinand III.—It appears by his letters, printed in the 6th volume of his works, that he was often consulted by the most celebrated astronomers of his time, as Kepler, Longomontanus, Snell, Hevelius, Galileo, Kircher, Bulliald, and others: and he has generally been esteemed one of the founders of the reformed philosophy, in opposition to the groundless hypotheses and empty subtleties of Aristotle and the schoolmen.

GATE, in Architecture, a large door leading or giving entrance into a city, town, castle, palace, or other considerable building.

GATE, in Fortification, is made of strong planks with iron bars to oppose an enemy. They are generally made in the middle of the curtain, whence they are seen and defended by the two flanks of the bastions. They should be covered with a good ravelin, that they may not be seen or inflamed by the enemy. These gates belonging to a fortified place, are passages through the rampart, which may be shut and opened by means of doors and a portcullis. They are either private or public.

Private Gates, are those passages by which the troops can go out of the town unseen by the enemy, when they pass to and fro on the relief of the duty in the outworks, or on any other occasion which is to be concealed from the besiegers.

Public Gates, are those passages through the middle of such curtains to which the great roads or public ways lead. The dimensions of these are usually about 13 or 14 feet high, and 9 or 10 feet wide, continued through the rampart, with proper recesses for foot passengers to stand in out of the way of wheel carriages.

GAUGE-Line, a line on the common gauging-rod, used for the purpose of gauging liquids. See *GAUGING-Rod*.

GAUGE-Point, of a solid measure, is the diameter of a circle, whose area is expressed by the same number as the solid content of that measure. Or it is the diameter of a cylinder, whose altitude is 1, and its content the same as of that measure. Thus, the solid content of a wine gallon being 231 cubic inches; if a circle be conceived to contain so many square inches, its diameter will be 17 $\frac{1}{15}$; which is therefore the gauge-point for wine measure. And an ale-gallon containing 282 cubic inches; by the same rule, the gauge-point for ale measure will be found to be 18 $\frac{9}{15}$. In like manner may the gauge-point for any other measure be determined. Hence it follows, that when the diameter of a cylinder in inches is equal to the gauge-point in any measure, given likewise in inches, every inch in its length will contain an integer of the same measure. So in a cylinder whose diameter is 17 $\frac{1}{15}$ inches, every inch in height contains one entire gallon in wine measure; and in another, whose diameter is 18 $\frac{9}{15}$, every inch in length contains one ale gallon.

GAUGER, an officer appointed by the commissioners of excise, to gauge, measure, or examine, all casks, tuns, pipes, barrels, hog-heads, of beer, wine, oil, &c.

GAUGING, the art or act of measuring the capacities or contents of all kinds of vessels; and determining the quantity of fluids, or other matters contained in them. These are principally pipes, tuns, barrels, rundlets, and other casks; also backs, coolers, vats, &c.

As to the solid contents of all prismatical vessels, as cubes, parallelopipedons, cylinders, &c., they are found by multiplying the area of the base by their altitude. And the contents of all pyramidal bodies, and cones, are equal to 1-3d of the same.

In gauging, it has been usual to divide casks into four varieties or forms, denominated as follows, from the supposed resemblance they bear to the frustums of solids of the same names: viz.

1. The middle frustum of a spheroid,
2. The middle frustum of a parabolic spindle,
3. The two equal frustums of a paraboloid,
4. The two equal frustums of a cone.

And particular rules, adapted to each of these forms, may be found in most books of gauging, and in my Mensuration, p. 436, &c. But as the form is imaginary, and only guessed at, it seldom happens that a true solution is obtained in this way; besides which, it is very troublesome and inconvenient to have so many rules to put in practice. I shall therefore give here one rule only, from p. 451 of that book, which is not only general for all casks that are commonly met with, but quite easy, and very accurate, as having been often verified and proved by filling the casks with a true gallon measure.

General Rule. Add into one sum,
39 times the square of the bung diameter,
25 times the square of the head diameter, and
26 times the product of those diameters;
multiply the sum by the length of the cask, and the product by the number .00034; then this last product divided by 9 will give the wine gallons, and divided by 11 will give the ale gallons.

Or, $(39B^2 + 25H^2 + 26BH) \times \frac{L}{114}$ is the content in inches; which being divided by 231 for wine gallons, or by 282 for ale gallons, will be the content.

For Example. If the length of a cask be 40 inches, the bung diameter 32, and the head diameter 24.

Here	-	$32^2 \times 39 = 39936$
and	-	$24^2 \times 25 = 14400$
and	-	$32 \times 24 \times 26 = 19968$
		the sum - 74304
		multiplied by - 40
		and divid. by 114) 2972160
		gives - - - 26071 cubic inches;

this divided by 231 gives 112 wine gallons,
or divided by 282 gives 92 ale gallons.

But the common practice of gauging is performed mechanically, by means of the gauging or diagonal rod, or the gauging sliding rule, the description and use of which here follow.

Gauging, or Diagonal Rod, is a rod or rule adapted for determining the contents of casks, by measuring the diagonal only, viz, the diagonal from the bung to the extremity of the opposite stave next the head. It is a square rule, having 4 sides or faces, being usually 4 feet long, and folding together by means of joints. On one face of the rule is a scale of inches, for taking the measure of the diagonal; to these are adapted the areas, in ale gallons, of circles to the corresponding diameters, like the lines on the under sides of the three slides in the sliding rule, described below. And on the opposite face are two scales, of ale and wine gallons, expressing the contents of casks having the corresponding diagonals; and these are the lines which chiefly constitute the difference between this instrument and the sliding rule; for all the other lines upon it are the same with those on that instrument, and are to be used in the same manner.

To use the Diagonal Rod. Unfold the rod quite straight and put it in at the bung hole of the cask to be gauged, till its end arrive at the intersection of the head and opposite stave, or to the farthest possible distance from the bung-hole, and note the inches and parts cut by the middle of the bung; then draw out the rod, and look for the same inches and parts on the opposite face of it, and annexed to them are the contents of the cask, both in ale and wine gallons.

For Example. Let it be required to find, by this rod, the

content of a cask whose diagonal measures 34·4 inches; which answers to the cask in the foregoing example, whose head and bung diameters are 32 and 24, and length 40 inches; for if to the square of 20, half the sum of the diameters, the square root of the sum will be 34·4 nearly. Now, to this diagonal 34·4, corresponds, on the rule, the content 91 ale gallons, or 111 wine gallons; which are but 1 less than the content found by the former general rule above given.

Gauging Rule, or Sliding Rule, is a sliding rule particularly adapted to the purposes of gauging. It is a square rule, of four faces or sides, three of which are furnished with sliding pieces running in grooves. The lines on these faces are mostly logarithmic ones, or distances which are proportional to the logarithms of the numbers placed at the ends of them; which kind of lines was disposed first upon rulers, by Mr. Edmund Gunter, for expeditiously performing arithmetical operations, using a pair of compasses for taking off and applying the several logarithmic distances. Instead of the compasses, sliding pieces were afterwards added, by Mr. Thomas Everard, as more certain and convenient in practice, from whom this sliding rule is often called Everard's Rule. For the more particular description and uses of this rule, see my Mensuration, p. 429, 4th ed.

The writers on gauging are, Beyer, Kepler, Dechales, Hunt, Everard, Dougherty, Shettleworth, Shirtcliffe, Leabetter, Moss, &c.

GAZONS, in Fortification, turfs, or pieces of fresh earth covered with grass, cut in form of a wedge, about a foot long and half a foot thick, to line or face the outside of works made of earth, to keep them up, and prevent their moulderling.

GELLIBRAND (HENRY), professor of astronomy at Gresham-college, was born in London the 27th of Nov. 1597. He was sent to Trinity-college, Oxford, in 1615, and took his degree in arts 1619. He then entered into orders, and became curate of Chiddingstone in Kent. Afterwards, taking a great fancy to mathematics, by happening to hear one of Sir Henry Saville's lectures in that science, he immediately applied himself to the close study of that noble science; and relinquished his fair prospects in the church. Content with his private patrimony, which was now come to his inheritance by the death of his father, the same year he entered again a student at Oxford, making mathematics his sole employment. He made such proficiency in this science before he proceeded A. M., which was in 1623, that he drew the attention and intimate friendship of Mr. Henry Briggs, then lately removed from the geometry professorship in Gresham-college to that of Savilian professor of geometry at Oxford, by the founder Sir Henry Saville, and who, upon the death of Mr. Gunter, procured for our author the professorship of astronomy in Gresham-college, to which he was elected in the beginning of the year 1627. His friend Mr. Briggs dying in 1630, before he had finished the introduction to his Trigonometria Britannica, he recommended the completing and publishing of that work to our author. Gellibrand accordingly added a preface, and the application of the logarithms to plane and spherical trigonometry, &c, and the whole was printed at Gouda, under the care of Adrian Vlaet, in 1633.

While Mr. Gellibrand was preparing that work, he was brought into trouble in the high-commission court, by Dr. Laud, then bishop of London, on account of an almanac,

published by William Beale, servant to Mr. Gellibrand, for the year 1631, with the approbation of his master. In this almanac, the popish saints, then usually put into calendars, were omitted, and the names of other saints and martyrs, mentioned in the Book of Martyrs, were placed in their stead, as they stand in Fox's calendars. This, it seems, gave much offence to the bishop, and occasioned the prosecution. But when the cause came to be heard, it appeared that other almanacs of the same kind had formerly been printed; upon which, both master and man were acquitted by Abp. Abbot and the whole court, Laud only excepted: which was afterward made one of the articles against him on his own trial.

It seems Gellibrand was strongly attached to the old Ptolemaic system. For when he went over to Holland, about the printing of Briggs's book above mentioned, he had some discourse with Lansberg, an eminent brother astronomer in Zealand, who affirming that he was fully persuaded of the truth of the Copernican system; our author observes, "that this so styled a truth he should receive as an hypothesis; and so be easily led on to the consideration of the imbecility of man's apprehension, as not able rightly to conceive of this admirable opifice of God, or frame of the world, without falling foul of so great an absurdity;" so firmly was he fixed in his adherence to the Ptolemaic system. Gellibrand wrote several things after this, chiefly tending to the improvement of navigation, which would probably have been further advanced by him, had his life been continued longer; but he was untimely carried off by a fever, in 1636, at 39 years of age.

The character of Mr. Gellibrand is that of a plain, plodding, industrious, well-intentioned man, with little invention or genius. His writings are chiefly as below.

1. Trigonometria Britannica; or the Doctrine of Triangles, being the 2d part of Briggs's work above mentioned.—2. A small tract concerning the longitude.—3. A discourse on the Variation of the Magnetic Needle; annexed to Wright's Errors in Navigation detected.—4. Institution Trigonometrical, with its application to astronomy and navigation; 8vo, 1633.—5. Epitome of Navigation, with the necessary tables; 8vo.—6. Several manuscripts never published; as, The Doctrine of Eclipses, A Treatise of Lunar Astronomy, A Treatise of Ship-building, &c.

GEMINI, in Astronomy, the Twins; a constellation or sign of the zodiac, the third in order, representing Castor and Pollux; and it is marked thus, **II**. The stars in the sign Gemini are, in Ptolemy's catalogue 25, in Tycho's 25, in Hevelius's 33, and in the Britannic catalogue 85.

GEMMA (RENIER), commonly called Gemma Frisius, from his native country Friezland, a Dutch physician and mathematician, who became medical professor at Louvain, where he died in 1558, at 50 years of age. He wrote, 1. Methodus Arithmetice: 2. De Usu Annuli Astronomici: 3. De Locorum describendorum Ratione, deque Distantiis eorum inveniendis: 4. Demonstrationes Geometricae de usu Radii Astronomici: 5. De Astrolabio Catholico Liber, &c. See further under FRISI.

GEMMA (CORNELIUS), son of the former, a good astronomer, was born at Louvain in 1535, and died 1579. He wrote several tracts, as, De Prodigiosa Specie Naturae Cometae: and one on the star which appeared in 1577, Antw. 1578, in 8vo.

GENERATE, in Music, is used to signify the operation of that mechanical power in nature, which every sound has in producing one or more general sounds. Thus

any given sound, however simple, produces along with itself, its octave and two other sounds extremely sharp, viz, its 12th above, that is to say, the octave of its fifth; and the other the 17th above, or, in other words, the double octave of its third major.

Whether we suppose this procreation of sounds to result from an aptitude in the texture and magnitude of certain particles in the air, for conveying to our ears vibrations that bear those proportions one to another, as being determined at once by the partial and total oscillations of any musical string; or from whatever economy of nature we choose to trace it; the power of one sound thus to produce another, when in action, is said to generate. The same word is applied by Signor Tartini and his followers, to any two sounds which, simultaneously heard, produce a third.

GENERATED, is used by some mathematical writers for whatever is produced by arithmetical operation, or in geometry by the motion of other magnitudes. Thus 20 is the product generated of 4 and 5; ab that of a and b , 4, 8, 16, &c, the powers generated of or from the root a , and a^2 , a^3 , a^4 , &c, those from the root a . So also, a circle is generated by the revolution of a line about one of its extremities; a cone by the rotation of a right-angled triangle about its perpendicular; a cylinder by the rotation of a rectangle about one of its sides, or, otherwise, by the motion of a circle in the direction of a right line, and keeping always parallel to it.

GENERATING Line or Figure, in Geometry, is that which, by any kind of supposed motion, may generate, or produce, some other figure, plane, or solid. Thus a line, according to Euclid, generates a circle; or a right-angle, triangle, a cone, &c.; and thus also Archimedes supposes his spirals to be generated by the motions of generating points and lines. The figure thus generated, is called the Generant.

It is a general theorem in geometry, that the measure of any generant, or figure produced by any kind of motion of any other figure, or generating quantity, is equal to the product of this generating quantity drawn into the length of the path described by its centre of gravity, whatever the kind of motion may be, whether rotatory, or direct, &c.—In the modern analysis, or fluxions, all sorts of quantities are considered as generated by some such motion, and the quantity hereby generated is called a Fluent.

GENERATION, in Mathematics, is used for the formation or production of any geometrical figure, or other quantities. Such as of the figures mentioned in the foregoing articles, or the generation of equations, curves, solids, &c.

GENERATOR, in Music, signifies the principal sound or sounds by which others are produced. Thus, the lowest c for the treble of the harpsichord, besides the octave, will strike an attentive ear with its 12th above, or e in alt, and with its 17th above, or e in alt. The e , therefore is called their generator, the c and e its products, or harmonies. But in the approximation of chords, for e , its octave below is substituted, which constitutes a fifth from the generator or lowest c ; and for e , is likewise substituted its 15th below, which, with the above-mentioned c , forms a third major. To the lowest notes, therefore, exchanged for these in alt, by substitution, the denominations of products or harmonies are likewise given, while the c retains the name of their generator. But still, according to the system of Tartini, two notes in concord, which when sounded, produce a third, may be termed the concurring generators of that third. See Generation Harmonique,

par M. Rameau; see also that delineation of Tartini's system called The Power and Principles of Harmony.

GENESIS, in Geometry, means much the same as generation mentioned above, being the formation of a line, surface, or solid, by the motion or flux of a point, line, or surface; as of a globe by the rotation of a semi-circle about its diameter, &c. In the genesis of figures, the line or surface which moves, is called the Describent; and the line round which, or according to which, the revolution or other motion is made, the Dirigent.

GEOCENTRIC, is said of a planet or its orbit, to denote its having the earth for its centre. The moon alone is properly geocentric. And yet the motions of all the planets may be considered in respect of the earth, or as they appear from the earth, and thence called their geocentric motions.—Hence also the terms geocentric place, or latitude, or longitude, &c, as explained below.

GEOCENTRIC Place, of a planet, is the place where it appears to us, from the earth; or it is a point in the ecliptic, to which a planet, seen from the earth, is referred.

GEOCENTRIC Latitude, of a planet, is its altitude as seen from the earth; or the inclination of a line, connecting the planet and the earth, to the plane of the earth's (or true) ecliptic. Or it is the angle which the said line, (connecting the planet and the earth) makes with a line drawn to meet a perpendicular let fall from the planet to the plane of the ecliptic.

GEOCENTRIC Longitude, of a planet, is the distance measured on the ecliptic, in the order of the signs, between the geocentric place and the first point of Aries.

GEODESIA, is properly that part of practical geometry that teaches how to divide or lay out lands and fields, among several owners.

GEODESIA is also applied, by some writers, to all measurements in the field, and as synonymous with surveying.

GEODESIA is defined by Vitalis, as the art of measuring surfaces and solids, not by imaginary lines, as is done in geometry, but by sensible and visible things; or by the sun's rays, &c.

GEODETICAL, something relating to the art of measuring the earth or land.

GEOPHYSICER, a person skilled in geography.

GEOPHYSICAL, relating to geography, as

GEOGRAPHICAL Mile, the sea-mile or minute, being the 60th part of a degree of a great circle.

GEOPHYSICAL Table. See MAP.

GEOGRAPHY, the science that teaches and explains the nature and properties of the earth, as to its figure, place, magnitude, motion, celestial appearances, &c, with the various lines, real or imaginary, on its surface.—Geography is distinguished from Cosmography, as a part from the whole; this latter considering the whole visible world, both heaven and earth. And from Topography and Chorography, it is distinguished, as the whole from a part. Golnitz considers geography as either exterior or interior: but Varenius more justly divides it into general and special; or universal and particular.

General or Universal GEOGRAPHY, is that which considers the earth in general, without regard to particular countries, or the affections common to the whole globe: as its figure, magnitude, motion, land, sea, &c.

Special or Particular GEOGRAPHY, is that which contemplates the constitution of the several particular regions, or countries; their bounds, figure, climate, seasons, weather, inhabitants, arts, customs, language, &c.

History of GEOGRAPHY. The study and practice of geography must have commenced at a very early period of the world. By the accounts we have remaining, it appears this science was in use among the Babylonians, Arabians, and Egyptians, from whom it passed to the Greeks first of any Europeans, and from these successively to the Romans, and the western nations of Europe. Herodotus relates that the Greeks first learned the pole, the gnomon, and the 12 divisions of the day, from the Babylonians. But Pliny and Diogenes Laertius assert, that Thales of Miletus, in the 6th century before Christ, first discovered the passage of the sun from tropic to tropic, and it is said was the author of two books, the one on the tropic and the other on the equinox; both probably determined by means of the gnomon; whence he was led to the discovery of the four seasons of the year, which are determined by the equinoxes and solstices. It is however probable that he learned these things of the Egyptians, as well as his division of the year into 365 days. This it is said was invented by the second Mercury, surnamed Trismegistus, who, according to Eusebius, lived about 50 years after the Exodus. Pliny expressly informs us that this discovery was made by observing when the shadow returned to its marks; a sufficient proof that it was by the gnomon. It is also said that Thales constructed a globe, and represented the land and sea upon a table of brass. Further, that Anaximander, a disciple of Thales, first drew the figure of the earth upon a globe; and that Hecataeus, Democritus, Eudoxus, and others, formed geographical maps, and brought them into common use in Greece.—Meton and Euctemon observed the summer solstice at Athens, on the 27th of June 432 years before Christ, by watching narrowly the shadow of the gnomon, with the design of fixing the beginning of their cycle of 19 years.

Timocharis and Aristillus, who began their observations about 295 B. C., it seems first attempted to fix the latitudes and longitudes of the fixed stars, by considering their distances from the equator, &c. One of their observations gave rise to the discovery of the precession of the equinoxes, which was first remarked by Hipparchus about 150 years after; who also made use of their method, for delineating the parallels of latitude and the meridians, on the surface of the earth; thus laying the foundation of this science as it now appears. The latitudes and longitudes, thus introduced by Hipparchus, were not however much attended to till Ptolemy's time. Strabo, Vitruvius, and Pliny, have all of them entered into a minute geographical description of the situation of places, according to the length of the shadows of the gnomon, without noticing the longitudes and latitudes.

Maps at first were little more than rude outlines, and topographical sketches of different countries. The earliest on record were those of Sesostris, mentioned by Eustathius; who observes, that "this Egyptian king, having traversed great part of the earth, recorded his march in maps, and gave copies of them not only to the Egyptians, but to the Scythians, to their great astonishment." Some have imagined with much probability, that the Jews made a map of the Holy Land, when they gave the different portions to the nine tribes at Shiloh: for Joshua tells us that they were sent to walk through the land, and that they described it in seven parts in a hook; and Josephus relates that when Joshua sent out people from the different tribes to measure the land, he gave them, as companions, persons well skilled in geometry, who could not be mistaken in the truth.

The first Grecian map on record, was that of Auaximander, mentioned by Strabo, lib. 1, p. 7, supposed to be the one referred to by Hipparchus under the designation of the ancient map. Herodotus minutely describes a map made by Aristagoras tyrant of Miletus, which will serve to give some idea of the maps of those times. He relates, that Aristagoras showed it to Cleomenes king of Sparta, to induce him to attack the king of Persia at Susa, in order to restore the Ionians to their ancient liberty. It was traced upon brass or copper, and seems to have been a mere itinerary, containing the route through the intermediate countries which were to be traversed in that march, with the rivers Halys, the Euphrates, and Tigris, which Herodotus mentions as necessary to be crossed in that expedition. It contained one straight line called the Royal Road or Highway, which took in all the stations or places of encampment, from Sardis to Susa; being 111 in the whole journey, and containing 13,500 stadia, or 1687½ Roman miles of 5000 feet each.

These itinerary maps of the places of encampment were indispensably necessary in all armies and marches; and indeed war and navigation seem to be the two grand causes of the improvements, both in geography and astronomy. Athenaeus cites Baetōn as author of a work entitled The encampments of Alexander's march; and likewise Amyntas to the same purpose. Pliny observes that Diogenetus and Baetōn were the surveyors of Alexander's marches, and then quotes the exact number of miles according to their mensuration; which he afterwards confirms by the letters of Alexander himself. The same author also remarks, that a copy of this great monarch's surveys was given by Xenoclus his treasurer to Patrocles the geographer, who was admiral of the fleets of Selucus and Antiochus. His book on geography is often cited both by Strabo and Pliny; and it appears that this author furnished Eratosthenes with the principal materials for constructing his map of the oriental part of the world.

The first attempt to reduce geography to a regular system, was made by Eratosthenes, who introduced a regular parallel of latitude, commencing at the straits of Gibraltar, and passing eastwards through the isle of Rhodes, and so on to the mountains of India, noting all the intermediate places through which it passed. In drawing this line, he was not regulated by the same latitude, but by observing where the longest day was 14 hours and a half, which Hipparchus afterwards determined was the latitude of 36 degrees. This first parallel through Rhodes was ever after considered with a degree of preference, in constructing all the ancient maps; and the longitude of the then known world was often attempted to be measured in stadia and miles, according to the extent of that line, by many succeeding geographers. Eratosthenes soon after attempted not only to draw other parallels of latitude, but also to trace a meridian at right angles to these, passing through Rhodes and Alexandria, down to Syene and Meroë; and at length he undertook the arduous task of determining the circumference of the globe, by an actual measurement of a segment of one of its great circles. To find the magnitude of the earth, is indeed a problem which has engrossed the attention of astronomers and geographers ever since the spherical figure of it was known. It seems Anaximander was the first among the Greeks who wrote upon this subject. Archytas of Tarentum, a Pythagorean, famous for his skill in mathematics and mechanics, also made some attempts in this way; and Dr. Long conjectures that these are the

authors of the most ancient opinion that the circumference of the earth is 400,000 stadia: Archimedes makes mention of the antients who estimated the circumference of the earth at only 50,000 stadia.

With respect to the methods of measuring the circumference of the earth, it would appear from what Aristotle says in his treatise *De Cœlo*, that they were much the same as those used by the moderns, deficient only in the accuracy of the instruments. For in that work he says, that different stars pass through our zenith, according as our situation is more or less northerly; and that in the southern parts of the earth stars come above our horizon, which are no longer visible if we go northward. Hence it appears that there are two ways of measuring the circumference of the earth; one by observing stars which pass through the zenith of one place, and do not pass through that of another; the other, by observing some stars which come above the horizon of one place, and are observed at the same time to be in the horizon of another. The former of these methods, which is the best, was followed by Eratosthenes at Alexandria in Egypt, 250 years before Christ. He knew that at the summer solstice, the sun was vertical to the inhabitants of Syene, a town on the confines of Ethiopia, under the tropic of Cancer, where they had a well made to observe it, at the bottom of which the rays of the sun fell perpendicularly the day of the summer solstice: he observed by the shadow of a wire set perpendicularly in an hemispherical basin, how far the sun was on that day at noon distant from the zenith of Alexandria; and found that distance to be equal to the 50th part of a great circle in the heavens. Then supposing Syene and Alexandria under the same meridian, he inferred that the distance between them was the 50th part of a great circle upon the earth; and this distance being by measure 5000 stadia, he concluded that the whole circumference of the earth was 250,000 stadia. But as this number divided by 360 would give 694½ stadia to a degree, either Eratosthenes himself, or some of his followers assigned the round number 700 stadia to a degree; which multiplied by 360, makes the circumference of the earth 252,000 stadia; whence both these measures are given by different authors, as that of Eratosthenes.

In the time of Pompey the Great, Posidonius determined the measure of the circumference of the earth by the 2d method above hinted by Aristotle, viz. the horizontal observations. Knowing that the star called Canopus was but just visible in the horizon of Rhodes, and at Alexandria finding its meridian height was the 48th part of a great circle in the heavens, or 7½ degrees, answering to the like quantity of a circle on the earth: he by considering these two places under the meridian, and the distance between them 5000 stadia, concluded the circumference of the earth to be 240,000 stadia; which is the first measure of Posidonius. But, according to Strabo, Posidonius made the measure of the earth to be 180,000 stadia, at the rate of 500 stadia to a degree. The reason of this difference is thought to be, that Eratosthenes measured the distance between Rhodes and Alexandria, and found it only 3750 stadia: taking this for a 48th part of the earth's circumference, which is the measure of Posidonius, the whole circumference will be 180,000 stadia. This measure was received by Marinus of Tyre, and is usually ascribed to Ptolemy. It is to be observed, however, that this method of determining the circumference of the earth is subject to great uncertainty, both on account of the great refraction of the stars near the horizon, the difficulty of

measuring the distance at sea between Rhodes and Alexandria, and by supposing those places under the same meridian, when they are really very different.

Several geographers afterwards made use of the different heights of the pole in distant places under the same meridian, to find the dimensions of the earth. About the year 800, the khalif Almamun had the distance measured between two places that were 2 degrees asunder, and under the same meridian in the plains of Sinjar near the Red Sea. And the result was, that the degree at one time was found equal to 56 miles, and at another $56\frac{1}{3}$ or $56\frac{2}{3}$ miles.

The next attempt to ascertain the circumference of the earth was in 1525, by Fernelius, a learned philosopher of France. For this purpose, he took the height of the pole at Paris, going from thence directly northwards, till he came to the place where the height of the pole was one degree more than at that city. The length of the way was measured by the number of revolutions made by one of the wheels of his carriage; and after proper allowances for the declivities and turnings of the road, he concluded that 68 Italian miles were equal to a degree on the earth. According to these methods many other measurements of the earth's circumference have since that time been made, with much greater accuracy: a particular account of which is given under the article DEGREE.

Though the maps of Eratosthenes were the best of his time, they were yet very imperfect and inaccurate. They contained little more than the states of Greece, and the dominions of the successors of Alexander, digested according to the surveys abovementioned. He had indeed seen, and has quoted, the voyages of Pythias into the great Atlantic ocean, which gave him some faint idea of the western parts of Europe; but so imperfect, that they could not be realised into the outlines of a chart. Strabo says he was very ignorant of Gaul, Spain, Germany, and Britain; and he was equally ignorant of Italy, the coasts of the Adriatic, Pontus, and all the countries towards the north. Such was the state of geography, and the nature of the maps, before the time of Hipparchus.

War has usually been the occasion of making or improving the maps of countries; and accordingly geography made great advances from the progress of the Roman arms. In all the provinces occupied by that people, camps were every where constructed at proper intervals, and good roads made for communication between them; and thus were civilisation and surveying carried on according to system, through the whole extent of that large empire. Every new war produced a new survey and itinerary of the countries where the scenes of action passed; so that the materials of geography were accumulated by every additional conquest. Polybius observes, that at the beginning of the second Punic war, when Hannibal was preparing his expedition against Rome, the countries through which he was to march were carefully measured by the Romans. And Julius Caesar caused a general survey of the Roman empire to be made, by a decree of the senate. Three surveyors had this task assigned them, which they completed in 25 years. The Roman itineraries that are still extant, also show what care and pains they had employed in making surveys in all the different provinces of their empire; and Pliny has filled the 3d, 4th, and 5th books of his Natural History with the Geographical distances that were thus measured. Other maps are also still preserved, known by the name of the Penteringer Tables, published by Welser and Bertius, which give a good spec-

cimen of what Vegetius calls the *Itinera Picta*, for the better direction of their armies in their march.

The Roman empire had been enlarged to its greatest extent, and all its provinces well known and surveyed, when Ptolemy, about 150 years after Christ, composed his system of geography. The chief materials he employed in composing this work, were the proportions of the gnomon to its shadow, taken by different astronomers at the times of the equinoxes and solstices; calculations founded on the length of the longest days; the measured or computed distances of the principal roads contained in their surveys and itineraries; and the various reports of travellers and navigators. All these were compared together, and digested into one uniform body or system; and afterwards were translated by him into a new mathematical language, expressing the different degrees of latitude and longitude, after the invention of Hipparchus, which had continued to be neglected for 250 years. Ptolemy's system of geography, notwithstanding it was still very imperfect, continued in vogue till the last three or four centuries, within which time the great improvements in astronomy, the many discoveries of new countries by voyagers, and the progress of war and arms, have contributed to bring it to a very considerable degree of perfection; the particulars of which will be found treated under their respective articles in this work.

Among the moderns, the chief authors on the subject of geography are Johannes de Sacrobosco, or John Halifax, who wrote a treatise on the sphere; Sebastian Munster, in his Cosmographia Universalis, in 1559; Clavius, on the sphere of Sacrobosco; Piccioli's Geographia et Hydrographia Reformata; Weigelius's Speculum Terrae; Dechales's Geography, in his Mundus Mathematicus; Cellarius's Geography; Cluverius's Introductio in Universam Geographiam; Leibnichi's Elementa Geographiae generalis; Stevenius's Compendium Geographicum; Wolfius's Geographia, in his Elementa Mathematicae; Busching's New System of Geography; Gordon's, Salmon's, Guthrie's and Myers's Grammars; Adams's Geography, ancient and modern; and Pinkerton's Geography, lately published in two volumes 4to, with an introduction by Professor Vince of Cambridge. But the most scientific and systematical work of all is Varenius's Geographia Generalis, with Jurin's additions. And it is much to be wished that some gentleman of proper qualifications would publish a new edition of this admirable performance suited to the present state of the science. Dr. Playfair has recently published a System of Geography, which is in many respects a very valuable performance; and perhaps best of all, in French, Fresnoy's most excellent work.

GEOLoGICAL, relating to the subject of Geology.

GEOLoGY, is that part of natural philosophy which treats of the structure of the earth, in regard to the origin, constitution, and the composition of its solid contents.

GEOMETER, or GEOMETRICIAN; which see.

GEOMETRICAL, something that has relation to geometry, or done after the manner, or by the means of geometry. As, a geometrical construction, a geometrical curve, a geometrical demonstration, genius, line, method, geometrical strictness, &c.

GEOMETRICAL Construction, of an equation, is the drawing of lines and figures, so as to express by them the same general property and relation, as are denoted by the algebraical equation. See CONSTRUCTION OF Equations.

GEOMETRICAL Curve or Line, called also an Algebraical

one, is that in which the relations between the abscissæ and ordinates may be expressed by a finite algebraical equation. See *ALGEBRAICAL Curves*.

GEOMETRICAL Lines, as observed by Newton, are distinguished into classes, orders, or genera, according to the number of the dimensions of the equation that expresses the relation between the ordinates and abscissæ; or, which comes to the same thing, according to the number of points in which they may be cut by a right line. Thus, a line of the first order, is a right line, since it can be only once cut by another right line, and is expressed by the simple equation $y + ax + b = 0$: those of the 2d, or quadratic order, will be the circle, and the conic sections, since all of these may be cut in two points by a right line, and expressed by the equation $y^2 + (ax + b)y + cx^2 + dx + e = 0$: those of the 3d or cubic order, will be such as may be cut in 3 points by a right line, whose most general equation is $y^3 + (ax + b)y^2 + (cx^2 + dx + e)y + fx^3 + gx^2 + hx + i = 0$; as the cubical and Neilian parabola, the cissoid, &c. And a line of an infinite order, is that which a right line may cut in infinite points: as the spiral, the cycloid, the quadratrix, and every line that is generated by the infinite revolutions of a radius, or circle, or wheel, &c. In each of the above equations, x is the abscissæ, y its corresponding ordinate, making any given angle with it; and $a, b, c, &c.$, are given or constant quantities, affected with their signs $+$ and $-$, of which one or more may vanish, be wanting or equal to nothing, provided that by such defect the line or equation does not become one of an inferior order.

It is to be noted that a curve of any kind is denominated by a number next less than the line of the same kind: thus, a curve of the 1st order, (because the right line cannot be reckoned among curves) is the same with a line of the 2d order; and a curve of the 2d kind, the same with a line of the 3d order, &c. We ought likewise to observe, that it is not so much the equation, as the construction or description, that makes any curve, geometrical or not. Thus, the circle is a geometrical line, not because it may be expressed by an equation, but because its description is a postulate: and it is not the simplicity of the equation, but the easiness of the description, that is to determine the choice of the lines for the construction of a problem. The equation that expresses a parabola, is more simple than that which expresses a circle; and yet the circle, by reason of its more simple construction, is admitted in preference. Again, the circle and the conic sections, with respect to the dimensions of the equations, are of the same order; and yet the circle is not numbered with them in the construction of problems, but by reason of its simple description is depressed to a lower order, viz. that of a right line; so that it is not improper to express that by a circle, which may be expressed by a right line; but it is a fault to construct that by the conic sections, which may be constructed by a circle. Either, therefore, the law must be taken from the dimensions of equations, as observed in a circle, and so the distinction be taken away between plane and solid problems; or the law must be allowed not to be strictly observed in lines of superior kinds, but that some, by reason of their more simple description, may be preferred to others of the same order, and be numbered with lines of inferior orders.

In constructions that are equally geometrical, the most simple are always to be preferred: and this law is so universal as to be without exception. But algebraical ex-

pressions add nothing to the simplicity of the construction; the bare descriptions of the lines here are only to be considered; and these alone were considered by those geometers who joined a circle with a right line. And as these are easy or hard, the construction becomes easy or hard: and therefore it is foreign to the nature of the thing, from any other circumstance to establish laws relating to constructions.

Either, therefore, with the ancients, we must exclude all lines besides the circle, and perhaps the conic sections, out of geometry; or admit all, according to the simplicity of the description. If the trochoid were admitted into geometry, we might by means of it divide an angle in any given ratio; would it be right therefore to blame those who would make use of this line to divide an angle in the ratio of one number to another; and contend, that you must make use only of such lines as are defined by equations, and therefore not of this line, which is not so defined? If, when an angle is proposed to be divided, for instance, into 10001 parts, we should be obliged to bring a curve defined by an equation of more than 100 dimensions to perform the same; which no body could describe, much less understand; and should prefer this to the trochoid, which is a line well known, and easily described by the motion of a wheel, or circle: who would not see the absurdity?

The trochoid therefore is either not to be admitted at all in geometry, or else, in the construction of problems, it is to be preferred to all lines of a more difficult description; and the reason is the same for other curves. Hence the trisection of an angle by a conchoid, which Archimedes in his Lemmas, and Pappus in his Collections, have preferred to the inventions of all others in this case, must be allowed as good; because we must either exclude all lines, beside the circle and right line, out of geometry, or admit them according to the simplicity of their descriptions; in which case the conchoid yields to none, except the circle. Equations are expressions of arithmetical computation, and properly have no place in geometry, excepting so far as quantities truly geometrical (that is, lines, surfaces, solids, and proportions) may be said to be some equal to others. Multiplications, divisions, and such like computations, are newly received into geometry, and that unwillingly, and contrary to the first design of this science. For whoever considers the construction of problems by a right line and a circle, discovered by the first geometers, will easily perceive that geometry was introduced for the purpose of avoiding the tediousness of computation. For which reason the two sciences ought not to be confounded together; the ancients so carefully distinguished between them, that they never introduced arithmetical terms into geometry; and the moderns, by blending them, have lost the simplicity in which all the elegance of geometry consists. In short, that is arithmetically more simple, which is determined by the more simple equations; but that is geometrically more simple, which is determined by the more simple drawing of lines; and in geometry that ought to be reckoned best which is geometrically most simple. Newton's Arith. Univers. appendix. See *CURVES*.

GEOMETRICAL Locus, or *Place*, called also simply *Locus*, is the path or track of some certain geometrical determination, in which it always falls. See *Locus*.

GEOMETRICAL Medium. See *MEDIUM*.

GEOMETRICAL Method of the Ancients. The ancients

established the higher parts of their geometry on the same principles as the elements of that science, by demonstrations of the same kind : and they were careful not to suppose any thing done, till by a previous problem they had shown that it could be done by actual operation. Much less did they suppose any thing to be done that cannot be conceived ; such as a line or series to be actually continued to infinity, or a magnitude diminished till it become infinitely less than what it is. The elements into which they resolved magnitudes were finite, and such as might be conceived to be real. Unbounded liberties have of late been introduced ; by which geometry, which ought to be perfectly clear, is filled with mysteries. Maclaurin's Fluxions, Introd. pa. 39.

GEOMETRICAL Pace, is a measure of 5 feet long.

GEOMETRICAL Plan, in Architecture. See **PLAN**.

GEOMETRICAL Plane. See **PLANE**.

GEOMETRICAL Progression, a progression in which the terms have all successively the same ratio : as 1, 2, 4, 8, 16, &c, where the common ratio is 2.—The general and common property of a geometrical progression is, that the product of any two terms, or the square of any one single term, is equal to the product of every other two terms that are taken at an equal distance on both sides from the former. So of these terms, 1, 2, 4, 8, 16, 32, 64, &c,

$$1 \times 64 = 2 \times 32 = 4 \times 16 = 8 \times 8 = 64.$$

In any geometrical progression, if

a denotes the least term,

z the greatest term,

r the common ratio,

n the number of the terms,

s the sum of the series, or all the terms ;

then any of these quantities may be found from the others, by means of these general values, or equations, viz,

$$r = n\sqrt[n]{\frac{z}{a}},$$

$$z = a \times r^{n-1},$$

$$a = z \div r^{n-1},$$

$$n = \frac{\log. \frac{z}{a}}{\log. r} = \frac{\log. z + \log. a - \log. r}{\log. r},$$

$$s = \frac{r^n - 1}{r - 1} \times a = \frac{r^n - 1}{r - 1} \times \frac{z}{r^{n-1}} = \frac{rz - a}{r - 1} =$$

$$\frac{z^{n+1} - a^{n+1}}{r^{n+1} - a^{n+1}} \div z^{n-1} - a^{n-1}.$$

When the series is infinite, then the least term a is nothing,

and the sum $s = \frac{r^z}{r - 1}$. See **PROGRESSION**.

GEOMETRICAL Proportion, called also simply **Proportion**, is the similitude or equality of ratios.

1 Thus, if $a : b : c : d$, or $a : b = c : d$, the terms a, b, c, d are in geometrical proportion ; also 6, 3, 14, 7, are in geometrical proportion, because $6 : 3 : 14 : 7$, or $6 : 3 = 14 : 7$.

In a geometrical proportion, the product of the extremes, or 1st and 4th terms, is equal to the product of the means, or the 2d and 3d terms : so $ad = bc$, and

$6 \times 7 = 3 \times 14 = 42$. See **PROPORTION**.

GEOMETRICAL Solution, of a problem, is when the problem is directly resolved according to the strict rules and principles of geometry, and by lines that are truly geometrical. This expression is used in contradistinction to an arithmetical, or a mechanical, or instrumental solution ; the problem being resolved only by a ruler and compasses. — The same term is also employed in opposition to all indirect and inadequate kinds of solutions, as by approximation, infinite series, &c. So, we have no geometrical

way of finding the quadrature of the circle, the duplication of the cube, or two mean proportionals ; though there are mechanical ways, and others, by infinite series, &c.

Pappus informs us, that the ancients endeavoured in vain to trisect an angle, and to find out two mean proportionals, by means of the right line and circle. Afterwards they began to consider the properties of several other lines ; as the conchoid, the cissoid, and the conic sections ; and by some of these they endeavoured to resolve some of those problems. At length, having more thoroughly examined the matter, and the conic sections being received into geometry, they distinguished geometrical problems and solutions into three kinds; viz,

1. *Plane* ones, which, deriving their origin from lines on a plane, may be properly resolved by a right line and a circle.—2. *Solid* ones, which are resolved by lines deriving their original from the consideration of a solid ; that is, of a cone.—3. *Linear* ones, to the solution of which are required lines more compounded. According to this distinction, we are not to resolve solid problems by other lines than the conic sections ; especially if no other lines besides the right line, circle, and the conic sections, must be received into geometry. But the moderns, advancing much farther, have received into geometry all lines that can be expressed by equations ; and have distinguished, according to the dimensions of the equations, those lines into classes or orders ; and have laid it down as a law, not to construct a problem by a line of a higher order, that may be constructed by one of a lower.

GEOMETRICIAN, or **GEOMETER**, a person skilled in, or professing geometry.

GEOMETRY, the science or doctrine of local extension, as of lines, surfaces, and solids, with that of ratios, &c.—The name geometry literally signifies measuring of the earth, as it was the necessity of measuring the land that first gave occasion to contemplate the principles and rules of this art ; which has since been extended to numberless other speculations ; insomuch that, together with arithmetic, geometry forms now the chief foundation of all the mathematics.

The invention of geometry, like many other things of antiquity, is variously ascribed.

Herodotus (lib. 2), Diodorus (lib 1), Strabo (lib. 17), and Proclus assign it to the Egyptians, and assert that the annual inundations of the Nile gave occasion to it ; for those waters bearing away the bounds and land-marks of estates and farms, covering the face of the ground uniformly with mud, the people, say they, were obliged every year to distinguish and lay out their lands by the consideration of their figure and quantity ; and thus by experience and habit they formed a method or art, which was the origin of geometry. A farther contemplation of the draught of figures of fields thus laid down, and plotted in proportion, might naturally lead them to the discovery of some of their excellent and wonderful properties ; which speculation continually improving, the art successively gained ground, and made advances more and more towards perfection.

Josephus however seems to ascribe the invention to the Hebrews : and others of the ancients make Mercury the inventor. Polyd. Virgil, de Invent. Rer. lib. 1, cap. 18.

From Egypt, this science passed into Greece, being carried thither by Thales ; where it was much cultivated and improved by himself, as also by Pythagoras, Anaxagoras of Clazomenae, Hippocrates of Chios, and Plato, who

testified his conviction of the necessity and importance of geometry to the successful study of philosophy, by this inscription over the door of his academy, " Let no one ignorant of geometry enter here." Plato thought the word geometry too mean a name for this science, and substituted instead of it the more extensive name of Mensuration; and after him others gave it the title of Pantometry. But even these are now become too scanty in their import, fully to comprehend its extent; for it not only inquires into, and demonstrates the quantities of magnitudes, but also their qualities, as the species, figures, ratios, positions, transformations, descriptions, divisions, the finding of their centres, diameters, tangents, asymptotes, curvature, &c. Some again define it as the science of inquiring, inventing, and demonstrating all the affections of magnitude. And Proclus calls it the knowledge of magnitudes and figures, with their limitations; as also of their ratios, affections, positions, and motions of every kind.

About 50 years after Plato, lived Euclid, who collected together all these theorems which had been invented by his predecessors in Egypt and Greece, and digested them into 15 books, called the Elements of Geometry; demonstrating and arranging the whole in a very accurate and perfect manner. The next to Euclid, of those ancient writers whose works are extant, is Apollonius Pergaeus, who flourished in the time of Ptolemy Euergetes, about 250 years before Christ, and about 100 years after Euclid. He was author of the first and principal work on Conic Sections; on account of which, and his other accurate and ingenious geometrical writings, he acquired from his patron the emphatical appellation of " The Great Geometrician." Contemporary with Apollonius, or perhaps a few years before him, flourished Archimedes, celebrated for his mechanical inventions at the siege of Syracuse, and not less so for his very ingenious geometrical compositions.

We can only mention Eudoxus of Cnidus, Archytas of Tarentum, Philolaus, Eratosthenes, Aristarchus of Samos, Dinostratus, the inventor of the quadratrix, Menecmus, his brother and the disciple of Plato, the two Aristeus's, Conon, Thracidius, Nicoteles, Leon, Theudius, Hermostinus, Hero, and Nicomedes the inventor of the conchoid: besides whom, there are many other ancient geometers, to whom this science has been indebted.

The Greeks continued their attention to it, even after they were subdued by the Romans. Whereas the Romans themselves were so little acquainted with it, even in the most flourishing time of their republic, that Tacitus informs us they gave the name of mathematicians to those who pursued the chimeras of divination and judicial astrology. Nor does it appear they were more disposed to cultivate geometry during the decline, and after the fall of the Roman empire. But the case was different with the Greeks; among whom are found many excellent geometers since the commencement of the Christian era, and after the translation of the Roman empire. Ptolemy lived under Marcus Aurius; and we have still extant the works of Pappus of Alexandria, who lived in the time of Theodosius; the commentary of Eutocius, the Ascalonite, who lived about the year of Christ 540, on Archimedes's mensuration of the circle; and the commentary on Euclid, by Proclus, who lived under the empire of Anastasius.

The consequent inundation of ignorance and barbarism was unfavourable to geometry, as well as to the other sciences; and the few who applied themselves to this science, were calumniated as magicians. However, in

those times of European darkness, the Arabians were distinguished as the guardians and promoters of science; and from the 9th to the 14th century, they produced many astronomers, geometers, geographers, &c; from whom the mathematical sciences were again received into Spain, Italy, and the rest of Europe, somewhat before the year 1400. Some of the earliest writers after this period, are Leonardus Pisanus, Lucas Pacioli or De Burgo, and others between 1400 and 1500. And after this appeared many editions of Euclid, or commentaries upon him: thus, Oronotus Fineus, in 1520, published a commentary on the first 6 books; as did James Peletarius, in 1557; and about the same time Nicholas Tartaglia published a commentary on the whole 15 books. There have been also the editions, or commentaries, of Commandine, Clavius, Billingsly, Scheubelius, Herlinus, Dasypodus, Ramus, Hierigon, Stevinus, Saville, Barrow, Taquet, Dechales, Furnier, Scarborough, Keill, Stone, Playfair, and many others; but the completest edition of all the works of Euclid, is that of Dr. Gregory, printed at Oxford 1703, in Greek and Latin: the edition of Euclid, by Dr. Robert Simson of Glasgow, containing the first 6 books, with the 11th and 12th, is much esteemed for its correctness. The principal other elementary writers, besides the editors of Euclid, are Borelli, Pardies, Marchetti, Wolfius, Simpson, Leslie, &c. And among those who have gone beyond Euclid in the nature of the Elementary parts of Geometry, may be chiefly reckoned, Apollonius, in his Conics, his Loci Plani, De Sectione Determinata, his Tangencies, Inclinations, Section of a Ratio, Section of a Space, &c; Archimedes, in his treatises of the Sphere and Cylinder, the Dimension of the Circle, of Conoids and Spheroids, of Spirals, and the Quadrature of the Parabola; Theodosius, in his Spheres; Serenus, in his Sections of the Cone and Cylinder; Kepler's Nova Stereometria; Cavalieri's Geometria Indivisibilium; Torricelli's Opera Geometrica; Viviani, in his Divinationes Geometrica; Exercitatio Mathematica, De Locis Solidis, De Maximis et Minimis, &c; Vieta, in his Effectio Geometrica; Supplementum Geometricarum, Sectiones Angulares, Responsum ad Problema, Apollonius Gallus, &c; Gregory St. Vincent's Quadratura Circuli; Fermat's Varia Opera Mathematica; Dr. Barrow's Lectures Geometricæ; Bulliald de Lineis Spiralibus; Cavalieri; Schooten and Gregory's Exercitationes Geometricæ, and Gregory's Pars Universalis, &c; De Billy's treatise De Proportionis Harmonicis; Le Louver's Geometria veterum promota; Slusius's Mesolabium, Problema Solida, &c; Wallis, in his treatises De Cycloide, Cissoida, &c; De Proportionibus, De Sectionibus Comicis, Arithmetica Infinitorum, De Centro Gravitatis, De Sectionibus Angularibus, De Angulo Contactus, Cuno-Cuneus, &c; Hugo De Omerique, in his Analysis Geometrica; Pascal on the Cycloid; Step. Angelii's Problemata Geometrica; Alex. Anderson's Suppl. Apollonii Redivivi, Variorum Problematum Practice, &c; Baronius's Geomet. Prob. &c; Guido Grandi Geometr. Demonstr. &c; Ghetaldi Apollonius Redivivus, &c; Ludolph van Ceulen, or a Ceulen, de Circulo et Adscripsis, &c; Snell's Apollonius Batavus, Cyclometricus, &c; Herberstein's Diotome Circulorum; Palma's Exercit. in Geometriam; Guldiini Centro-Barica; with several others equally eminent, of more modern date, as Dr. Rob. Simson, Dr. Mat. Stewart, Tho. Simpson, John Leslie, Legendre, &c. Since the introduction of the new geometry, or the geometry of curve lines, as expressed by algebraical equations, in this

part of geometry, the following names, among many others, are more especially to be respected; viz, Descartes, Schooten, Newton, Maclaurin, Brackenridge, Cramer, Cotes, Waring, &c, &c.—As to the subject of practical geometry, the chief writers are Beyer, Kepler, Ramus, Clavius, Mallet, Tacquet, Ozanam, Wolfius, Gregory, with innumerable others.

Geometry is distinguished into theoretical or speculative, and practical.

Theoretical or Speculative GEOMETRY, treats of the various properties and relations in magnitudes, demonstrating the theorems, &c. And

Practical GEOMETRY, is that which applies those speculations and theorems to particular uses in the solution of problems, and in the measurements in the ordinary concerns of life.

Speculative geometry again may be divided into elementary and sublime.

Elementary or Common GEOMETRY, is that which is employed in the consideration of right lines and plane surfaces, with the solids generated from them.

Higher or Sublime GEOMETRY, is that which is employed in the consideration of curve lines, conic sections, and the bodies formed of them. This part has been chiefly cultivated by the moderns, by help of the improved state of algebra, and the modern analysis or fluxions.

Descriptive GEOMETRY, a name given to a new species of geometry, chiefly treated on by M. Monge. When one surface penetrates another, there often result from their intersection curves of double curvature, the description of which is necessary in some of the arts; as, in groined vault-work, and in cutting arch-stones, or wood-cutting, for ornamental work, &c, the form of which is often very fantastical and complicated: it is in the solution of problems relating to these subjects that descriptive geometry is chiefly useful.

Some architects, more versed in geometry than usual with persons of that profession, have long since thrown some light on the first principles of this kind of geometry. There is, for instance, a work by a Jesuit named Father Courcier, showing how to describe the curves resulting from the mutual penetration of cylindrical, spherical, and conical surfaces: this work was published at Paris in 1663. P. Derand, M. Jousse, Frazier, &c, had also contributed a little towards the promotion of this branch of geometry. But Monge has given it very great extension, not only by proposing and resolving various problems both curious and difficult, but by the invention of several new and interesting theorems. We can only mention in this place one or two of these. As, 1st, Two right lines being given in space, which are neither parallel nor in the same plane, to find in both of them the points of their least distance, and the position of the line joining these points. 2d, Three spheres being given in space, to determine the position of the plane which touches them. There are also curious problems relative to lines of double curvature, and to surfaces resulting from the application of a right line that leans continually upon two or three others given in position in space. Among the theorems, the following may be mentioned: If a plane surface, given in space, be projected on three planes, the one horizontal, and the two others vertical and perpendicular to each other, the square of that surface will be equal to the sum of the squares of the three surfaces of projection. This theorem is as interesting in the geometry of solids, as that of Pythagoras

(Eucl. i, 47) is in plane geometry. But for more on this subject, reference may be made to Monge's and Lacroix's ingenious works on Geometric Descriptive.

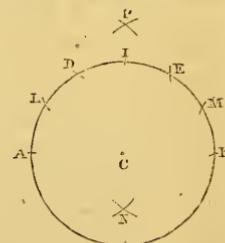

GEOMETRY of the Compasses, a new species of geometry, more ingenious than profound or useful, lately proposed by the Abbé Mascheroni. Hitherto both the ruler and the compasses have been employed in the solution of problems in plane geometry; and it had not been imagined that such problems could be solved or constructed without the combined use of these two instruments. But that author has shown a great number of problems, which are rendered very piquant and amusing, by the new condition of employing only the compasses in their solution. Thus: Two points terminating a right line being given, to find either between or without those two points, any number of points which shall be in the same right line with the former, and which shall make the intervals between them in a given ratio: 2d, To a given line to draw parallels, or perpendiculars, or lines making given angles with them: 3d, To inscribe or circumscribe within or about a circle, the various problems which are constructible by plane geometry: 4th, To determine the mean proportional, between two given distances; or to find third or fourth proportionals. All the problems indeed of the Euclidean geometry are thus resolved by the mere intersection of arcs of circles, without drawing a single right line. The author also resolves, by ingenious approximations, many problems which lie beyond the limits of common geometry; such as those relating to duplications, trisections, &c, still employing only the compasses. The work above alluded to is entitled, *Geometria del Compas*, and of which a French translation was published in 1798, in 1 vol. 8vo. A chapter on the same practice has also been lately given in Leslie's Geometry.

The following problem, proposed by the Emperor Napoleon to the French mathematicians, with several others in this geometry, are here constructed to show the method.

1. *Imperial Problem*. To divide the circumference of a circle into four equal parts by the compasses only, let *ADEB* be the given circle, whose centre is *c*. From any point *a* in its circumference, with a distance equal to the given radius *ac*, lay off the three successive divisions *AD*, *DE*, *EB*, and *AB* will be a diameter. With the centres *a* and *b*, and radius *AE* or *BD*, the chord of two divisions, describe arcs intersecting each other in *r*; and *rc* will be the chord of a quadrant of the given circle; which being applied four times to its circumference will divide it as required.

The truth of this is readily shown thus: Because $AB^2 = 4AC^2 = AE^2 + AC^2$ (the angle AEB in a semicircle being a right angle); $AB^2 = 3AC^2$. But $Ar^2 = AE^2$ by construction; therefore $Ar^2 = 3AC^2$; and since if *AC* and *cr* were drawn, the angle ACr would be a right angle, $Ar^2 = AC^2 + cr^2$; hence $AC^2 + cr^2 = 3AC^2$; and consequently $cr^2 = 2AC^2$ which is the square of the chord of 90° . Therefore, &c, Q.E.D.

From the above solution the division of the circumference into 8 equal parts is readily derived. For from

the intersection P with the radius AC of the given circle, describe an arc intersecting the circumference in D . This intersection will bisect the arc of 90° above determined.

2. To divide the circumference of a circle into five equal parts, or to construct a regular pentagon by means of the compasses only: Let AB be the given circle; then having found the diameter AB and AI the chord of a quadrant or 90° as before; with centre I and radius AC , set off the arcs IL, LM . From the points L and M , with the radius AI , describe arcs intersecting at N , on that side of the chord LM as the centre C of the circle; and the distance of this intersection from either extremity of the diameter AB will be the side of the pentagon required.

The demonstration is simple.

Nearly to this construction of the pentagon is that given by Ptolemy in his Almagest, for finding the chord of the fifth part of the circumference.

An ingenious friend (Mr. J. B. Wise, of Boynt Hill, near Maidenehead) has favoured us with a construction, in one simple diagram, for all the regular polygons inscribed in a circle, of the following number of sides, viz, 3, 4, 5, 6, 7, 8, 9, 10, 12, 15, 16, 18, 24, 30, 40, 60, &c.

GEORGIUM SIDUS. See HERSCHEL, and URANUS.

GERBERT, Pope Silvester the Second, was born of indigent parents at Auvergne, in the early part of the 10th century. Scarcely had he acquired the first principles of the sciences, when he left a country then immersed in ignorance, and travelled into Spain, where he remained several years. Having made great progress in the mathematics, he returned into France, where he taught the sciences, which he had learned from the Arabians, particularly arithmetic, which he thus had the honour of communicating to the western Christians, about the year 960 or 970. His merit and wisdom afterwards elevated him to the papal chair; which he filled respectfully till the time of his death, in the year 1003.

GHETALDUS (MARINUS), a Ragusan nobleman, and very respectable geometrician, who flourished about the beginning of the 17th century. He was author of several ingenious works on geometry, after the manner of the ancients; of which the titles and dates of those that are in my possession are the following: 1. Promotus Archimedes, &c, 4to, Romæ, 1603.—2. Problematum Collectio, 4to, Venet. 1607.—3. Apollonius Redivivus, &c, 4to, Venet. 1607 and 1613.—4. Supplementum Apollonii Galli, Venet. 1607, 4to.—5. De Resolut. et Composit. Mathemat. in folio, Romæ, 1630. And there might be others.

GIBBOUS, is used for the shape of one state of the enlightened part of the moon, being that in which she appears more than half full or enlightened, which is the time between the first quarter and the full moon, and from the full moon to the last quarter; appearing then gibbous, that is, bunched out, or convex on both sides of the enlightened part; as contradistinguished from the state when she is less than half full, when she is said to be horned, or a crescent.

GILBERT (Wm.), a physician, who was born at Colchester in 1540, and educated at Cambridge, but took his degree of M. D. abroad. On his return he was elected a fellow of the college of physicians, and became physician to queen Elizabeth. Dr. Gilbert discovered several of the properties of the loadstone; and in 1660 he published a work in 4to, entitled, *De Magnete, magneticisque Corporibus, et de magno Magnete Tellure, Physiologia*

nova

; in which are many important suggestions for the improvement of navigation. He died in 1603, consequently at 63 years of age.

GIMBOLS, are the brass rings by which a sea-compass is suspended in its box that usually stands in the binnacle.

GIN, in Artillery and Mechanics, is a machine for raising great weights, usually composed of three long legs, &c.

GIRARD (ALEBERT). See an account of him in the article ALGEBRA.

GIRDERS, in Architecture, are the largest beams or pieces of timber supporting the floors. Their ends are usually fastened into the summers, or breast-summers; and the joists are framed in at one end to the girders. By the statute for rebuilding London, no girder is to lie less than 10 inches into the wall, and their ends to be always laid in loam, &c. The shorter bearings a girder has, and the oftener it is supported by the internal or partition walls, so much the better. The established breadth and depth of a girder, according to its length of bearing, are as in the following tablet:

Girders and Summers in length	From	to	must be in	
			Breadth	Depth
10 feet	15 feet	11 inches	8 inches	
15	18	13	9	
18	21	14	10	
21	24	16	12	
24	26	17	14	

GIRT, in Timber-measuring, is the circumference of a tree; though some use this word for the quarter or 4th part of the circumference only, on account of the great use that is made of it; for the square of this 4th part is esteemed and used as equal to the area of the section of the tree; which square therefore multiplied by the length of the tree, is accounted the solid content. This content however is always about one-fourth part less than the true quantity; being nearly equal to what this will be after the tree is hewed square in the usual way: so that it seems intended to make an allowance for the squaring of the tree.

GIRT-Line, is a line on the common or carpenter's sliding rule, employed in computing the contents of trees by means of their girt.

GIVEN, Datum, a term often used in mathematics, and signifies something that is supposed to be known.

Thus, if a magnitude be known, or if we can find another equal to it, it is said to be given in magnitude. Or when the position of any thing is known, it is said to be given in position. And when the diameter of a circle is known, the circle is given in magnitude. Or the circle is given in position when its centre is given in position. When the kind or species of a figure is known, or remains the same, it is given in species, &c.

Euclid wrote a book of *Data*, or concerning things given, in 95 propositions, usually accompanying his *Elements*, in the best editions, and which Pappus reckons as one of the best specimens of the analytical works of the ancients.

GLACIS, in Fortification, a sloping bank reaching from the parapet of the counterscarp, or covered-way, to the level side of the field, commonly at the distance of about 40 yards.

GLOBE, a round or spherical body, more usually called a sphere, bounded by one uniform convex surface, every point of which is equally distant from a point within called

its centre. Euclid defines the globe, or sphere, to be a solid figure described by the revolution of a semi-circle about its diameter, which remains unmoved. Also, its axis is the fixed line or diameter about which the semi-circle revolves; and its centre is the same with that of the revolving semi-circle, a diameter of it being any right line that passes through the centre, and terminated both ways by the superficies of the sphere. ELEM. 11. def. 14, 15, 16, 17.

Euclid, at the end of the 12th book, shows that spheres are to one another in the triplicate ratio of their diameters, that is, their solidities are to one another as the cubes of their diameters. And Archimedes determines the real magnitudes and measures of the surfaces and solidities of spheres and their segments, in his treatise de Sphaera et Cylindro: viz, 1, That the superficies of any globe is equal to 4 times a great circle of it.—2, That any sphere is equal to $\frac{2}{3}$ of its circumscribing cylinder, or of the cylinder of the same diameter and altitude.—3, That the curve surface of the segment of a globe, is equal to the circle whose radius is the line drawn from the vertex of the segment to the circumference of the base.—4, That the content of a solid sector of the globe is equal to a cone whose altitude is the radius of the globe, and its base equal to the curve superficies or base of the sector. With many other properties. And from hence are easily deduced these practical rules for the surfaces and solidities of globes and their segments; viz,

1. For the Surface of a Globe, multiply the square of the diameter by 3·1416; or multiply the diameter by the circumference.

2. For the Solidity of a Globe, multiply the cube of the diameter by 5236 (viz $\frac{4}{3}$ of 3·1416); or multiply the surface by $\frac{6}{5}$ of the diameter.

3. For the Surface of a Segment, multiply the diameter of the globe by the altitude of the segment, and the product again by 3·1416.

4. For the Solidity of a Segment, multiply the square of the diameter of the globe by the difference between 3 times that diameter and 2 times the altitude of the segment, and the product again by 5236, or $\frac{6}{5}$ of 3·1416.

Hence, if d denote the diameter of the globe, c the circumference, a the altitude of any segment, and $p = 3\cdot1416$; then

	The Surface	The Solidity
In the Globe	$pd^2 = cd$	$\frac{6}{5} pd^3$
In the Segt.	pad	$\frac{6}{5} pa^2 \times (3d - 2a)$

See the art. SPHERE, and my Mensuration, pa. 197, &c, 2d ed.

The GLOBE, Terraqueous, is the body or mass of the earth and water together, which is nearly globular.

GLOBE, or artificial GLOBE, is more particularly used for a globe of metal, plaster, paper, pasteboard, &c, on the surface of which is drawn a map, or representation of either the heavens or the earth, with the several circles conceived upon them. And hence

GLOBES are of two kinds, terrestrial, and celestial; which are of considerable use in geography and astronomy, by serving to give a lively representation of their principal objects, and for performing and illustrating many of their operations in a manner easy to be perceived by the senses, and so as to be conceived even without any knowledge of the mathematical grounds of those sciences.

Description of the Globes.

The fundamental parts that are common to both globes,

are an axis, representing the axis of the world, passing through the two poles of a spherical shell, representing those of the world, which shell makes the body of the globe, upon the external surface of which is drawn the representation of the whole surface of the earth, sea, rivers, islands, &c, for the terrestrial globe, and the stars and constellations of the heavens, for the celestial one; besides the equinoctial and ecliptic lines, the zodiac, the tropics and polar circles, and a number of meridian lines. There is also a brazen meridian, being a strong circle of brass, circumscribing the globe, at a small distance from it, quite around, in which the globe is hung by its two poles, upon which it turns round within this circle, which is divided into 4 times 90 degrees, beginning at the equator on both sides, and ending with 90 at the two poles. There are also two small hour circles, of brass, divided into twice 12 hours, and fitted on the meridian round the poles, which carry an index pointing to the hour. The whole is set in a wooden ring, placed parallel to, and representing the horizon, in which the globe slides by the brass meridian, elevating or depressing the pole according to any proposed latitude. There is also a thin slip of brass, called a Quadrant of Altitude, made to fit on occasionally upon the brass meridian, at the highest or vertical point, to measure the altitude of any object above the horizon. A magnetic compass is sometimes set underneath. See the figure of the globes so mounted, at fig. 1, part xiv.

Such is the plain and simple construction of the artificial globe, whether celestial or terrestrial, as adapted to the time only for which it is made. But as the angle formed by the equator and ecliptic, as well as their points of intersection, is always changing; to remedy these inconveniences, several contrivances have been made, so as to adapt the same globes to any other time, either past or to come; as well as other contrivances to answer particular purposes.

Thus, Mr. Senex, a celebrated maker of globes, had a contrivance which, by means of a nut and screw, caused the pole of the equator to revolve about the pole of the ecliptic, by any quantity answering to the precession of the equinoxes, since the time for which the globe was made. Philos. Trans. No. 447, or my Abr. vol. 8, pa. 176, also Philos. Trans. vol. 40, pa. 290.

Mr. Joseph Harris, late assay-master of the Mint, made some contrivances to show the effects of the earth's motions. He fixed two horary circles under the brass meridian, to the axis, one at each pole, so as to turn round with the globe, and that meridian served as an index to cut the horary divisions. The globe in this state served equally for resolving problems in both north and south latitudes, as also in places near the equator; whereas, in the common construction, the axis and horary circle prevent the brass meridian from being moveable quite round in the horizon. This globe is also adapted for showing how the vicissitudes of day and night, and the alteration of their lengths, are really occasioned by the motion of the earth: for this purpose, he divides the brass meridian, at one of the poles, into months and days, according to the sun's declination, reckoning from the pole. Therefore, by bringing the day of the month to the horizon, and rectifying the globe according to the time of the day, the horizon will represent the circle separating light and darkness, and the upper half of the globe the illuminated hemisphere, the sun being in the zenith. Mr. Harris also gives an ac-

count of a cheap machine for showing how the annual motion of the earth in its orbit causes the change of the sun's declination, without the great expense of an orrery. Philos. Trans. No. 456.

The late Mr. George Adams made also some useful improvements in the construction of the globes. Besides what is usual, his globes have a thin brass semi-circle moveable about the poles, with a small thin sliding circle upon it. On the terrestrial globe, the former of these is a moveable meridian, and the latter is the visible horizon of any particular place to which it is set. But on the celestial globe, the semi-circle is a moveable circle of declination, and its small annexed circle an artificial sun or planet. Each globe has a brass wire circle, placed at the limits of the twilight. The terrestrial globe has many additional circles, as well as the rhumb-lines, for resolving all the necessary geographical and nautical problems: and on the celestial globe are drawn, on each side of the ecliptic, 8 parallel circles, at the distance of one degree from each other, including the zodiac; which are crossed at right-angles by segments of great circles, at every 5th degree of the ecliptic, for the more readily noting the place of the moon or of any planet on the globe. On the strong brass circle of the terrestrial globe, and about 23 $\frac{1}{2}$ degrees on each side of the north pole, the days of each month are laid down according to the sun's declination: and this brass circle is so contrived, that the globe may be placed with the north and south poles in the plane of the horizon, and with the south pole elevated above it. The equator, on the surface of either globe, serves the purpose of the horary circle, by means of a semi-circular wire placed in the plane of the equator, carrying two indices, one of which is occasionally to be used to point out the time. For a farther account of these globes, with the method of using them, see Mr. Adams's Treatise on their construction and use.

There are also what are called Patent Globes, made by Mr. Neale; by means of which he resolves several astronomical problems, which do not admit of solution by the common globes.

Mr. Ferguson also made several improvements of the globes, particularly one for constructing dials, and another called a planetary globe. See Philos. Trans. vol. 44, pa. 535, and Ferguson's Astron. pa. 291 and 292.

Lastly, in the Philos. Trans. for 1789, vol. 79, pa. 1, Mr. Smeaton has proposed some improvements of the celestial globe, especially with respect to the quadrant of altitude, for the resolution of problems relating to the azimuth and altitude. The difficulty, he observes, that has occurred in fixing a semi-circle, so as to have a centre in the zenith and nadir points of the globe, at the same time that the meridian is left at liberty to raise the pole to its desired elevation, I suppose, has induced the globe-makers to be contented with the strip of thin flexible brass, called the quadrant of altitude; and it is well known how imperfectly it performs its office. The improvement I have attempted, is in the application of a quadrant of altitude of a more solid construction; which being affixed to a brass socket of some length, and this ground, and made to turn upon an upright steel spindle, fixed in the zenith, steadily directs the quadrant, or rather arc of altitude, to its true azimuth, without being at liberty to deviate from a vertical circle to the right hand or left: by which means the azimuth and altitude are given with the same exactness as the measure of any other of the great circles. For

a more particular description of this improvement, illustrated with figures, see the reference above.

For the practical uses of the globes, see any of the little books on this subject.

GLOBULAR, relating to, or partaking of the property or shape of the globe. As globular chart, globular projection, or globular sailing, &c.

GLOBULAR Chart, is a representation of the surface, or part of the surface, of the terraqueous globe on a plane; in which the parallels of latitude are circles nearly concentric; and the meridians are curves bending towards the poles; the rhumb-lines being curves also.

The merits of this chart consist in these particulars, viz., that the distances between places on the same rhumb are all measured by the same scale of equal parts; and the distance of any two places in the arch of a great circle, is nearly represented in this chart by a straight line.

Land maps also, made according to this projection, would have great advantages over those made in any other way. But for sea charts for the use of navigation, Mercator's are preferable, as both the meridians and parallels, as also the rhumbs, are all straight lines.

This projection is not new, though not much noticed till of late. It is mentioned by Ptolemy, in his Geography; and also by Blundeville, in his Exercises.

For globular projection of maps or charts; see **MAP**.

GLOBULAR Sailing, is the method of resolving the cases of sailing on principles deduced from the spherical figure of the earth. Such as Mercator's sailing, or great-circle sailing; which see.

GLOSSOCOMON, in Mechanics, is a name given by Heron to a machine, composed of divers dented wheels with pinions, serving to raise huge weights.

GNOMON, in Astronomy, is an instrument or apparatus for measuring the altitudes, declinations, &c, of the sun and stars. The gnomon is usually a pillar, or column, or pyramid, erected upon level ground, or a pavement. For making the more considerable observations, both the ancients and moderns have made great use of it, especially the former; and many have preferred it to the smaller quadrants, both as more accurate, easier made, and more easily applied.

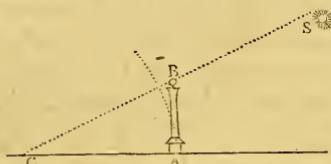

The most ancient observation of this kind extant, is that made by Pytheas, in the time of Alexander the Great, at Marseilles, where he found the height of the gnomon was in proportion to the meridian shadow at the summer solstice, as 213 $\frac{1}{2}$ to 600; just the same as Gassendi found it to be, by an observation made at the same place, almost 2000 years after, viz. in the year 1636. Ricciol. Almag. vol. 1, lib. 3, cap. 14.

Ulugh Beigh, king of Parthia, &c, used a gnomon in the year 1437, which was 180 Roman feet high. That erected by Ignatius Dante, in the church of St. Petronius, at Bologna, in the year 1576, was 67 feet high. M. Cassini erected another of 20 feet high, in the same church, in the year 1655.

The Egyptian obelisks were also used as gnomens; and it is thought by some modern travellers that this was the very use they were designed and built for; it has also been found that their four sides stand exactly facing the four cardinal points of the compass. It may be added, that the Spaniards in their conquest of Peru, found pillars of curious and costly workmanship, set up in several places, by the meridian shadows of which their amatas or philo-

sophers had, by long experience and repeated observations, learned to determine the times of the equinoxes; which seasons of the year were celebrated with great festivity and rich offerings, in honour of the sun. Garcillasso de la Vega, Hist. Peru, lib. 2, cap. 22.

*USE of the GNOMON, in taking the meridian altitude of the Sun, and thence finding the Latitude of the place.—*A meridian line being drawn through the centre of the gnomon, note the point where the shadow of the gnomon terminates when projected along the meridian line, and measure the distance of that extreme point from the centre of the gnomon, which will be the length of its shadow. Then having the height of the gnomon, and the length of the shadow, the sun's altitude is thence easily found.

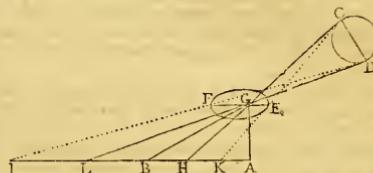

Suppose, ex. gr. AB the gnomon, and AC the length of the shadow. Here, in the right-angled triangle ABC , are given the base AC , and the perpendicular AB , to find the angle c , or the sun's altitude, which will be found by this analogy, as $CA : AB :: \text{radius} : \tan. \angle c$; that is, as the length of the shadow is to the height of the gnomon, so is the radius to the tangent of the sun's altitude above the horizon.—The following example will serve to illustrate this proposition: Pliny says, Nat. Hist. lib. 2, cap. 72, that at Rome, at the time of the equinoxes, the shadow is to the gnomon as 8 to 9; therefore, as $8 : 9 :: 1 : \text{radius}$; $\frac{9}{8} = 1\cdot125$ a tangent, to which answers the angle $48^\circ 22'$, which is the height of the equator at Rome, and its complement $41^\circ 38'$ is therefore the height of the pole, or the latitude of the place.

Riccioli remarks the following defects in the observations of the sun's height, made with the gnomon by the ancients, and some of the moderns; viz, that they neglected the sun's parallax, which makes his apparent altitude less, by the quantity of the parallax, than it would be, if the gnomon were placed at the centre of the earth: 2d, they neglected also the refraction, by which the apparent height of the sun is a little increased: and 3dly, they made the calculations from the length of the shadow, as if it were terminated by a ray coming from the centre of the sun's disc, whereas the shadow is really terminated by a ray coming from the upper edge of the sun's disc; so that, instead of the height of the sun's centre, their calculations gave the height of the upper edge of his disc. And therefore, to the altitude of the sun found by the gnomon, the sun's parallax must be added, and from the sum must be subtracted the sun's semidiameter, and refraction, which is different at different altitudes; which being done, the correct height of the equator at Rome will be $48^\circ 4' 13''$, the complement of which is the latitude, or $41^\circ 55' 46''$. Ricciol. Geogr. Refor. lib. 7, cap. 4.

The preceding problem may be resolved more accurately by means of a ray of light let in through a small hole, than by a shadow, thus: Make a circular perforation in a brass plate, to transmit enough of the sun's rays to exhibit his image on the floor, or a stage; fix the plate parallel to the horizon in a high place, proper for observation, the

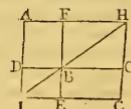

height of which above the floor let be accurately measured with a plummet. Let the floor, or stage, be perfectly plane and horizontal, and coloured over with some white substance, to show the sun more distinctly. Upon this horizontal plane draw a meridian line passing through the foot or centre of the gnomon, i. e. the point upon which the plummet falls from the centre of the hole; and on this line note the extreme points I and K of the sun's image or diameter, and from each end subtract the image of half the diameter of the aperture, viz KL and LI : then will IL be the image of the sun's diameter, which, when bisected in B , gives the point on which the rays fall from the centre of the sun.

Now having given the line AB , and the altitude of the gnomon AG , besides the right angle A , the angle a , or the apparent altitude of the sun's centre, is easily found, thus: as $AB : AG :: \text{radius} : \tan. \text{angle } a$.

GNOMON, in Dialling, is the style, pin, or cock of a dial, the shadow of which points out the hours. This is always supposed to represent the axis of the world, to which it is therefore parallel, or coincident, the two ends of it pointing straight to the north and south poles of the world.

GNOMON, in Geometry, is a figure formed of the two complements, in a parallelogram, together with either of the parallelograms about the diameter. Thus the parallelogram AC being divided into four parallelograms by the two lines DG , EF parallel to the sides, forming the two complements AB and BC , with the two DE , FG about the diameter II : then the two gnomons are $AB + BC + DE$, and $AB + BC + FG$.

GNOMONIC Projection of the Sphere, is the representation of the circles of an hemisphere on a plane touching it in the vertex, by the eye in the centre, or by lines or rays issuing from the centre of the hemisphere, to all the points in the surface.—In this projection of the sphere, all the great circles are projected into right lines, on the plane, of an indefinite length; and all lesser circles that are parallel to the plane, into circles; but if oblique to the plane, then are they projected either into ellipses or hyperbolas, according to their different obliquity. It has its name from gnomonics, or dialling, because the lines on the face of every dial are from a projection of this kind: for if the sphere be projected on any plane, and upon that side of it on which the sun is to shine; also the projected pole be made the centre of the dial, and the axis of the globe the style or gnomon, and the radius of projection its height; you will have a dial drawn with all its furniture. See Emerson's Projection of the Sphere.

GNOMONICS, the same as *DIALLING*; or the art of drawing sun and moon dials, on any given plane; being so called, because it shows how to find the hour of the day or night by the shadow of a gnomon or style.

GOLDEN Number, is the particular year of the Metonic or Lunar Cycle. See *Lunar CYCLE*.

To find the *Golden Number*:
Add 1 to the given year, and divide the sum by 19, and what remains is the golden number; unless 0 remain, for then 19 is the golden number. Thus, the golden number for the year 1812 is 8; as by the operation in the margin.

1812

$$\begin{array}{r} 1 \\ 19) 1813 (95 \\ \underline{-171} \\ 103 \\ \underline{-95} \\ \hline \end{array}$$

Golden No. 8

GOLDEN Rule, a rule so called on account of its excellent use, in arithmetic, and especially in ordinary calculations, by which numbers are found in certain proportions, viz., having three numbers given, to find a 4th number in proportion. On this account, it is otherwise called The Rule of Three, and The Rule of Proportion. See *RULE OF THREE*.

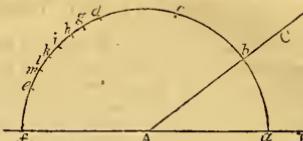

Having stated, or set down in a line, the three terms, in the order in which they are proportional, multiply the 2d and 3d together, and divide the product by the 1st, so shall the quotient be the answer, or the 4th term sought.—Thus, if 3 yards of cloth cost a guinea or 21 shillings, what will 20 yards cost. Here the two prices or values must bear the same proportion to each other as the two quantities, or number of yards of cloth, i.e. 3 must bear the same proportion to 20, as 21 is, the value of the former, must bear to the value of the latter: and therefore the stating and operation of the numbers will be thus. Then multiplying the 2d and 3d together, and dividing the product by the 1st, it gives 140s. or 7l. for the answer, being the cost of 20 yards.

$$\begin{array}{r} 3 : 20 :: 21 : 140s. \\ \hline 20 \\ 3) 420 \\ \hline \text{Quot. } 140s. \text{ or } 7l. \end{array}$$

GNOMETRICAL Lines, are lines used for measuring or determining the quantity of angles: such as sines, tangents, secants, versed sines, &c. Mr. Jones, in the Philos. Trans. No. 483, sect. 26, gave a paper, containing a commodious disposition of equations for exhibiting the relations of goniometrical lines; from which a multitude of curious theorems may be derived. See also Robertson's Elem. of Navigation, vol. 1, p. 181, edit. 4.

GNOMETRY, a method of measuring angles, so called by M. De Lagny, who gave several papers, on this method, in the Mémoires of the Royal Acad. an. 1724, 1725, 1729. M. De Lagny's method of gnometry consists in measuring the angles with a pair of compasses, and that without any scale whatever, except an undivided semicircle. Thus, having any angle drawn upon paper, to be measured; produce one of the sides of the angle backwards; then with a pair of fine compasses describe a pretty large semicircle, from the angular point as a centre, cutting the sides of the proposed angle, which will intercept a part of the semicircle. Take then this intercepted part very exactly between the points of the compasses, and turn them successively over upon the arc of the semicircle, to find how often it is contained in it, after which there is commonly some remainder: then take this remainder in the compasses, and in like manner find how often it is contained in the last of the integral parts of the 1st arc, with again some remainder: find in like manner how often this last remainder is contained in the former; and so on continually, till the remainder become too small to be taken and applied as a measure. By this means he obtains a series of quotients, or fractional parts, one of another, which being properly reduced into one fraction, give the

ratio of the first arc to the semicircle, or of the proposed angle to two right angles, or 180 degrees, and consequently that angle itself in degrees and minutes.

Thus, suppose the angle BAC be proposed to be measured. Produce BA out towards f ; and from the centre A describe the semicircle $abcf$, in which ab is the measure of the proposed angle. Take ab in the compasses, and apply it 4 times on the semicircle, as at $b, c, d,$ and e ; then take the remainder ef , and apply it back upon ed , which is but once, viz at g ; again take the remainder gd , and apply it 5 times on ge , as at $h, i, k, l,$ and m ; lastly, take the remainder me , and it is contained just 2 times in ml . Hence the series of quotients is $4, 1, 5, 2$; consequently the 4th or last arc em is $\frac{1}{4}$ the third ml or gd , and therefore the 3d arc gd is $\frac{1}{5\frac{1}{2}}$ or $\frac{2}{17}$ of the 2d arc ef ; therefore again this 2d arc ef is $\frac{1}{1\frac{2}{17}}$ or $\frac{13}{63}$ of the 1st arc ab ; and consequently this 1st arc ab is $\frac{1}{4\frac{1}{13}}$ or $\frac{13}{63}$ of the whole semicircle af . But $\frac{13}{63}$ of 180° are $37\frac{1}{3}^\circ$ degrees, or $37^\circ 34\frac{2}{3}''$, which therefore is the measure of the angle sought. When the operation is nicely performed, this angle may be within 2 or 3 minutes of the truth; though M. De Lagny pretends to measure much nearer than that.

It may be added, that the series of fractions forms what is called a continued fraction. Thus, in the example above, the continued fraction, and its reduction, will be as follow:

$$\frac{1}{4} + \frac{1}{1} + \frac{1}{5\frac{1}{2}} = \frac{1}{4} + \frac{1}{1\frac{2}{17}} = \frac{1}{4\frac{1}{13}} = \frac{13}{63};$$

the quotients being the successive denominators, and 1 always for each numerator.

GÖRGE, or Neck, in Architecture, the narrowest part of the Tuscan or Doric capitals, lying above the shaft of the pillar, between the astragal and annulets.

It is also a kind of concave moulding, serving for compartments &c, larger than a scotia, but not so deep.

GORGÉ, in Fortification, is the entrance into a bastion, or a ravelin, or other out-work.

The GORGÉ of a Bastion, is what remains of the sides of the polygon of a place, after cutting off the curtains; in which case it makes an angle in the centre of the bastion, viz, the angle made by two adjacent curtains produced to meet within the bastion.—In flat bastions, the gorge is a right line on the curtain, reaching between the two flanks.

GORGÉ of a Half-moon, or of a *Ravelin*, is the space between the two ends of their faces next the place.

GORGÉ of the other out-works, is the interval between their sides next the great ditch. All the gorges are to be made without parapets: otherwise the besiegers, having taken possession of a work, might make use of them to defend themselves from the shot of the place. So that they are only fortified with pallisadoes, to prevent a surprise.

The **Demi-GORGÉ**, or **Half the GORGÉ**, is that part of

the polygon between the flank and the centre of the bastion.

GOTHIC *Architecture*, is that which deviates from the manner, character, proportions, &c, of the antique; having its ornaments wild and chimerical, and its profiles incorrect. This manner of building came originally from the North, whence it was brought, in the 5th century, by the Goths into Germany, and has since been introduced into other countries. The first or most ancient style of Gothic building was very solid, heavy, massive and simple, with semicircular arches, &c: but the more modern style of the Gothic is exceedingly rich, light, and delicate; having an abundance of little whimsical ornaments, with sharp-pointed arches formed by the intersections of different circular segments; also lofty and light spires and steeples, large ramified windows, clustered pillars, &c. Of this kind are our English cathedrals, and many other old buildings.

GRADUATION, is used for the act of graduating, or dividing any thing into degrees.—For an account of the various methods of graduating mathematical and astronomical instruments, by straight and circular diagonals, and by concentric arcs, &c; see *Plain SCALE*, *Nomius*, and *Vernier*. And for an account of Mr. Bird's improved method of dividing astronomical instruments, see *MURAL Arch.*

Mr. Ramsden, an ingenious mathematical instrument-maker of London, has lately published, by encouragement of the commissioners of longitude, an explanation and description of an engine contrived by him for dividing mathematical instruments, accompanied with proper drawings; in consideration of which, the said commissioners granted him the sum of 615*l.* See his book, 4to, 1777.

On the subject of dividing a foot into many thousand parts, for mathematical purposes, see *Philos. Trans.* vol. 2, p. 457, 459, 541, or my Abr. vol. 1, pa. 161, 195, &c. And for an account of various other methods and graduations, see a paper of Mr. Smeaton's in the *Philos. Trans.* vol. 76, for the year 1786, pa. 1; being "Observations on the graduation of astronomical instruments; with an explanation of the method invented by the late Mr. Henry Hindley, of York, clock-maker, to divide circles into any given number of parts." Also Mr. Troughton's method and history of such operations, in the vol. for 1809.

GRAHAM (GEORGE), clock- and watch-maker, the most ingenious and accurate artist in his time, was born at Gratiwick, a village in the north of Cumberland, in 1675. He came up to London in 1688, and was put apprentice to a person in that profession; but after being some time with his master, he was received, purely on account of his merit, into the family of the celebrated Mr. Tompion, who treated him with a kind of parental affection as long as he lived. That Mr. Graham was, without competition, the most eminent of his profession, is but a small part of his character: he was the best general mechanic of his time, and had a complete knowledge of practical astronomy; so that he not only gave to various movements for measuring time a degree of perfection which had never before been attained, but invented several astronomical instruments, by which considerable advances have been made in that science: he made great improvements in those which had before been in use; and, by a wonderful manual dexterity, constructed them with greater precision and accuracy than perhaps any other person in the world.

A great mural arch in the observatory at Greenwich was made for Dr. Halley, under Mr. Graham's immediate inspection, and divided by his own hand: and from this incomparable original, the best foreign instruments of the kind are copies made by English artists. The sector by which Dr. Bradley first discovered two new motions in the fixed stars, was of our author's invention and fabric. He comprised the whole planetary system within the compass of a small cabinet; from which, as a model, all the modern orreries have been constructed. And when the French academicians were sent to the North, to make observations for ascertaining the figure of the earth, Mr. Graham was thought the fittest person in Europe to supply them with instruments; by which means they finished their operations in one year; while those who went to the South, not being so well furnished, were very much embarrassed and retarded in their operations.

Mr. Graham was many years a member of the Royal Society, to which he communicated several ingenious and important discoveries, viz, from the 31st to the 42d volume of the *Philos. Transactions*, chiefly on astronomical and philosophical subjects; particularly a kind of horary alteration of the magnetic needle; a quicksilver pendulum, and many curious particulars relating to the true length of the simple pendulum, on which he continued to make experiments till almost the time of his death, which happened in 1751, at 76 years of age.

His temper was not less communicative than his genius was penetrating; and his principal view was the advancement of science, and the benefit of mankind. As he was perfectly sincere, he was above suspicion; and as he was above envy, he was candid.

GRANADO, in Artillery, is a small shell or hollow globe of iron, or other matter, which, being filled with powder, is fired by means of a small fusee, and thrown either by the hand, or a piece of ordnance. As soon as it is kindled, the case flies in pieces, to the great danger of all that stand near it. Granadoes serve to set fire to close and narrow passages, and are often thrown with the hand among the soldiers, to disorder their ranks; more especially in those posts where they stand thickest, as in trenches, redoubts, lodgments, &c.

GRANDI (GUIDO), a learned Italian mathematician, was born at Cremona in 1671; appointed professor of mathematics at Pisa in 1714; and died in 1742. In 1699 he published, in 4to, the demonstration of Viviani's wonderful or quadrable dome, under the title of *Geometrica Divinatio Vivianiorum Problematum*; a work which contains more than its title would lead us to expect, and in which the author remarks many other curiosities in geometry of the same kind, and among others, a portion of the surface of a right cone, which is perfectly quadrable, and to which he gives the name of *Velum Camaldulense*, he being a friar of the order of Camaldulines; from which it seems he did not know the same thing, in a more general form, had before been given by John Bernoulli, in the Leipzic Acts. In 1701, he published his demonstration of Huygen's theorems on the Logistic Curve, which that author had simply announced without demonstration; being an excellent specimen of the ancient geometrical method; in which piece also, as well as in his letter to the Jesuit Ceva, which follows it, are found several other curious and novel particulars.—Another paper of Grandi's is also inserted in the 33d volume of the *Philos. Trans.*, called a Handful or a Bouquet of Geometrical Roses, being a dis-

sertation on certain curves geometrically described in a circle. This he afterwards enlarged in another treatise, published in 1728, entitled *Flores Geometrici ex Rhodonearum, &c.* He was also author of several other miscellaneous pieces, on the ancient and modern geometry; as, his *Quadrature of the Circle and Hyperbola by Infinite Parabolæ*, in 1703 and 1710; his *Dissertation on Infinites of Infinites, &c.*, in 1710; an Italian edition of Euclid's Elements; and a posthumous treatise on Conic Sections, also in the Italian language, in 1744. Grandi it seems was of a turbulent and quarrelsome disposition, being almost always engaged in disputes on various subjects, geometrical, theological, metaphysical, or philological.

G R A P E - S H O T, in Artillery, is a combination of small shot, put into a thick canvassbag, and corded strongly together, so as to form a kind of cylinder, of a diameter suited to the intended piece of ordnance, from the smallest to the largest. The number of shot in a grape varies according to the service, or size of the guns. Of late the grape-shot have been superseded by canister-shot, and by shrapnel shells, &c, as more convenient and efficacious.

G R A P H O M E T E R, a mathematical instrument, used in land-surveying &c, and is otherwise called **S E M I C I R C L E**; which see

G R A V E, in Music, is applied to a sound which is in a low or deep tone. The thicker the chord or string, the more grave the tone or note; and the smaller, the acuter. Notes are supposed to be the more grave, in proportion as the vibrations of the chord are less quick.

G R A V E S A N D E (WILLIAM JAMES), a very celebrated Dutch mathematician and philosopher, was born at Bois-le-duc, Sept. 27, 1688. He studied the civil law at Leyden, but mathematical learning was his favourite amusement. When he had taken his doctor's degree, in 1707, he went and settled at the Hague, where he practised at the bar, and cultivated an acquaintance with learned men; with a society of whom he published a periodical review, entitled *Le Journal Litteraire*, which was continued without interruption from the year 1713 to the year 1722. The parts of it written or extracted by Gravesande were chiefly those relating to geometry and physics. But he enriched it also with several original pieces entirely of his own composition; viz, *Remarks on the Construction of Pneumatic Engines*; *A Moral Essay on Lying*; and a celebrated *Essay on the Collision of Bodies*; which, as it opposed the Newtonian philosophy, was attacked by Dr. Clarke, and many other learned men. In 1715, when the States sent to congratulate George the 1st, on his accession to the throne, Dr. Gravesande was appointed secretary to the embassy. During his stay in England he was admitted a member of the Royal Society, and became intimately acquainted with Sir Isaac Newton. On his return to Holland, he was chosen professor of mathematics and astronomy at Leyden; where he had the honour of first teaching the Newtonian philosophy, which was then in its infancy. He died in 1742, at 54 years of age.

Gravesande was a man amiable in his private character, and respectable in his public one; for few men of letters have rendered more eminent services to their country. The ministers of the republic consulted him on all occasions when his talents were requisite to assist them, which his skill in calculation often enabled him to do in financial concerns. He was of great service as a decipherer, in detecting the secret correspondence of their enemies. And, in his own profession, none ever applied the powers of na-

ture with more success, or to more useful purposes.—Of his publications, the principal are,

1. An Introduction to the Newtonian Philosophy; or, a Treatise on the Elements of Physics, confirmed by Experiments. This performance, being only a more perfect copy of his public lectures, was first printed in 1720; and went through many editions, with considerable improvements; the 5th edit. is in English, in 2 large vols. 4to, by Dr. Desaguliers, in 1747, under the title of Mathematical Elements of Natural Philosophy, confirmed by Experiments.
